**FIGURE 18-13** The Pancreas. A, Pancreas dissected to show main and accessory ducts. The main duct may join the common bile duct, as shown here, to enter the duodenum by a single opening at the major duodenal papilla, or the two ducts may have separate openings. The accessory pancreatic duct is usually present and has a separate opening into the duodenum. B, Exocrine glandular cells (around small pancreatic ducts) and endocrine glandular cells of the pancreatic islets (adjacent to blood capillaries). Exocrine pancreatic cells secrete pancreatic juice, alpha endocrine cells secrete glucagon, and beta cells secrete insulin. (From Patton KT, Thibodeau GA: Structure & function of the body, ed 15, St Louis, 2016, Mosby.)

**Insulin**

The beta cells of the pancreas synthesize **insulin** from the precursor proinsulin, which is formed from a larger precursor molecule, preproinsulin. Proinsulin is composed of A peptide and B peptide connected by a C peptide and two disulfide bonds. C peptide is cleaved by proteolytic enzymes, leaving the bonded A and B peptides as the insulin molecule. Insulin circulates freely in the plasma and is not bound to a carrier. C peptide level can be measured in the blood and used as an
indirect measurement of serum insulin synthesis.

Secretion of insulin is regulated by chemical, hormonal, and neural control. Insulin secretion is pulsatile, increasing when the beta cells are stimulated by the parasympathetic nervous system usually before eating a meal. Other factors stimulating insulin secretion include increased blood levels of glucose, amino acids (leucine, arginine, and lysine), and gastrointestinal hormones (glucagon, gastrin, cholecystokinin, secretin). Insulin secretion diminishes in response to low blood levels of glucose (hypoglycemia), high levels of insulin (through negative feedback to the beta cells), and sympathetic stimulation of the beta cells in the islets. Prostaglandins also inhibit insulin secretion.

At the target cell, insulin signaling is initiated when insulin binds and activates its cell surface receptor. These receptors are found on cells throughout the body. Insulin promotes cellular glucose uptake through glucose transporters (GLUT). An intracellular cascade of phosphorylation events, protein-protein interactions, and second-messenger generation then occurs, resulting in diverse metabolic events throughout the body\textsuperscript{25} (see details in Figure 18-14).
Insulin Action on Cells. Binding of insulin to its receptor causes autophosphorylation of the receptor, which then itself acts as a tyrosine kinase that phosphorylates insulin receptor substrates 1-4 (IRS-1-4). Numerous target enzymes, such as protein kinase B and MAP kinase, are activated and these enzymes have a multitude of effects on cell function. The glucose transporter (GLUT4) is recruited to the plasma membrane, where it facilitates glucose entry into the cell. The transport of amino acids, potassium, magnesium, and phosphate into the cell is also facilitated. The synthesis of various enzymes is induced or suppressed, and cell growth is regulated by signal molecules that modulate gene expression. (Redrawn from Levy MN et al, editors: Berne & Levy principles of physiology, ed 4, St Louis, 2006, Mosby)

The sensitivity of the insulin receptor is a key component in maintaining normal cellular function. Insulin sensitivity is affected by age, weight, abdominal fat, and physical activity. Insulin resistance has been implicated in numerous diseases, including hypertension, heart disease, and type 2 diabetes mellitus. Adipocytes release a number of hormones and cytokines that are altered in obesity and have an important impact on insulin sensitivity. The most effective measures shown to improve insulin sensitivity in humans are weight loss and exercise.26

Insulin is an anabolic hormone that promotes glucose uptake primarily in liver, muscle, and adipose tissue. It also increases the synthesis of proteins, carbohydrates, lipids, and nucleic acids. It functions mainly in the liver, muscle, and adipose tissue. Table 18-7 summarizes the actions of insulin. The net effect of insulin in these tissues is to stimulate protein and fat synthesis and decrease blood glucose level. The brain, red blood cells, kidney, and lens of the eye do not require insulin for glucose transport. Insulin also facilitates the intracellular transport of potassium (K+), phosphate, and magnesium.

### Amylin

*Amylin* (or islet amyloid polypeptide) is a peptide hormone co-secreted with insulin by beta cells in response to nutrient stimuli. It regulates blood glucose concentration by delaying gastric emptying and suppressing glucagon secretion after meals. Amylin also has a satiety effect, which reduces food intake. Through these mechanisms, amylin has an antihyperglycemic effect.27

### Glucagon

*Glucagon* is produced by the alpha cells of the pancreas and by cells lining the gastrointestinal tract. Glucagon acts primarily in the liver and increases blood glucose concentration by stimulating glycogenolysis and gluconeogenesis in muscle and lipolysis in adipose tissue. Amino acids, such as alanine, glycine, and asparagine, stimulate glucagon secretion. Glucagon release is inhibited by high glucose levels and stimulated by low glucose levels and sympathetic stimulation; thus it is antagonistic to insulin.28

### Pancreatic Somatostatin

*Somatostatin* is produced by delta cells of the pancreas in response to food intake and is essential in carbohydrate, fat, and protein metabolism. It is different from hypothalamic somatostatin, which inhibits the release of growth hormone and TSH. Pancreatic somatostatin is involved in regulating alpha-cell and beta-cell function within the islets by inhibiting secretion of insulin, glucagon, and pancreatic polypeptide.29

### Gastrin, Ghrelin, and Pancreatic Polypeptide

Pancreatic *gastrin* stimulates the secretion of gastric acid. It is postulated that fetal
pancreatic gastrin secretion is necessary for adequate islet cell development. **Ghrelin** stimulates GH secretion, controls appetite, and plays a role in obesity and the regulation of insulin sensitivity. **Pancreatic polypeptide** is released by F cells in response to hypoglycemia and protein-rich meals. It inhibits gallbladder contraction and exocrine pancreas secretion and is frequently increased in individuals with pancreatic tumors or diabetes mellitus. 

### Adrenal Glands

The **adrenal glands** are paired, pyramid-shaped organs behind the peritoneum and close to the upper pole of each kidney. Each gland is surrounded by a capsule, embedded in fat, and well supplied with blood from the aorta and phrenic and renal arteries. Venous return from the left adrenal gland is to the renal vein and from the right adrenal gland is to the inferior vena cava.

Each adrenal gland consists of two separate portions—an outer cortex and an inner medulla. These two portions have different embryonic origins, structures, and hormonal functions. The adrenal cortex and medulla function like two separate but interrelated glands (Figure 18-15).
Adrenal Cortex

The adrenal cortex accounts for 80% of the weight of the adult gland. The cortex is histologically subdivided into the following three zones:

1. The zona glomerulosa, the outer layer, constitutes about 15% of the cortex and primarily produces the mineralocorticoid aldosterone.

2. The zona fasciculata, the middle layer, constitutes 78% of the cortex and secretes the glucocorticoids cortisol, cortisone, and corticosterone.

3. The zona reticularis, the inner layer, constitutes 7% of the cortex and secretes mineralocorticoids (aldosterone), adrenal androgens and estrogens, and
glucocorticoids.

The cells of the adrenal cortex are stimulated by adrenocorticotropic hormone (ACTH) from the pituitary gland. All hormones of the adrenal cortex are synthesized from cholesterol. The best known pathway of steroidogenesis involves the conversion of cholesterol to pregnenolone, which is then converted to the major corticosteroids.

**Glucocorticoids**

**Functions of the glucocorticoids.**

The glucocorticoids are steroid hormones that have metabolic, neurologic, anti-inflammatory, and growth-suppressing effects. These functions (Figure 18-16) have direct effects on carbohydrate metabolism. These hormones increase blood glucose concentration by promoting gluconeogenesis in the liver and by decreasing uptake of glucose into muscle cells, adipose cells, and lymphatic cells. In extrahepatic tissues, the glucocorticoids stimulate protein catabolism and inhibit amino acid uptake and protein synthesis. The ultimate effect on the body is protein catabolism.
The glucocorticoids act at several sites to suppress immune and inflammatory reactions. One major immunosuppressant effect is the glucocorticoid-mediated decrease in the proliferation of T lymphocytes, primarily T-helper lymphocytes. There is a greater effect on T-helper 1 (Th1) cytokine production (including antiviral interferons) than there is on T-helper 2 (Th2) cytokine production and therefore greater depression of cellular immunity than humoral immunity (see Chapter 7). Glucocorticoids affect innate immunity through several pathways, including decreasing the activity of pattern receptors on the surface of macrophages (see Chapter 6). Anti-inflammatory effects of glucocorticoids also include decreased function of natural killer cells, suppression of inflammatory cytokines,
and stabilization of lysosomal membranes, which decreases the release of proteolytic enzymes. The pro-inflammatory effects of glucocorticoids are not clearly understood. Psychological and physiologic stress increases glucocorticoid production, which provides a pathway for the well-described decrease in immunity seen in both acute and chronic stress conditions (see Chapter 9). Use of glucocorticoids for the treatment of disease also leads to suppression of innate and adaptive immunity and the challenging complications of infection and poor wound healing (see Chapter 8).

Other effects of glucocorticoids include inhibition of bone formation, inhibition of ADH secretion, and stimulation of gastric acid secretion. Glucocorticoids appear to potentiate the effects of catecholamines, including sensitizing the arterioles to the vasoconstrictive effects of norepinephrine. Thyroid hormone and growth hormone effects on adipose tissue are also potentiated by glucocorticoids. A metabolite of cortisol may act like a barbiturate and depress nerve cell function in the brain, accounting for the noted effects on mood, such as anxiety and depression, associated with steroid level fluctuation in disease or stress.

Pathologically high levels of glucocorticoids increase the number of circulating erythrocytes (leading to polycythemia), increase the appetite, promote fat deposition in the face and cervical areas, increase uric acid excretion, decrease serum calcium levels (possibly by inhibiting gastrointestinal absorption of calcium), suppress the secretion and synthesis of ACTH, and interfere with the action of growth hormone so that somatic growth is inhibited (see Chapter 19).

**Cortisol.**

The most potent naturally occurring glucocorticoid is cortisol. It is the main secretory product of the adrenal cortex and is needed to maintain life and protect the body from stress (see Figure 9-2). The liver is primarily responsible for the deactivation of cortisol.

Cortisol secretion is regulated primarily by the hypothalamus and the anterior pituitary gland (Figure 18-17). **Corticotropin-releasing hormone (CRH)** is produced by several nuclei in the hypothalamus and stored in the median eminence. Once released, CRH travels through the portal vessels to stimulate the production of ACTH, β-lipotropin, γ-lipotropin, endorphins, and enkephalins by the anterior pituitary. ACTH is the main regulator of cortisol secretion and adrenocortical growth.
ACTH is synthesized as part of a precursor called proopiomedullin (POMC). Three factors appear to be primarily involved in regulating the secretion of ACTH: (1) negative-feedback effects of high circulating levels of cortisol and synthetic glucocorticoids suppress both CRH and ACTH, whereas low cortisol levels stimulate their secretion; (2) diurnal rhythms affect ACTH and cortisol levels (in persons with regular sleep-wake patterns, ACTH peaks 3 to 5 hours after sleep begins and declines throughout the day, and cortisol levels follow a similar pattern); and (3) psychological and physiologic (e.g., hypoxia, hypoglycemia, hyperthermia, exercise) stress increases ACTH secretion, leading to increased cortisol levels. (Neurologic mechanisms regulating sleep are discussed in Chapter 14.) A form of immunoreactive ACTH (irACTH) is produced by the cells of the immune system and may account, in part, for integration of the immune and endocrine systems.

Once ACTH is secreted, it binds to specific plasma membrane receptors on the cells of the adrenal cortex and on other extra-adrenal tissues. Because both adrenal and extra-adrenal tissues have ACTH receptors, a number of effects result from stimulation by ACTH. In addition to increasing adrenocortical secretion of cortisol, ACTH maintains the size and synthetic functions of the adrenal cortex through activation of crucial enzymes and storage of cholesterol for metabolism into steroid hormones. Extra-adrenal effects of ACTH include stimulation of melanocytes and
activation of tissue lipase.

Once ACTH stimulates the cells of the adrenal cortex, cortisol synthesis and secretion immediately occur. In the healthy person, the secretory patterns of ACTH and cortisol are nearly identical. After secretion, some cortisol circulates in bound form attached to albumin but primarily it is bound to the plasma protein transcortin. A smaller amount circulates in the free form and diffuses into cells with specific intracellular receptors for cortisol. ACTH is rapidly inactivated in the circulation, and the liver and kidneys remove the deactivated hormone.

**Mineralocorticoids: aldosterone.**

Mineralocorticoid steroids directly affect ion transport by epithelial cells, causing sodium retention and potassium and hydrogen loss. Aldosterone is the most potent naturally occurring mineralocorticoid and conserves sodium by increasing the activity of the sodium pump of epithelial cells. (The sodium pump is described in Chapter 1.)

The initial stages of aldosterone synthesis occur in the zona fasciculata and zona reticularis. The final conversion of corticosterone to aldosterone is confined to the zona glomerulosa. Aldosterone synthesis and secretion is regulated primarily by the renin-angiotensin system (described in Chapter 29). The renin-angiotensin system is activated by sodium and water depletion, increased potassium levels, and a diminished effective blood volume (Figure 18-18). Angiotensin II is the primary stimulant of aldosterone synthesis and secretion; however, sodium and potassium levels also may directly affect aldosterone secretion. ACTH may transiently stimulate aldosterone synthesis but does not appear to be a major regulator of secretion.
When sodium and potassium levels are within normal limits, approximately 50 to 250 mg of aldosterone is secreted daily. Of the secreted aldosterone, 50% to 75% binds to plasma proteins. The large proportion of unbound aldosterone contributes to its rapid metabolic turnover in the liver, its low plasma concentration, and its short half-life (about 15 minutes). Aldosterone is degraded in the liver and is excreted by the kidney.

Aldosterone maintains extracellular volume by acting on distal nephron epithelial cells to increase reabsorption of sodium and excretion of potassium and hydrogen. This renal effect takes 90 minutes to 6 hours. Fluid and electrolyte regulation is addressed in more detail in Chapter 5. Other effects of aldosterone include
enhancement of cardiac muscle contraction, stimulation of ectopic ventricular activity through secondary cardiac pacemakers in the ventricles, stiffening of blood vessels with increased vascular resistance, and decrease in fibrinolysis. Pathologically elevated levels of aldosterone have been implicated in the myocardial changes associated with heart failure, resistant hypertension, insulin resistance, and systemic inflammation.\textsuperscript{32}

**Adrenal estrogens and androgens.**

The healthy adrenal cortex secretes minimal amounts of estrogen and androgens. ACTH appears to be the major regulator. Some of the weakly androgenic substances secreted by the cortex (dehydroepiandrosterone [DHEA], androstenedione) are converted by peripheral tissues to stronger androgens, such as testosterone, thus accounting for some androgenic effects initiated by the adrenal cortex. Peripheral conversion of adrenal androgens to estrogens is enhanced in aging or obese persons as well as in those with liver disease or hyperthyroidism.\textsuperscript{33} The biologic effects and metabolism of the adrenal sex steroids do not vary from those produced by the gonads (see Chapter 32).

**Adrenal Medulla**

The chromaffin cells (pheochromocytes) of the adrenal medulla secrete and store the catecholamines epinephrine (adrenaline) and norepinephrine (noradrenaline). Both are synthesized from the amino acid phenylalanine (Figure 18-19). The adrenal medulla, together with the sympathetic division of the autonomic nervous system, is embryonically derived from neural crest cells. Only 30% of circulating epinephrine comes from the adrenal medulla; the other 70% is released from nerve terminals. The medulla is only a minor source of norepinephrine. The adrenal medulla functions as a sympathetic ganglion without postganglionic processes. Sympathetic cholinergic preganglionic fibers terminate on the chromaffin cells and secrete catecholamines directly into the bloodstream. The catecholamines acting in the blood are therefore hormones and not neurotransmitters.
Physiologic stress to the body (e.g., traumatic injury, hypoxia, hypoglycemia, and many others) triggers release of adrenal catecholamines through acetylcholine (from the preganglionic sympathetic fibers), which depolarizes the chromaffin cells (see Chapter 9). Depolarization causes exocytosis of the storage granules from the chromaffin cells with release of epinephrine and norepinephrine into the bloodstream. Secretion of adrenal catecholamines also is increased by ACTH and the glucocorticoids.\(^{34}\)
Once released, the catecholamines remain in the plasma for only seconds to minutes. The catecholamines exert their biologic effects after binding to plasma membrane receptors ($\alpha_1$, $\alpha_2$, $\beta_1$, $\beta_2$, and $\beta_3$) in target cells. This binding activates the adenylyl cyclase system. Catecholamines are rapidly removed from the plasma by being absorbed by neurons for storage in new cytoplasmic granules, or they may be metabolically inactivated and excreted in the urine. The catecholamines directly inhibit their own secretion by decreasing the formation of the enzyme tyrosine hydroxylase (the rate-limiting step).

Catecholamines have diverse effects on the entire body. Their release and the body's response have been characterized as the “fight or flight” response (stress response) (see Figures 9-2 and 9-3 and Tables 9-3 and 9-4). Metabolic effects of catecholamines promote hyperglycemia through a variety of mechanisms including interference with the usual glucose regulatory feedback mechanisms.

Quick Check 18-4

1. What are the islets of Langerhans? Where are they located?

2. Compare and contrast the actions of alpha, beta, delta, and F cells.

3. What is the most potent naturally occurring glucocorticoid, and how is its secretion related to that of adrenocorticotropic hormone (ACTH)?

4. How does aldosterone influence fluid and electrolyte balance?

5. What are catecholamines?
Aging & Its Effects on Specific Endocrine Glands

General Endocrine Changes with Aging

Aging has many effects on the neuroendocrine system. There are complex changes within the hypothalamic/pituitary axis; and altered biologic activity of hormones, altered circulating levels of hormones, altered secretory response of the endocrine glands, altered metabolism of hormones, and loss of circadian control of hormone secretion are among the findings.

Pituitary

Posterior: Decrease in size; reduced antidiuretic hormone (ADH) secretion.

Anterior: Increased fibrosis and moderate increase in size of gland; decline in growth hormone release.

Thyroid

Glandular atrophy, fibrosis, nodularity, and increased inflammatory infiltrates; decreased T₄ secretion and turnover, decline in T₃ (especially in men), diminished thyroid-stimulating hormone (TSH) secretion; reduced response of plasma TSH concentration to thyroid-releasing hormone (TRH) administration (especially in men).

Growth Hormone and Insulin-like Growth Factors

The amounts of GH and IGF decline with aging, which contributes to decreases in muscle size and function, reduced fat and bone mass, and changes in reproductive and cognitive function. Increased visceral fat, decreased lean body mass, and decreased bone density are common in older adults.

Pancreas

It is common for older individuals to have glucose intolerance or diabetes, and
these disorders frequently are undiagnosed in aging adults. Mechanisms include decreased insulin receptor activity and decreased beta-cell secretion of insulin.

**Adrenal**

Decreased DHEA levels lead to decreased synthesis of androgen-derived estrogen and testosterone; decreased metabolic clearance of glucocorticoids and cortisol causes decreased cortisol secretion; there also are decreased levels of aldosterone. Circadian patterns of ACTH and cortisol secretion may change with aging.

**Gonads**

Postmenopausal women have decreased estrogen and progesterone, increased follicle-stimulating hormone, and relative increases in androgen levels; these changes have numerous physiologic and pathophysiologic consequences (see Chapter 32); in men there is a gradual decrease in serum testosterone levels, leading to decreased sexual activity, decreased muscle strength, and decreased bone mineralization.
Did You Understand?

Mechanisms of Hormonal Regulation

1. The endocrine system has diverse functions, including sexual differentiation, growth and development, and continuous maintenance of the body's internal environment and responses to stress.

2. Hormones are chemical messengers synthesized by endocrine glands and when released have intracrine, autocrine, paracrine and endocrine effects.

3. Hormones have specific negative- and positive-feedback mechanisms. Most hormone levels are regulated by negative feedback, in which hormone secretion raises the level of a specific hormone, ultimately causing secretion to subside, maintaining the hormone within a normal physiologic range.

4. Endocrine feedback is described in terms of short, long, and ultra-short feedback loops.

5. Water-soluble hormones circulate throughout the body in unbound form, whereas lipid-soluble hormones (e.g., steroid and thyroid hormones) circulate throughout the body bound to carrier proteins.

6. Hormones affect only target cells with appropriate receptors and then act on these cells to initiate specific cell functions or activities.

7. Hormones have two general types of effects on cells: (1) direct effects, or obvious changes in cell function, and (2) permissive effects, or less obvious changes that facilitate cell function.

8. Receptors for hormones may be located on the plasma membrane or in the intracellular compartment of a target cell.

9. Water-soluble hormones act as first messengers, binding to receptors in the cell's plasma membrane. The signals initiated by hormone-receptor binding are then transmitted into the cell by the action of second messengers (i.e., cAMP, cGMP, or tyrosine kinase) and mediate the action of the hormone on the target cell (i.e., protein synthesis or cellular growth).

10. Lipid-soluble hormones (including steroid and thyroid hormones) cross the
plasma membrane by diffusion. These hormones diffuse directly into the cell nucleus and bind to nuclear receptors. Rapid responses of steroid hormones may be mediated by plasma membrane receptors.

**Structure and Function of the Endocrine Glands**

1. The pituitary gland, consisting of anterior and posterior portions, is connected to the central nervous system through the hypothalamus.

2. The hypothalamus regulates anterior pituitary function by secreting releasing or inhibiting hormones and factors into the portal circulation.

3. Hypothalamic hormones include prolactin-releasing factor (PRF), which stimulates secretion of prolactin; prolactin-inhibiting factor (PIF, dopamine), which inhibits prolactin secretion; thyrotropin-releasing hormone (TRH), which affects release of thyroid hormones; growth hormone–releasing hormone (GHRH), which stimulates the release of growth hormone (GH); somatostatin, which inhibits the release of GH; gonadotropin-releasing hormone (GnRH), which facilitates the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH); corticotropin-releasing hormone (CRH), which facilitates the release of adrenocorticotropic hormone (ACTH) and endorphins; and substance P, which inhibits ACTH release and stimulates the release of a variety of other hormones.

4. Hormones of the anterior pituitary are regulated by (1) secretion of hypothalamic-releasing hormones or factors, (2) negative feedback from hormones secreted by target organs, and (3) mediating effects of neurotransmitters.

5. Hormones of the anterior pituitary include ACTH, melanocyte-stimulating hormone (MSH), somatotropic hormones (growth hormone [GH], prolactin), and glycoprotein hormones—follicle-stimulating hormone (FSH), luteinizing hormone (LH), and thyroid-stimulating hormone (TSH).

6. The posterior pituitary secretes antidiuretic hormone (ADH), which also is called vasopressin, and oxytocin.

7. ADH controls serum osmolality, increases permeability of the renal tubules to water, and causes vasoconstriction when administered pharmacologically in high doses. ADH also may regulate some central nervous system functions.

8. Oxytocin causes uterine contraction and lactation in women and may have a role
in sperm motility in men. In both men and women, oxytocin has an antidiuretic effect similar to that of ADH.

9. Melatonin is secreted by the pineal gland and regulates circadian rhythms and reproduction.

10. The two-lobed thyroid gland contains follicles, which secrete some of the thyroid hormones, and C cells, which secrete calcitonin and somatostatin.

11. Regulation of thyroid hormone (TH) levels is complex and involves the hypothalamus, anterior pituitary, thyroid gland, and numerous biochemical variables.

12. Thyroid hormone (TH) secretion is regulated by thyroid-releasing hormone (TRH) through a negative-feedback loop that involves the anterior pituitary and hypothalamus.

13. Thyroid-stimulating hormone (TSH), which is synthesized and stored in the anterior pituitary, stimulates secretion of TH by activating intracellular processes, including uptake of iodine necessary for the synthesis of TH in the thyroid gland.

14. Once secreted, TH acts on the thyroid gland, the anterior pituitary, and the median eminence to regulate further TH production.

15. Synthesis of TH depends on the glycoprotein thyroglobulin (TG), which contains a precursor of TH, tyrosine. Tyrosine then combines with iodine to form precursor molecules of the thyroid hormones thyroxine (T$_4$) and triiodothyronine (T$_3$). These hormones are then stored within thyroid colloid until released into the circulation.

16. When released into the circulation, T$_3$ and T$_4$ are bound by carrier proteins in the plasma, which store these hormones and provide a buffer for rapid changes in hormone levels. The free form is the active form.

17. Thyroid hormones alter protein synthesis and have a wide range of metabolic effects on proteins, carbohydrates, lipids, vitamins, and other hormones and neurotransmitters. TH also affects heat production and cardiac function.

18. The paired parathyroid glands normally are located behind the upper and lower poles of the thyroid. These glands secrete parathyroid hormone (PTH), an important
regulator of serum calcium and phosphate levels.

19. PTH secretion increases levels of ionized calcium and decreases levels of phosphate in the plasma.

20. In bone, PTH causes bone breakdown and resorption. At low doses it can promote bone formation. In the kidney, PTH increases reabsorption of calcium and decreases reabsorption of phosphorus and bicarbonate.

21. The endocrine pancreas contains the islets of Langerhans, which secrete hormones responsible for much of the carbohydrate metabolism in the body.

22. The islets of Langerhans consist of alpha cells, beta cells, delta cells, and F cells, which release hormones that regulate protein, fat, and carbohydrate metabolism.

23. Alpha cells produce glucagon, which is secreted inversely to blood glucose concentrations.

24. Delta cells secrete somatostatin, which inhibits glucagon and insulin secretion.

25. Beta cells secrete proinsulin, which is ultimately converted to insulin, and amylin, which suppresses glucagon secretion and has a satiety effect.

26. F cells secrete pancreatic polypeptide, which inhibits gallbladder contraction and exocrine pancreatic secretion.

27. Insulin is a hormone that regulates blood glucose concentrations and overall body metabolism of fat, protein, and carbohydrates.

28. The paired adrenal glands are situated above the kidneys. Each gland consists of an adrenal medulla, which secretes catecholamines, and an adrenal cortex, which secretes steroid hormones.

29. The steroid hormones secreted by the adrenal cortex are synthesized from cholesterol. These hormones include glucocorticoids, mineralocorticoids, and adrenal androgens and estrogens.

30. Glucocorticoids directly affect carbohydrate metabolism by increasing blood glucose concentration through gluconeogenesis in the liver and by decreasing use of glucose. Glucocorticoids also inhibit immune and inflammatory responses, suppress growth, and promote protein catabolism.
31. The most potent naturally occurring glucocorticoid is cortisol, which is necessary for the maintenance of life and for protection from stress. Secretion of cortisol is regulated by the hypothalamus and anterior pituitary.

32. Cortisol secretion is related to secretion of adrenocorticotropic hormone (ACTH), which is stimulated by corticotropin-releasing hormone (CRH). ACTH binds with receptors of the adrenal cortex, which activates intracellular mechanisms (specifically cyclic AMP) and leads to cortisol release.

33. Mineralocorticoids are steroid hormones that directly affect ion transport by renal tubular epithelial cells, causing sodium retention and potassium and hydrogen loss.

34. Aldosterone is the most potent of the naturally occurring mineralocorticoids. Its primary role is renal reabsorption of sodium and excretion of potassium and hydrogen.

35. Aldosterone secretion is regulated primarily by the renin-angiotensin system and by the serum sodium concentration.

36. Aldosterone acts by binding to a site on the cell nucleus and altering protein production within the cell. Its principal site of action is the kidney, where it causes sodium reabsorption and potassium and hydrogen excretion.

37. Androgens and estrogens secreted by the adrenal cortex act in the same way as those secreted by the gonads.

38. The adrenal medulla secretes the catecholamines epinephrine and norepinephrine. Epinephrine is 10 times more potent than norepinephrine in exerting metabolic effects. Their release is stimulated by sympathetic nervous system stimulation, ACTH, and glucocorticoids.

39. Catecholamines bind with various target cells and are taken up by neurons or excreted in the urine. They cause a range of metabolic effects characterized as the “fight or flight” response and include hyperglycemia and immunosuppression.

40. The endocrine system acts together with the nervous system to respond to stressors.

41. The response to stressors involves (1) activation of the sympathetic division of
the autonomic nervous system and (2) activation of the endocrine system.

42. Other hormones that are secreted in response to stress include growth hormone (GH), prolactin, testosterone, antidiuretic hormone (ADH), and insulin.

43. The adrenal glands and the sympathetic neurons that innervate these glands form the sympathoadrenal axis.

- Disorders of the Adrenal Medulla, 485
Functions of the endocrine system involve complex interactions between hormones and most body systems that maintain dynamic steady states and influence tissue growth and reproductive capabilities. Endocrine system dysfunction is usually caused by hypersecretion or hyposecretion of the various hormones, leading to abnormal hormone concentrations in the blood. Dysfunction also may result from abnormal cell receptor function or from altered intracellular response to the hormone-receptor complex.
Mechanisms of Hormonal Alterations

Significantly elevated or significantly depressed hormone levels may result from various causes (Table 19-1). Dysfunction of an endocrine gland may involve its failure to produce adequate amounts of biologically free or active hormone (hyposecretion), or a gland may synthesize or release too much hormone (hypersecretion). Feedback systems that recognize the need for a particular hormone may fail to function properly or may respond to inappropriate signals.

Once hormones are released into the circulation, they may be degraded at an altered rate or be inactivated before reaching the target cell by antibodies that function as circulating hormone inhibitors (e.g., thyroid disease). Other causes of decreased hormone delivery to the target cell include an inadequate blood supply to the gland or target tissues or an insufficient amount of the appropriate carrier proteins in the serum. Ectopic sources of hormones (hormones produced by nonendocrine tissues) may cause abnormally elevated hormone levels without the benefit of the normal feedback system for hormone control (e.g., hormone-producing tumors); in this case, the ectopic hormone production is said to be autonomous.

Target cells may not respond appropriately to hormonal stimulation for a number of reasons. The following are the two general types of target cell insensitivity to hormones:

1. **Cell surface receptor–associated disorders.** These disorders have been identified primarily in water-soluble hormones, such as insulin. They may involve a decrease in the number of receptors, leading to decreased or defective hormone-receptor binding; impairment of receptor function, resulting in insensitivity to the hormone; presence of antibodies against specific receptors that either reduce available binding
sites or mimic hormone action, suppressing or exaggerating, respectively, the target cell response; or unusual expression of receptor function, as occurs in some tumor cells.

2. *Intracellular disorders.* These disorders involve acquired defects in postreceptor signaling cascades or inadequate synthesis of a second messenger, such as cyclic adenosine monophosphate (cAMP), needed to transduce the hormonal signal into intracellular events. The target cell for water-soluble hormones may have a faulty response to hormone-receptor binding and thus fail to generate the required second messenger, or the cell may respond abnormally to the second messenger if levels of intracellular enzymes or proteins are altered. (Second messengers for various hormones are listed in Table 18-3.) As a result, the target cell fails to express the usual hormonal effect (e.g., pseudohypoparathyroidism, see p. 487).

Pathogenic mechanisms affecting target cell response for lipid-soluble hormones are recognized less often than those affecting water-soluble hormones. When they do occur, the mechanisms are similar to those for water-soluble hormones, including changes in the number and binding affinity of intracellular receptors or altered generation of new messenger ribonucleic acid (mRNA) and substrates for new protein synthesis. In other cases, hormone responsiveness may be linked to alterations in nuclear co-regulators, which are proteins (such as cAMP response element–binding protein that facilitate or inhibit the transcription of the target gene.\(^1\)
Alterations of the Hypothalamic-Pituitary System

Perhaps the most common cause of apparent hypothalamic dysfunction is interruption of the pituitary stalk caused by destructive lesions, rupture after head injury, surgical transection, or tumor. In these cases, interruption of the physical connections between the hypothalamus and the pituitary gland causes apparent pituitary disease. For example, without hypothalamic hormones (Figure 19-1), women cease to menstruate and men experience hypogonadism and impaired spermatogenesis. Adrenocorticotropin hormone (ACTH) response to low serum cortisol levels is decreased because of the absence of corticotropin-releasing hormone (CRH). Hypothalamic hypothyroidism is caused by the absence of thyrotropin-releasing hormone (TRH). Low levels of growth hormone–releasing hormone (GHRH) result in growth hormone (GH) deficiency and growth failure in children. Hyperprolactinemia is caused by an absence of the usual inhibitory control of prolactin secretion (dopamine).

**FIGURE 19-1** Loss of Hypothalamic Hormones. ACTH, Adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PIF, prolactin inhibitory factor (probably dopamine); TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.
Diseases of the Posterior Pituitary

Diseases of the posterior pituitary cause abnormal secretion of antidiuretic hormone (ADH, arginine vasopressin). An excess amount of this hormone results in water retention and a hypoosmolar state, whereas deficiencies in the amount or response to ADH result in serum hyperosmolarity (see Chapter 5). These complex pathophysiologic states not only have significant clinical effects on the modulation of body fluids and electrolytes but also affect cognitive and emotional responses to stress.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

The **syndrome of inappropriate ADH secretion (SIADH)** is characterized by high levels of ADH in the absence of normal physiologic stimuli for its release. A common cause of SIADH is the ectopic production of ADH by tumors, such as small cell carcinoma of the duodenum, stomach, and pancreas; cancers of the bladder, prostate, and endometrium; lymphomas; and sarcomas. Pulmonary disorders associated with SIADH include bronchogenic carcinoma, pneumonia (e.g., tuberculosis), asthma, cystic fibrosis, and respiratory failure requiring mechanical ventilation. Central nervous system disorders that may cause SIADH include encephalitis, meningitis, intracranial hemorrhage, tumors, and trauma.

Another important cause of SIADH is surgery. Any surgery can result in increased ADH secretion for as long as 5 to 7 days after surgery. The precise mechanism is uncertain but is likely related to fluid and volume changes following surgery, the amount and type of intravenous fluids given, and the use of narcotic analgesics. Transient SIADH also may follow pituitary surgery because stored ADH is released in an unregulated fashion.\(^2\)

Medications are an important cause of SIADH, especially in the elderly. These include hypoglycemic medications (e.g., chlorpropamide), narcotics, general anesthetics, antidepressants, antipsychotics, chemotherapeutic agents, nonsteroidal anti-inflammatory drugs, and synthetic ADH analogs.\(^3\)

Pathophysiology

The cardinal features of SIADH are the result of enhanced renal water retention. ADH increases renal collecting duct permeability to water by inducing the insertion of aquaporin-2, a water channel protein, into the tubular luminal membrane, which increases water reabsorption by the kidneys.\(^4\) (Renal function is discussed in Chapter 29.) This results in an expansion of extracellular fluid volume that leads to dilutional hyponatremia (low serum sodium concentration), hypoosmolarity, and urine that is inappropriately concentrated with respect to serum osmolarity because
water is reabsorbed that normally would be excreted.

**Clinical manifestations**

The symptoms of SIADH result from hyponatremia (see Chapter 5) and are determined by its severity and rapidity of onset. Thirst, impaired taste, anorexia, dyspnea on exertion, fatigue, and dulled sensorium occur when the serum sodium level decreases rapidly from 140 to 130 mEq/L. Peripheral edema is absent. Gastrointestinal symptoms, including vomiting and abdominal cramps, occur with a drop in sodium concentration from 130 to 120 mEq/L. There is weight gain from water retention, even with nausea and vomiting. Even if hyponatremia develops slowly, serum sodium levels below 110 to 115 mEq/L cause confusion, lethargy, muscle twitching, and convulsions; severe and sometimes irreversible neurologic damage may occur. Symptoms usually resolve with correction of hyponatremia (see Chapter 5).

**Evaluation and treatment**

A diagnosis of SIADH requires the following manifestations: (1) serum hypoosmolality and hyponatremia, (2) urine hyperosmolarity (i.e., urine osmolality is greater than expected for the concomitant serum osmolality), (3) urine sodium excretion that matches sodium intake (i.e., sodium excretion is normal in spite of excessive water reabsorption), (4) normal adrenal and thyroid function, and (5) absence of conditions that can alter volume status (e.g., congestive heart failure, hypovolemia from any cause, or renal insufficiency).

The treatment of SIADH involves the correction of any underlying causal problems and fluid restriction with careful monitoring of sodium status and neurologic symptoms. In severe SIADH, emergency correction of severe hyponatremia by careful administration of hypertonic saline may be required. Resolution usually occurs within 3 days, with a 2- to 3-kg weight loss and correction of hyponatremia and salt wasting. If hyponatremia is corrected too rapidly, a severe neurologic syndrome called central pontine myelinolysis can ensue. Demeclocycline, which causes the renal tubules to develop resistance to ADH, may be used to treat resistant or chronic SIADH. Vasopressin (ADH) receptor antagonists, known as vaptans, have recently been shown to be effective in treating SIADH.\(^5\)

**Diabetes Insipidus**

**Diabetes insipidus (DI)** is an insufficiency of ADH activity, leading to polyuria (frequent urination) and polydipsia (frequent drinking). The two forms of DI are as
follows:

1. **Neurogenic or central DI.** Caused by the insufficient secretion of ADH, it occurs when any organic lesion of the hypothalamus, pituitary stalk, or posterior pituitary interferes with ADH synthesis, transport, or release. Causative lesions include primary brain tumors, hypophysectomy, aneurysms, thrombosis, infections, and immunologic disorders. Central DI is a well-recognized complication of traumatic brain injury. It can also be caused by hereditary disorders that affect ADH genes or result in structural changes in the pituitary gland.

2. **Nephrogenic DI.** Caused by inadequate response of the renal tubules to ADH, nephrogenic DI is usually acquired or may be genetic. Acquired nephrogenic DI is generally related to disorders and drugs that damage the renal tubules or inhibit the generation of cAMP in the tubules. These disorders include pyelonephritis, amyloidosis, destructive uropathies, and polycystic kidney disease, all of which lead to irreversible diabetes insipidus. Drugs that may induce a reversible form of nephrogenic diabetes insipidus include lithium carbonate, colchicines, amphotericin B, loop diuretics, general anesthetics (such as methoxyflurane), and demeclocycline. Several genetic causes of nephrogenic DI have been identified. One of the best described is a mutation in the gene that codes for aquaporin-2, which is one of the four water transport channels in the renal tubule.

There is a rare form of DI associated with pregnancy. In gestational DI, the level of the vasopressin-degrading enzyme vasopressinase is increased. Clinical manifestations are usually mild and do not require treatment.

*Dipsogenic or primary polydipsia* may be confused with diabetes insipidus. It is caused by the chronic ingestion of extremely large quantities of fluid that wash out the renal medullary concentration gradient, which results in a partial resistance to ADH. This condition resolves with decreased fluid ingestion. Psychogenic causes of polydipsia must be differentiated from true DI because administering an ADH analog to an individual with psychogenic DI will result in severe hypoosmolality.

**Pathophysiology**

Individuals with diabetes insipidus have a partial to total inability to concentrate urine. Insufficient ADH activity causes excretion of large volumes of dilute urine, leading to increased plasma osmolality. In conscious individuals, the thirst mechanism is stimulated and induces polydipsia—usually a craving for cold drinks. Dehydration develops rapidly without ongoing fluid replacement. If the individual with DI cannot conserve as much water as is lost in the urine, serum hypernatremia
and hyperosmolality occur. Concentrations of other serum electrolytes generally are not affected.

**Clinical manifestations**

The clinical manifestations of diabetes insipidus include polyuria, nocturia, continuous thirst, and polydipsia. The urine output is varied but can increase from the normal output of 1 to 2 L/day to as much as 8 to 12 L/day and can be higher than daily fluid intake. Individuals with long-standing diabetes insipidus develop a large bladder capacity and hydronephrosis (see Chapter 30). Neurogenic diabetes insipidus usually has an abrupt onset and many individuals can specifically recall the date of onset of their symptoms. Nephrogenic DI usually has a more gradual onset. Table 19-2 compares the signs and symptoms of DI and SIADH.

**Evaluation and treatment**

Diabetes insipidus must be distinguished from other polyuric states, including diabetes mellitus, osmotically induced diuresis, and psychogenic polydipsia. The criteria for the diagnosis of DI include low urine specific gravity, low urine osmolality, hypernatremia, high serum osmolality, and continued diuresis despite a serum sodium concentration of 145 mEq/L or greater. The diagnosis of DI is generally confirmed through water deprivation testing. Psychogenic polydipsia can be differentiated from nephrogenic DI based on plasma ADH levels. ADH levels are low in psychogenic polydipsia and normal or high in nephrogenic DI.

Treatment of neurogenic DI is based on the extent of the ADH deficiency and on the patient's age, endocrine and cardiovascular status, and lifestyle. Some individuals require ADH replacement, but fluid replacement using oral or intravenous routes is usually adequate. ADH replacement therapy for symptomatic central or neurogenic diabetes insipidus includes intravascular or, more commonly, oral or intranasal administration of the synthetic vasopressin analog DDAVP (desmopressin). Management of nephrogenic DI requires treatment of any
reversible underlying disorders, discontinuation of etiologic medications, and correction of associated electrolyte disorders. Surprisingly, thiazide diuretics may improve renal tubular salt and water retention in individuals with moderate nephrogenic DI. New treatments aimed at reversing aquaporin-2 dysfunction are being developed. Drugs that potentiate the action of otherwise insufficient amounts of endogenous ADH, such as chlorpropamide, carbamazepine, and clofibrate, may be used in individuals with incomplete ADH deficiency.

Diseases of the Anterior Pituitary

Hypopituitarism

Hypopituitarism can be characterized by the absence of one or more anterior pituitary hormones or the complete failure of all anterior pituitary hormone functions. Hypopituitarism results from either an inadequate supply of hypothalamic-releasing hormones, because of damage to the pituitary stalk, or an inability of the gland to produce hormones. The most common causes of hypopituitarism are pituitary infarction or space-occupying lesions, such as pituitary adenomas or aneurysms. Pituitary infarction may occur in women during the postpartum period (Sheehan syndrome) because of blood loss and hypovolemic shock. Traumatic brain injury is increasingly recognized as an important cause of hypopituitarism and can have a significant impact on acute and long-term recovery. Other causes of hypopituitarism include removal or destruction of the gland, infections (e.g., meningitis, syphilis, tuberculosis), autoimmune hypophysitis, certain drugs (e.g., bexarotene, carbamazepine, ipilimumab), or mutation of the prophet of pituitary transcription factor (PROP-1) gene involved in early embryonic pituitary development.

Pathophysiology

The pituitary gland is highly vascular and relies heavily upon portal blood flow from the hypothalamus. It is, therefore, vulnerable to ischemia and infarction. Infarction results in tissue necrosis and edema with swelling of the gland. Expansion of the pituitary within the fixed compartment of the sella turcica further impedes blood supply to the pituitary. Over time, fibrosis of pituitary tissue occurs and the symptoms of hypopituitarism develop. Adenomas and aneurysms may compress otherwise normal secreting pituitary cells and lead to compromised hormonal output.

Clinical manifestations
The signs and symptoms of hypofunction of the anterior pituitary are variable and depend on which hormones are affected. In **panhypopituitarism**, all hormones are deficient and the individual suffers from multiple complications including cortisol deficiency from lack of ACTH, thyroid deficiency from lack of thyroid-stimulating hormone (TSH), and loss of secondary sex characteristics because of the lack of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Low levels of growth hormone (GH) and insulin-like growth factor 1 (IGF-1) affect growth in children and can cause physiologic and psychologic symptoms in adults. Finally, postpartum women cannot lactate because of decreased or absent prolactin.

ACTH deficiency with associated loss of cortisol is a potentially life-threatening disorder. ACTH deficiency usually is encountered with generalized pituitary hypofunction; it rarely occurs as an isolated event. Within 2 weeks of the complete absence of ACTH, symptoms of cortisol insufficiency develop, including nausea, vomiting, anorexia, fatigue, and weakness. Hypoglycemia results from increased insulin sensitivity, decreased glycogen reserves, and decreased gluconeogenesis associated with hypocortisolism. ACTH deficiency also limits maximal aldosterone secretion, although the renin-angiotensin system can stimulate some aldosterone secretion. The glomerular filtration rate decreases, causing decreased urine output.

TSH deficiency is rarely seen in isolation but often occurs with other pituitary hormone deficiencies. Symptoms develop 4 to 8 weeks after hypothyrotropinemia occurs and include cold intolerance, skin dryness, mild myxedema, lethargy, and decreased metabolic rate. The symptoms usually are less severe than those of primary hypothyroidism.

The onset of FSH and LH deficiencies in women of reproductive age is associated with amenorrhea and atrophy of the vagina, uterus, and breasts. In postpubertal males, the testicles atrophy and facial hair growth is diminished. Both men and women experience decreased body hair and diminished libido.

GH deficiency occurs in both children and adults. Several genetic defects have been identified in the growth hormone axis in children, including a recessive mutation in the GH gene, resulting in a failure of growth hormone secretion. Mutations also may involve the GH receptor, IGF-1 biosynthesis, IGF-1 receptors, or defects in GH signal transduction. In adults, GH deficiency is most often caused by structural or functional abnormalities of the pituitary. In both children and adults, acute GH and IGF-1 deficiency has been implicated in significant metabolic perturbations seen with critical illness.

GH deficiency in children is manifested by growth failure and a condition known as hypopituitary dwarfism (Figure 19-2); however, not all children with short stature have growth hormone deficiency. Symptoms of chronic adult GH deficiency syndrome include increased body fat, decreased strength and lean body mass,
osteoporosis, reduced sweating, dry skin, and psychologic problems, including depression, social withdrawal, fatigue, loss of motivation, and a diminished feeling of well-being. Without adequate GH replacement, increased mortality can occur as a result of myocardial infarction and stroke associated with dyslipidemias and atherosclerosis.¹³

**FIGURE 19-2** Hypopituitary Dwarfism and Pituitary Giantism. A pituitary giant and dwarf contrasted with normal-size men. Excessive secretion of growth hormone by the anterior lobe of the pituitary gland during the early years of life produces giants of this type, whereas deficient secretion of this substance produces well-formed dwarfs. (From Patton KT, Thibodeau GA: Anatomy & physiology, ed 8, St Louis, 2013, Mosby)

**Evaluation and treatment**

The diagnostic evaluation of suspected pituitary disease is often challenging and
must be carefully interpreted together with the individual's signs and symptoms. Simultaneous measurements of the levels of tropic hormones from the pituitary and target endocrine glands are crucial, and the more complicated dynamic testing of insulin, TRH, and gonadotropin-releasing hormone (GnRH) may be indicated. Imaging of the pituitary (magnetic resonance imaging [MRI] or computed tomography [CT] scans) is critical to assess for anatomic lesions, such as tumors.

Management of hypopituitarism requires correction of the underlying disorder as quickly as possible. Replacement of target gland hormones that are deficient because of lack of tropic anterior pituitary hormones is essential (such as cortisol, thyroid hormone, growth hormone, and gender-specific steroid hormones). In cases of circulatory collapse, immediate therapy with glucocorticoids and intravenous fluids is critical.

**Hyperpituitarism: Primary Adenoma**

**Pituitary adenomas** usually are benign, slow-growing tumors that arise from cells of the anterior pituitary. The cause of pituitary adenomas is not known and most occur sporadically. Altered gene expression is commonly detected and familial pituitary adenomas occur as part of syndromes affecting other organs, such as multiple endocrine neoplasia. Most are microscopic (microadenomas) and are found only on postmortem examinations or incidentally discovered on MRI examinations. The majority of pituitary microadenomas are hormonally silent and do not pose significant hazards to the individual. Larger adenomas (macroadenomas) are associated with morbidity and mortality attributable to alterations in hormone secretion or to invasion or impingement of surrounding structures.

**Pathophysiology**

Local expansion of the adenoma may impinge on the optic chiasma and cause various visual disturbances, depending on the portion of the nerve compressed. If the tumor is locally aggressive, invasion of the cavernous sinuses may occur, resulting in compromise of the oculomotor, trochlear, abducens, and trigeminal nerves with attending symptoms (see Table 13-6 for review of cranial nerves). Extension to the hypothalamus disturbs control of wakefulness, thirst, appetite, and temperature.

Hormonal effects of adenomas include hypersecretion from the adenoma itself and hyposecretion from surrounding pituitary cells. The adenomatous tissue secretes the hormone of the cell type from which it arose, without regard to the needs of the body and without benefit of regulatory feedback mechanisms.
(autonomous function). Because of the pressure exerted by the tumor in the unexpandable bony sella turcica, hyposecretion from those cells that are most sensitive to pressure is common (GH-, FSH-, and LH-secreting cells).\textsuperscript{16}

**Clinical manifestations**

The clinical manifestations of pituitary adenomas are related to tumor growth and hormone hypersecretion or hyposecretion. Increased tumor size causes headache, fatigue, neck pain or stiffness, and seizures. Visual changes include visual field impairments (often beginning in one eye and progressing to the other) and temporary blindness. If the tumor infiltrates other cranial nerves, neuromuscular function is affected.

Pituitary adenomas are most often associated with increased secretion of growth hormone and prolactin (see Hypersecretion of Growth Hormone: Acromegaly and Prolactinoma sections in this chapter). Gonadotropin hyposecretion results in menstrual irregularity in women, decreased libido, and receding secondary sex characteristics in both men and women. If the tumor exerts sufficient pressure, thyroid and adrenal hypofunction may occur because of lack of TSH and ACTH, resulting in the symptoms of hypothyroidism and hypocortisolism, respectively.

**Evaluation and treatment**

Diagnosis of pituitary adenoma involves physical and laboratory evaluations, including pertinent hormone assays and radiographic examination of the skull (MRI [preferred] or contrast-enhanced CT). The goal of treatment is to protect the individual from the effects of tumor growth and to control hormone hypersecretion while minimizing damage to appropriately secreting portions of the pituitary. Depending on tumor size and type, individuals may be treated by administration of specific medications to suppress tumor growth, transsphenoidal tumor resection, or radiation therapy including stereotactic treatments.\textsuperscript{16}

---

**Quick Check 19-1**

1. What is the mechanism of receptor-associated hormonal disorder?

2. Why do individuals with the syndrome of inappropriate antidiuretic hormone (SIADH) secrete concentrated urine?

3. Why may individuals with a pituitary adenoma develop visual disturbances?
Hypersecretion of Growth Hormone: Acromegaly

Acromegaly results from continuous exposure to high levels of growth hormone (GH) and insulin-like growth factor 1 (IGF-1); it almost always is caused by a GH-secreting pituitary adenoma (it rarely results from the ectopic production of GHRH). Acromegaly usually occurs in adults in the 40- to 59-year-old age group, although it is often present for years before diagnosis. It is a slowly progressive disease and, if untreated, is associated with a decreased life expectancy. Deaths from acromegaly are caused by heart disease secondary to hypertension and coronary artery disease, stroke, diabetes mellitus, or malignancy (colon or lung cancers).

Pathophysiology

With a GH-secreting adenoma, the usual GH baseline secretion pattern and sleep-related GH peaks are lost, and a totally unpredictable secretory pattern ensues. However, GH levels in acromegalics are never completely suppressed. Only slight elevations of GH and IGF-1 can stimulate growth. In children and adolescents whose epiphyseal plates have not yet closed, the effect of increased GH levels is termed giantism (see Figure 19-2). Skeletal growth is excessive, with some individuals becoming 8 or 9 feet tall. In the adult, epiphyseal closure has occurred, and increased amounts of GH and IGF-1 cause connective tissue proliferation and increased cytoplasmic matrix, as well as bony proliferation that results in the characteristic appearance of acromegaly (Figure 19-3).
GH also has significant effects on glucose, lipid, and protein metabolism. Hyperglycemia results from adipocyte inflammation and GH inhibition of peripheral glucose uptake and increased hepatic glucose production, followed by compensatory hyperinsulinism and, finally, insulin resistance. Diabetes mellitus occurs when the pancreas cannot secrete enough insulin to offset the effects of GH. Excessive levels of GH and IGF-1 also affect the cardiovascular system. Although
the associated pathophysiologic mechanism is not clearly understood at present, hypertension and left ventricular heart failure are seen in one third to one half of individuals with acromegaly. Cardiomyopathy associated with progressive and unrestrained myocardial growth is a significant factor. GH also acts on the renal tubules to increase phosphate reabsorption, leading to mild hyperphosphatemia. Because the adenoma becomes increasingly a space-occupying lesion, hypopituitarism may occur because of compression of surrounding hormone-secreting cells. Hyperprolactinemia can occur in 30% to 40% of individuals with acromegaly.17

Clinical manifestations
With connective tissue proliferation, individuals with acromegaly have an enlarged tongue, interstitial edema, enlarged and overactive sebaceous and sweat glands (leading to increased body odor), and coarse skin and body hair. Bony proliferation involves periosteal vertebral growth and enlargement of the bones of the face, hands, and feet (see Figure 19-3). The lower jaw and forehead also protrude. Skeletal abnormalities are irreversible.

Increased IGF-1 levels cause ribs to elongate at the bone-cartilage junction, leading to a barrel-chested appearance, and increased proliferation of cartilage in joints, which causes backache and arthralgias. With bony and soft tissue overgrowth, nerve entrapment occurs, leading to peripheral nerve damage manifested by weakness, muscular atrophy, footdrop, and sensory changes in the hands.

Symptoms of diabetes mellitus, such as polyuria and polydipsia, may occur because of decreased insulin sensitivity. Acromegaly-associated hypertension is usually asymptomatic until heart failure symptoms develop. Increased tumor size results in central nervous system symptoms of headache, seizure activity, visual disturbances, and papilledema. If compression hypopituitarism occurs, gonadotropin secretion may be affected, causing amenorrhea in women and sexual dysfunction in men. Approximately 20% of growth hormone–secreting tumors also secrete prolactin, resulting in hypogonadism. Cardiovascular, metabolic, and symptoms of tumor compression often improve with treatment.

Evaluation and treatment
Diagnosis is confirmed by clinical features of the disease, MRI scans, and elevated levels of IGF-1. GH level is typically elevated and not suppressed with oral glucose tolerance testing. The goals of treatment are to normalize or reduce GH secretion and relieve or prevent complications related to tumor expansion. The treatment of choice in acromegaly is transsphenoidal surgical removal of the GH-
secreting adenoma. Radiation therapy may be effective when rapid control of GH levels is not essential, when the individual is not a good surgical candidate, or when hyperfunction persists after subtotal resection. Somatostatin analogs, such as octreotide, octreotide LAR, and lanreotide, normalize IGF-1 levels and lower growth hormone levels. Pegvisomant can be used to supplement somatostatin analogs and is an effective drug that induces tissue insensitivity to GH by blocking the GH receptor.\textsuperscript{17} Dopaminergic agonists, such as cabergoline, also may be helpful, especially if the tumor also secretes prolactin.

**Prolactinoma**

Pituitary tumors that secrete prolactin, **prolactinomas**, are the most common hormonally active pituitary tumors. Other conditions or medications can elevate prolactin levels in the absence of a pituitary pathologic condition. For example, renal failure, polycystic ovarian disease, primary hypothyroidism, breast stimulation, or even the stress of venipuncture can increase prolactin levels. Prolactin is under tonic inhibitory hypothalamic control through the secretion of dopamine. Thus medications that block the effects of dopamine can increase prolactin level and stimulate proliferation of prolactin-secreting cells (lactotrophs). These include antipsychotics (risperidone, chlorpromazine), metoclopramide, tricyclic antidepressants, and methyldopa. Estrogens increase prolactin concentration by stimulating hyperplasia of prolactin-secreting cells. Any process that interferes with the delivery of dopamine from the hypothalamus to the lactotrophs (pituitary stalk tumor, pituitary stalk transection, or compressive pituitary tumor) also results in hyperprolactinemia. Because thyrotropin-releasing hormone (TRH) stimulates prolactin secretion, in addition to enhancing TSH release, prolactin concentration may be elevated in individuals with primary hypothyroidism.

**Pathophysiology**

The hallmark of a prolactinoma is sustained increases in the levels of serum prolactin. The physiologic actions of prolactin include breast development during pregnancy, postpartum milk production, and suppression of ovarian function in nursing women. Pathologic elevation of prolactin levels in women results in amenorrhea, nonpuerperal milk production (galactorrhea), hirsutism, and osteopenia or osteoporosis resulting from estrogen deficiency. Hyperprolactinemia in men causes hypogonadism and erectile dysfunction.

Because the adenoma becomes an increasingly space-occupying lesion, hypopituitarism may occur because of the compression of surrounding hormone-
secreting cells. Central nervous system symptoms may develop because of growth and pressure of the adenoma within the sella turcica. These complications are especially common with what are called macro (>1 cm in diameter) or giant (>4 cm in diameter) prolactinomas and are often more difficult to treat.21

Clinical manifestations
Women with hyperprolactinemia generally present with galactorrhea (nonpuerperal milk production) and menstrual disturbances including amenorrhea. In susceptible women, hirsutism develops because of estrogen deficiency. If not detected until after many years, this estrogen deficiency also may result in osteopenia or osteoporosis. Men often present late with symptoms related to the increasing size of the adenoma (i.e., headache or visual impairment).

Evaluation and treatment
The diagnostic evaluation of hyperprolactinemia includes a careful history to exclude medications that may cause elevations in prolactin concentration. Symptoms of hypothyroidism should be elicited, and screening with a serum TSH level is mandatory. MRI scanning of the pituitary is indicated to determine the size and location of an adenoma. If serum prolactin level is less than 50 ng/ml, a careful search for a nonpituitary cause should be pursued.

Dopaminergic agonists (cabergoline) are the treatment of choice for prolactinomas. Restoration of fertility in previously anovulatory women is common. In individuals resistant or intolerant to these medications, transsphenoidal surgery and radiotherapy are options.22 New chemotherapeutic and targeted molecular therapies are being explored in selected cases.23
Alterations of Thyroid Function

Disorders of thyroid function develop as a result of primary dysfunction or disease of the thyroid gland or, secondarily, as a result of pituitary or hypothalamic alterations. Primary thyroid disorders result in alterations of thyroid hormone (TH) levels with secondary feedback effects on pituitary thyroid-stimulating hormone (TSH). For example, when there are primary elevations in TH level, TSH level will secondarily decrease because of negative feedback. When TH level is decreased because of a condition affecting the thyroid gland, TSH level will be elevated. Thyroid disease also can present with minimal or no symptoms but with abnormal laboratory values, known as subclinical thyroid disease. Central (secondary) thyroid disorders are related to disorders of pituitary gland TSH production. When there is excessive TSH production, TH level is elevated secondary to the primary elevation of TSH concentration. The reverse is true with inadequate TSH production.

Thyrotoxicosis/Hyperthyroidism

Pathophysiology

Thyrotoxicosis is a condition that results from any cause of increased TH levels. Hyperthyroidism is a form of thyrotoxicosis in which excess amounts of TH are secreted from the thyroid gland (Figure 19-4). The terms thyrotoxicosis and hyperthyroidism are often used interchangeably. Common diseases that cause primary hyperthyroidism include Graves disease, toxic multinodular goiter, and solitary toxic adenoma. Central (secondary) hyperthyroidism is less common and is caused by TSH-secreting pituitary adenomas. Thyrotoxicosis not associated with hyperthyroidism includes ectopic thyroid tissue, and ingestion of excessive TH. Each condition is associated with a specific pathophysiology and manifestations; however, all forms of thyrotoxicosis share some common characteristics.
Clinical manifestations

The clinical features of thyrotoxicosis are attributable to the metabolic effects of increased circulating levels of thyroid hormones. This usually results in an increased metabolic rate with heat intolerance and increased tissue sensitivity to stimulation by the sympathetic nervous system. The major manifestations are summarized in Figure 19-5. Enlargement of the thyroid gland (goiter) is common in hyperthyroid conditions caused by stimulation of TSH receptors.
Elevated serum thyroxine (T₄) and triiodothyronine (T₃) levels and suppressed serum TSH levels are diagnostic for primary hyperthyroidism. By contrast, central (secondary) hyperthyroidism caused by TSH-secreting pituitary tumors is characterized by normal to increased TSH levels despite elevated thyroid hormone concentrations. Radioactive iodine is used to test for increased uptake in primary hyperthyroidism (Figure 19-6). Treatment is directed at controlling excessive TH production, secretion, or action and employs antithyroid drug therapy, radioactive iodine therapy (absorbed only by thyroid tissue, causing death of cells), and surgery. A major complication of all forms of treatment for hyperthyroidism is
excessive ablation of the gland leading to hypothyroidism.

**Graves Disease**

*Graves disease* is the underlying cause of 50% to 80% of cases of hyperthyroidism with a prevalence of approximately 0.5% in the U.S. population. It occurs more commonly in women. Although the exact cause of Graves disease is not known, genetic factors interacting with environmental triggers play an important role in the pathogenesis. Graves disease is classified as an autoimmune disease and results from a form of type II hypersensitivity (see Chapter 8) in which there is stimulation of the thyroid by autoantibodies directed against the TSH receptor. These autoantibodies, called thyroid-stimulating immunoglobulins (TSIs), override the normal regulatory mechanisms. The TSI stimulation of TSH receptors in the gland results in hyperplasia of the gland (goiter) and increased synthesis of TH, especially of triiodo-L-thyronine ($T_3$). Increased levels of TH result in the classic signs and
symptoms of hyperthyroidism illustrated in Figure 19-6. TSH production by the pituitary is inhibited through the usual negative feedback loop.  

TSI also contributes to the two major distinguishing clinical manifestations of Graves disease (ophthalmopathy and dermopathy [pretibial myxedema]). Two categories of ophthalmopathy associated with Graves disease (Figure 19-7) are (1) functional abnormalities resulting from hyperactivity of the sympathetic division of the autonomic nervous system (lag of the globe on upward gaze and of the upper lid on downward gaze) and (2) infiltrative changes involving the orbital contents with enlargement of the ocular muscles. These changes affect more than half of individuals with Graves disease. Orbital connective tissue accumulation, inflammation, and edema of the orbital contents result in exophthalmos (protrusion of the eyeball), periorbital edema, and extraocular muscle weakness, leading to diplopia (double vision). The individual may experience irritation, pain, lacrimation, photophobia, blurred vision, decreased visual acuity, papilledema, visual field impairment, exposure keratosis, and corneal ulceration.

A small number of individuals with Graves disease and very high levels of TSI experience pretibial myxedema (Graves dermopathy), characterized by subcutaneous swelling on the anterior portions of the legs and by indurated and erythematous skin. Graves dermopathy is associated with thyrotropin receptor
antigens on fibroblasts and recruited T lymphocytes that stimulate excessive amounts of hyaluronic acid production in the dermis and subcutaneous tissue.\textsuperscript{26} These manifestations occasionally appear on the hands, giving the appearance of clubbing of the fingers (thyroid acropachy).

**Hyperthyroidism resulting from nodular thyroid disease.**

The thyroid gland normally enlarges in response to the increased demand for TH that occurs in puberty, pregnancy, and iodine-deficient states as well as in individuals with immunologic, viral, or genetic disorders. When the condition resulting in increased TH resolves, TSH secretion normally subsides and the thyroid gland returns to its original size.

Irreversible changes can occur in some follicular cells so these cells function autonomously and produce excessive amounts of TH. On the other hand, some follicular cells may cease to function. The balance between the amount of TH produced by hyperfunctioning nodules and that produced by the remainder of the gland determines whether an individual develops hyperthyroidism. **Toxic multinodular goiter** occurs when there are several hyperfunctioning nodules leading to hyperthyroidism. Unlike Graves disease, there is absence of an autoimmune stimulus. If only one nodule is hyperfunctioning, it is termed **toxic adenoma**. The classic clinical manifestations of hyperthyroidism (see Figure 19-5) usually develop slowly, and exophthalmos and pretibial myxedema do not occur. Nodules may be palpable on physical examination and there is increased uptake of radioactive iodine. The incidence of malignancy in toxic nodular goiter is estimated to be as high as 9%, so most individuals should undergo a fine needle aspiration biopsy of suspicious nodules before treatment. Treatment consists of a combination of radioactive iodine, surgery, and antithyroid medications.\textsuperscript{27}

**Thyrotoxic crisis.**

**Thyrotoxic crisis (thyroid storm)** is a rare but dangerous worsening of the thyrotoxic state in which death can occur within 48 hours without treatment. The condition may develop spontaneously, but it usually occurs in individuals who have undiagnosed or partially treated Graves disease and are subjected to excessive stress, such as infection, pulmonary or cardiovascular disorders, trauma, seizures, surgery (especially thyroid surgery), obstetric complications, emotional distress, or dialysis. The symptoms of thyroid crisis are caused by the increased action of thyroxine ($T_4$) and triiodothyronine ($T_3$) exceeding metabolic demands.\textsuperscript{28}

The systemic symptoms of thyrotoxic crisis include hyperthermia; tachycardia, especially atrial tachydysrhythmias; high-output heart failure; agitation or delirium;
and nausea, vomiting, or diarrhea contributing to fluid volume depletion. Treatment includes (1) the use of drugs that block TH synthesis (i.e., propylthiouracil or methimazole), (2) the use of beta-blockers for control of cardiovascular symptoms, the administration of (3) steroids or (4) iodine (e.g., saturated solution of potassium iodide [SSKI]), and (5) supportive care.

Hypothyroidism

Hypothyroidism results from deficient production of TH by the thyroid gland. Hypothyroidism is the most common disorder of thyroid function, affects between 1% and 2% of the U.S. population, and occurs more commonly in women. It may be primary or central. Primary hypothyroidism accounts for 99% of all cases. Central (secondary) hypothyroidism is less common and is related to either pituitary or hypothalamic failure.

The most common cause of primary hypothyroidism in the United States is autoimmune thyroiditis (Hashimoto disease, chronic lymphocytic thyroiditis), which results in gradual inflammatory destruction of thyroid tissue by infiltration of autoreactive T lymphocytes and circulating thyroid autoantibodies (antithyroid peroxidase and antithyroglobulin antibodies). This disorder is linked with several genetic risk factors and is commonly associated with other autoimmune conditions. Infiltration of thyroid autoantibodies, autoreactive T lymphocytes, natural killer cells, and inflammatory cytokines and induction of apoptosis are involved in the tissue destruction seen in Hashimoto thyroiditis. Radioactive iodine uptake is normal or elevated.

Spontaneous recovery of thyroid function is seen in three conditions: subacute thyroiditis, painless thyroiditis, and postpartum thyroiditis. Subacute thyroiditis (de Quervain thyroiditis) is a rare nonbacterial inflammation of the thyroid gland often preceded by a viral infection. It is accompanied by fever, tenderness, and enlargement of the thyroid gland. The inflammatory process initially results in elevated levels of thyroid hormone through the release of stored thyroglobulin, which then is associated with transient hypothyroidism before the gland recovers normal activity. Thyroid antibodies are not present in the blood. Symptoms may last for 2 to 4 months, and nonsteroidal anti-inflammatory drugs or corticosteroids usually resolve symptoms. Painless (silent) thyroiditis has a course similar to that of subacute thyroiditis but is pathologically identical to Hashimoto disease. Postpartum thyroiditis is pathologically related to Hashimoto disease and generally occurs up to 6 months after delivery with a course similar to that seen in subacute thyroiditis. Thus a hyperthyroid phase (with a low thyroid radioiodine uptake) precedes the hypothyroid phase in typical cases of subacute, painless, or
postpartum thyroiditis. Spontaneous recovery occurs in 95% of these conditions.

**Congenital Hypothyroidism**

Hypothyroidism in infants occurs when thyroid tissue is absent (thyroid dysgenesis) or with hereditary defects in TH synthesis. Thyroid dysgenesis occurs more often in female infants, with permanent abnormalities in 1 of every 4000 live births. Because TH is essential for embryonic growth, particularly of brain tissue, the infant will be cognitively disabled if there is no thyroxine during fetal life. The fetus is dependent on maternal thyroxine for the first 20 weeks of gestation. Hypothyroidism may not be evident at birth. Symptoms may include high birth weight, hypothermia, delay in passing meconium, and neonatal jaundice. Cord blood can be examined in the first days of life for measurement of T₄ and TSH levels. The probability of normal growth and intellectual function is high if treatment with levothyroxine is started before the child is 3 or 4 months old. The earlier thyroid hormone replacement is initiated, the better the child's outcome.

Without early screening, hypothyroidism may not be evident until after 4 months of age. Symptoms include difficulty eating, hoarse cry, and protruding tongue caused by myxedema of oral tissues and vocal cords; hypotonic muscles of the abdomen with constipation, abdominal protrusion, and umbilical hernia; subnormal temperature; lethargy; excessive sleeping; slow pulse rate; and cold, mottled skin. Skeletal growth is stunted because of impaired protein synthesis, poor absorption of nutrients, and lack of bone mineralization. The child will be dwarfed with short limbs, if not treated. Dentition is often delayed. Cognitive disability varies with the severity of hypothyroidism and the length of delay before treatment is initiated.

**Pathophysiology**

In *primary hypothyroidism*, loss of thyroid function leads to decreased production of TH and increased secretion of TSH and TRH (Figure 19-8). The most common causes of primary hypothyroidism in adults include autoimmune thyroiditis (Hashimoto disease), iatrogenic loss of thyroid tissue after surgical or radioactive treatment for hyperthyroidism or after head and neck radiation therapy, medications (e.g., lithium and amiodarone), and endemic iodine deficiency. Infants and children may present with hypothyroidism because of congenital defects. *Central (secondary) hypothyroidism* is caused by the pituitary's failure to synthesize adequate amounts of TSH or a lack of TRH. Pituitary tumors that compress surrounding pituitary cells or the consequences of their treatment are the most common causes of central hypothyroidism. Other causes include traumatic brain injury, subarachnoid hemorrhage, or pituitary infarction. Hypothalamic dysfunction results
in low levels of TH, TSH, and TRH. Subclinical hypothyroidism is a mild thyroid failure estimated to occur in 4% to 8% of U.S. adults. It is defined as an elevation in TSH levels with normal levels of circulating TH.

**Clinical manifestations**

Hypothyroidism generally affects all body systems and occurs insidiously over months or years. The decrease in TH level lowers energy metabolism and heat production. The individual develops a low basal metabolic rate, cold intolerance, lethargy, and slightly lowered basal body temperature (see Figure 19-5). The decrease in the level of TH can lead to excessive TSH production, which stimulates thyroid tissue and causes goiter.

The characteristic sign of severe or long-standing hypothyroidism is myxedema, which results from the altered composition of the dermis and other tissues. The connective tissue fibers are separated by large amounts of protein and mucopolysaccharide. This complex binds water, producing nonpitting, boggy edema, especially around the eyes, hands, and feet and in the supraclavicular fossae (Figure 19-9). The tongue and laryngeal and pharyngeal mucous membranes thicken, producing thick, slurred speech and hoarseness. Myxedema coma, a
medical emergency, is a diminished level of consciousness associated with severe hypothyroidism. Signs and symptoms include hypothermia without shivering, hypoventilation, hypotension, hypoglycemia, and lactic acidosis. Older individuals with comorbid conditions, such as pulmonary or urinary infections, congestive heart failure, or cerebrovascular accident, and with moderate or untreated hypothyroidism are particularly at risk for developing myxedema coma. It also may occur after overuse of narcotics or sedatives or after an acute illness in hypothyroid individuals. Symptoms of hypothyroidism in older adults should not be attributed to normal aging changes.  

![Myxedema](image)

**Evaluation and treatment**

The diagnosis of primary hypothyroidism is made by documentation of the clinical symptoms of hypothyroidism, and measurement of increased levels of TSH and decreased levels of TH (total T₃ and both total and free T₄). When hypothyroidism is caused by pituitary deficiencies, serum TSH levels and basal metabolic rate (BMR) decrease. Hormone replacement therapy with the hormone levothyroxine is the
treatment of choice. The restoration of normal TH levels should be timed appropriately; a regimen of hormonal therapy depends on the individual's age, the duration and severity of the hypothyroidism, and the presence of other disorders, particularly cardiovascular disorders. Pregnant women need to be evaluated for thyroid function.

**Thyroid Carcinoma**

**Thyroid carcinoma** is the most common endocrine malignancy, accounting for 62,450 estimated new cases and 1950 estimated cancer deaths in 2015 in the United States, less than 4% of all neoplasms. Exposure to ionizing radiation, especially during childhood, is the most consistent causal factor. Papillary and follicular thyroid carcinomas are the most frequent and medullary and anaplastic thyroid carcinomas are less common. Most tumors are well differentiated.

Most individuals with thyroid carcinoma have normal T
\(^3\) and T
\(^4\) levels and are therefore euthyroid. The cancer is typically discovered as a small thyroid nodule or metastatic tumor in the lungs, brain, or bone. Changes in voice and swallowing and difficulty breathing are related to tumor growth impinging on the trachea or esophagus. Ultrasonographic characteristics may be suggestive of malignancy, but are neither sensitive nor specific. The diagnosis of thyroid cancer is generally made by fine needle aspiration of a thyroid nodule.

Treatment may include partial or total thyroidectomy, TSH suppression therapy (levothyroxine), radioactive iodine therapy (in iodine-concentrating tumors), postoperative radiation therapy, and chemotherapy (especially in anaplastic carcinoma). New insights into the molecular pathogenesis of thyroid carcinoma are leading to new therapies.

Alterations of Parathyroid Function

Hyperparathyroidism

Hyperparathyroidism is characterized by greater than normal secretion of parathyroid hormone (PTH) and hypercalcemia. Hyperparathyroidism is classified as primary, secondary, or tertiary.\(^4\)

Pathophysiology

Primary hyperparathyroidism is characterized by inappropriate excess secretion of PTH by one or more of the parathyroid glands. It is one of the most common endocrine disorders. Approximately 80% to 85% of cases are caused by parathyroid adenomas, another 10% to 15% result from parathyroid hyperplasia, and approximately 1% of cases are caused by parathyroid carcinoma. In addition, primary hyperparathyroidism may be caused by a variety of genetic causes, especially the genes that cause multiple endocrine neoplasia.\(^4\)

In primary hyperparathyroidism, PTH secretion is increased and is not under the usual feedback control mechanisms. The calcium level in the blood increases because of increased bone resorption and gastrointestinal absorption of calcium, but fails to inhibit PTH secretion by the parathyroid gland.

Secondary hyperparathyroidism is a compensatory response of the parathyroid glands to chronic hypocalcemia, which can be associated with decreased renal activation of vitamin D (renal failure) (see Chapter 30). Secretion of PTH is elevated, but PTH cannot achieve normal calcium levels because of insufficient levels of activated vitamin D. Other causes of secondary hyperparathyroidism include dietary deficiency in vitamin D or calcium; decreased intestinal absorption of vitamin D or calcium; and ingestion of drugs, such as phenytoin, phenobarbital, and laxatives, which either accelerate the metabolism of vitamin D or decrease intestinal absorption of calcium.

Tertiary hyperparathyroidism is excessive secretion of PTH and hypercalcemia that occurs after long-standing secondary hyperparathyroidism. The etiology is unknown but represents autonomous secretion of PTH from persistent parathyroid stimulation even after withdrawal of calcium and calcitriol therapy.\(^4\) Treatment is surgical removal of one of the parathyroid glands.

Clinical manifestations

Hypercalcemia and hypophosphatemia are the hallmarks of primary hyperparathyroidism and may be discovered incidentally. Hypercalcemia and hypophosphatemia may be asymptomatic or affected individuals may present with
symptoms related to the muscular, nervous, and gastrointestinal systems, including fatigue, headache, depression, anorexia, and nausea and vomiting. Excessive osteoclastic and osteocytic activity resulting in bone resorption may cause pathologic fractures, kyphosis of the dorsal spine, and compression fractures of the vertebral bodies. (Bone resorption is discussed in Chapter 39.)

The increased renal filtration load of calcium leads to hypercalciuria. Hypercalcemia also affects proximal renal tubular function, causing metabolic acidosis and production of an abnormally alkaline urine. PTH hypersecretion enhances renal phosphate excretion and results in hypophosphatemia and hyperphosphaturia (see Chapter 5). The combination of these three variables—hypercalciuria, alkaline urine, and hyperphosphaturia—predisposes the individual to the formation of calcium stones, particularly in the renal pelvis or renal collecting ducts. These may be associated with infections. Both kidney stones and renal infection can lead to impaired renal function. Hypercalcemia also impairs the concentrating ability of the renal tubule by decreasing its response to ADH. Chronic hypercalcemia of hyperparathyroidism is associated with mild insulin resistance, necessitating increased insulin secretion to maintain normal glucose levels.

Secondary hyperparathyroidism caused by renal disease presents clinically not only with bone resorption but also with the symptoms of hypocalcemia and hyperphosphatemia. Hypocalcemia can cause many significant clinical problems (see Chapter 5) and hyperphosphatemia can cause deleterious effects on the cardiovascular system.

**Evaluation and treatment**

The concurrent findings of increased ionized calcium concentration despite elevated PTH concentration are suggestive of primary hyperparathyroidism. PTH levels also may be inappropriately within the normal range because hypercalcemia should completely suppress PTH production. Imaging procedures are used to localize adenomas before surgery. Observation of asymptomatic individuals with mild hypercalcemia is recommended; these individuals are advised to avoid dehydration and limit dietary calcium intake. Definitive treatment of severe primary hyperparathyroidism involves surgical removal of the solitary adenoma or, in the case of hyperplasia, complete removal of three and partial removal of the fourth hyperplastic parathyroid glands. In those individuals who fail surgery, other treatments such as bisphosphonates and calcimimetics (e.g., cinacalcet, a new class of calcium-lowering drugs) may be considered.

If serum calcium concentration is low but PTH level is elevated, secondary hyperparathyroidism is likely. Evaluation for renal function may indicate chronic renal disease. Treatment for secondary hyperparathyroidism in chronic renal
disease requires calcium replacement, dietary phosphate restriction and phosphate binders, and vitamin D replacement. Treatment also may include calcimimetics, which work to increase parathyroid calcium receptor sensitivity, thus lowering PTH levels.⁴⁴,⁴⁵

**Hypoparathyroidism**

**Hypoparathyroidism** (abnormally low PTH levels) is most commonly caused by damage to the parathyroid glands during thyroid surgery. This occurs because of the anatomic proximity of the parathyroid glands to the thyroid (see Figure 18-11). Hypoparathyroidism also is associated with genetic syndromes, including familial hypoparathyroidism and DiGeorge syndrome (see Chapter 8). Hypomagnesemia also can cause a decrease in both PTH secretion and PTH function. An idiopathic or autoimmune form of hypoparathyroidism also is recognized.⁴⁶ There is an inherited condition associated with hypocalcemia but with normal to elevated levels of PTH called pseudohypoparathyroidism; it is caused by a postreceptor defect in PTH action.

**Pathophysiology**

A lack of circulating PTH causes depressed serum calcium levels and increased serum phosphate levels. In the absence of PTH, resorption of calcium from bone and regulation of calcium reabsorption from the renal tubules are impaired. Phosphate reabsorption by the renal tubules is therefore increased, causing decreased renal phosphate excretion and hyperphosphatemia.

Hypomagnesemia inhibits PTH secretion. When serum magnesium levels return to normal, however, PTH secretion returns to normal, as does the responsiveness of peripheral tissues to PTH. Hypomagnesemia may be related to chronic alcoholism, malnutrition, malabsorption, increased renal clearance of magnesium caused by the use of aminoglycoside antibiotics or certain chemotherapeutic agents, or prolonged magnesium-deficient parenteral nutritional therapy.

**Clinical manifestations**

Symptoms associated with hypoparathyroidism are primarily those of hypocalcemia (see Table 5-7). Hypocalcemia causes a lowered threshold for nerve and muscle excitation so that a nerve impulse may be initiated by a slight stimulus anywhere along the length of a nerve or muscle fiber. This creates tetany, a condition characterized by muscle spasms, hyperreflexia, clonic-tonic convulsions, laryngeal spasms, and, in severe cases, death by asphyxiation. Chvostek and Trousseau signs may be used to evaluate for neuromuscular irritability. Chvostek
sign is elicited by tapping the cheek, resulting in twitching of the upper lip. Trousseau sign is elicited by sustained inflation of a sphygmomanometer placed on the upper arm to a level above the systolic blood pressure with resultant painful carpal spasm. Other symptoms of hypocalcemia include dry skin, loss of body and scalp hair, hypoplasia of developing teeth, horizontal ridges on the nails, cataracts, basal ganglia calcifications (which may be associated with a parkinsonian syndrome), and bone deformities, including brachydactyly and bowing of the long bones.

Phosphate retention caused by increased renal reabsorption of phosphate is also associated with hypoparathyroidism (see Table 5-7). Hyperphosphatemia results from PTH deficiency and, in turn, hyperphosphatemia further lowers calcium concentration by inhibiting the activation of vitamin D, thereby lowering the gastrointestinal absorption of calcium.

**Evaluation and treatment**

A low serum calcium concentration and a high phosphorous level in the absence of renal failure, intestinal disorders, or nutritional deficiencies suggest hypoparathyroidism. PTH levels are low in hypoparathyroidism and measurement of serum magnesium level and urinary calcium excretion also can help in diagnosis. Treatment is directed toward alleviation of the hypocalcemia. In acute states, this involves parenteral administration of calcium, which corrects serum calcium concentration within minutes. Maintenance of serum calcium level is achieved with pharmacologic doses of cholecalciferol (vitamin D$_3$) and oral calcium.

Hypoplastic dentition, cataracts, bone deformities, and basal ganglia calcifications do not respond to the correction of hypocalcemia, but the other symptoms of hypocalcemia are reversible.

**Dysfunction of the Endocrine Pancreas: Diabetes Mellitus**

**Diabetes mellitus** is a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both. In the United States in 2012, 29.1 million people had diabetes and another 8.1 million were estimated to be undiagnosed. The American Diabetes Association (ADA) classifies four categories of diabetes mellitus, as follows:

1. Type 1 (beta-cell destruction, usually leading to absolute insulin deficiency)
2. Type 2 (ranging from predominantly insulin resistance with relative insulin deficiency to predominantly an insulin secretory defect with insulin resistance)
3. Other specific types
4. Gestational diabetes

The diagnosis of diabetes mellitus is based on glycosylated hemoglobin (HbA$_{1C}$) levels; fasting plasma glucose (FPG) levels; 2-hour plasma glucose levels during oral glucose tolerance testing (OGTT) using a 75-g oral glucose load; or random glucose levels in an individual with symptoms (Box 19-1). Glycosylated hemoglobin refers to the permanent attachment of glucose to hemoglobin molecules and reflects the average plasma glucose exposure over the life of a red blood cell (approximately 120 days). It provides a more accurate measure for monitoring long-term control of blood glucose levels. This test is critically dependent upon the method of measurement and must be related to established standards.

**Box 19-1**

**Diagnostic Criteria for Diabetes Mellitus**

1. HbA$_{1C}$ (as measured in a DCCT-referenced assay) $\geq 6.5\%$

OR

2. FPG $\geq 126$ mg/dl (7.0 mmol/L); fasting is defined as no caloric intake for at least 8 hr

OR

3. 2-hr plasma glucose $\geq 200$ mg/dl (11.1 mmol/L) during OGTT

OR

4. In an individual with classic symptoms of hyperglycemia or hyperglycemic crisis, a random plasma glucose $\geq 200$ mg/dl (11.1 mmol/L)

**Categories of Increased Risk for Diabetes**

1. FPG 100 to 125 mg/dl

2. 2-hr PG 140 to 199 mg/dl during OGTT
3. HbA$_{1C}$ 5.7% to 6.4%

*DCCT*, Diabetes Control and Complications Trial; *FPG*, fasting plasma glucose; *HbA$_{1C}$*, hemoglobin A$_{1C}$ or glycosylated hemoglobin; *OGTT*, oral glucose tolerance testing; *PG*, plasma glucose.

*In the absence of unequivocal hyperglycemia, criteria 1 through 3 should be confirmed by repeat testing.*

The ADA classification “categories at increased risk for diabetes” (or prediabetes) describes nondiabetic elevations of *HbA$_{1C}$*, *FPG*, or 2-hour plasma glucose value during *OGTT* (see Box 19-1). The Centers for Disease Control and Prevention (CDC) estimates that 37% of U.S. adults aged 20 years or older have prediabetes (51% of those aged 65 years or older). This classification includes impaired glucose tolerance (IGT), which results from diminished insulin secretion, and impaired fasting glucose (IFG), which is caused by enhanced hepatic glucose output. Individuals with IGT and IFG are at increased risk of cardiovascular disease and premature death and carry a 15% to 50%, 5-year risk of developing diabetes, particularly type 2 diabetes. Thus, prevention of diabetes with lifestyle interventions is essential.

**Types of Diabetes Mellitus**

**Type 1 Diabetes Mellitus**

*Type 1 diabetes mellitus* is the most common pediatric chronic disease and affects 0.17% of U.S. children, and the incidence is increasing. Between 10% and 13% of individuals with newly diagnosed type 1 diabetes have a first-degree relative (parent or sibling) with type 1 diabetes. There is a 50% concordance rate in twins. Diagnosis is rare during the first 9 months of life and peaks at 12 years of age. Two distinct types of type 1 diabetes have been identified: idiopathic and autoimmune.

**Pathophysiology**

Idiopathic type 1 diabetes is far less common than autoimmune diabetes, has a strong genetic component, and occurs mostly in people of Asian or African descent. Affected individuals have varying degrees of insulin deficiency.
Autoimmune type 1 diabetes mellitus is a slowly progressive autoimmune T-cell–mediated disease that destroys beta cells of the pancreas. There is a deficient immune tolerance linked to abnormalities in immune cells and changes in beta-cell antigens. Destruction of beta cells is related to genetic susceptibility and environmental factors. The strongest genetic association is with histocompatibility leukocyte antigen (HLA) class II alleles HLA-DQ and HLA-DR. The HLA-DR marker is associated with other autoimmune disorders, such as celiac, Graves, Hashimoto, and Addison diseases. Environmental factors that have been implicated include exposure to certain drugs, foods, and viruses. These gene-environment interactions result in the formation of autoantigens that are expressed on the surface of pancreatic beta cells and circulate in the bloodstream and lymphatics. Cellular immunity (T-cytotoxic cells and macrophages) and humoral immunity (autoantibodies) are stimulated, resulting in beta-cell destruction and apoptosis. The destruction of beta cells results from lymphocyte and macrophage infiltration of the islets, resulting in release of inflammatory cytokines, activation of T-helper and T-cytotoxic lymphocytes, and death of islet beta cells. Beta-cell destruction also is mediated by the production of autoantibodies against islet cells, insulin, glutamic acid decarboxylase (GAD), and other cytoplasmic proteins. Insulin synthesis declines and hyperglycemia develops over time.
For insulin synthesis to decline enough such that hyperglycemia occurs, 80% to 90% of the insulin-secreting beta cells of the islet of Langerhans must be destroyed. Insulin normally suppresses secretion of glucagon and, thus, hypoinsulinemia leads to a marked increase in glucagon secretion. Glucagon, a hormone produced by the alpha cells of the islets, acts in the liver to increase blood glucose level by stimulating glycogenolysis and gluconeogenesis. In addition to the decline in insulin secretion, there is decreased secretion of amylin, another beta-cell hormone. One of the critical actions of amylin is to suppress glucagon release from the alpha cells. Thus both alpha-cell and beta-cell functions are abnormal and both a lack of insulin and a relative excess of glucagon contribute to hyperglycemia in type 1 diabetes.

Clinical manifestations
Historically, type 1 diabetes mellitus was thought to have an abrupt onset. It is now known, however, that the natural history involves a long preclinical period with gradual destruction of beta cells, eventually leading to insulin deficiency and hyperglycemia. In general, this latent period is longer in adults with onset of type 1 diabetes and often results in misclassification of those affected as having type 2 diabetes.

Type 1 diabetes mellitus affects the metabolism of fat, protein, and carbohydrates.
Glucose accumulates in the blood and appears in the urine as the renal threshold for glucose is exceeded, producing an osmotic diuresis and symptoms of polyuria and thirst (Table 19-4). Wide fluctuations in blood glucose levels occur. In addition, protein and fat breakdown occurs because of the lack of insulin, resulting in weight loss. Increased metabolism of fats and proteins leads to high levels of circulating ketones, causing a condition known as diabetic ketoacidosis (DKA) (see p. 477).

**TABLE 19-4**
Clinical Manifestations and Mechanisms for Type 1 Diabetes Mellitus

<table>
<thead>
<tr>
<th>Manifestation</th>
<th>Rationale</th>
</tr>
</thead>
<tbody>
<tr>
<td>Polydipsia</td>
<td>Because of elevated blood glucose levels, water is osmotically attracted from body cells, resulting in intracellular dehydration and stimulation of thirst in hypothalamus</td>
</tr>
<tr>
<td>Polyuria</td>
<td>Hyperglycemia acts as an osmotic diuretic; amount of glucose filtered by glomeruli of kidney exceeds that which can be reabsorbed by renal tubules; glycosuria results, accompanied by large amounts of water lost in urine</td>
</tr>
<tr>
<td>Polyphagia</td>
<td>Depletion of cellular stores of carbohydrates, fats, and protein results in cellular starvation and a corresponding increase in hunger</td>
</tr>
<tr>
<td>Weight loss</td>
<td>Weight loss occurs because of fluid loss in osmotic diuresis and loss of body tissue as fats and proteins are used for energy</td>
</tr>
<tr>
<td>Fatigue</td>
<td>Metabolic changes result in poor use of food products, contributing to lethargy and fatigue</td>
</tr>
<tr>
<td>Recurrent infections (e.g., boils, carbuncles, and bladder infection)</td>
<td>Growth of microorganisms is stimulated by increased glucose levels and diabetes is associated with some immunocompromised individuals</td>
</tr>
<tr>
<td>Prolonged wound healing</td>
<td>Impaired blood supply hinders healing</td>
</tr>
<tr>
<td>Genital pruritus</td>
<td>Hyperglycemia and glycosuria favor fungal growth; candidal infections, resulting in pruritus, are a common presenting symptom in women</td>
</tr>
<tr>
<td>Visual changes</td>
<td>Blurred vision occurs as water balance in eye fluctuates because of elevated blood glucose levels; diabetic retinopathy may ensue</td>
</tr>
<tr>
<td>Paresthesias</td>
<td>Paresthesias are common manifestations of diabetic neuropathies</td>
</tr>
<tr>
<td>Cardiovascular symptoms (e.g., chest pain, extremity pain, and neurologic deficits)</td>
<td>Diabetes contributes to formation of atherosclerotic plaques that involve coronary, peripheral, and cerebrovascular circulations and alterations in microvessels</td>
</tr>
</tbody>
</table>

Currently half of individuals with type 1 diabetes are obese and there are increasing numbers of individuals who have both type 1 diabetes and the clinical manifestations of metabolic syndrome, including obesity, dyslipidemia, and hypertension (see Box 19-1). These individuals are at high risk for chronic complications of diabetes, including heart disease and stroke.

**Evaluation and treatment**

The criteria for diagnosis of type 1 diabetes are the same as those for type 2 diabetes (see Box 19-1). Many children are first diagnosed when they present with the signs and symptoms of DKA. In DKA, acetone (a volatile form of ketones) is exhaled by hyperventilation and gives the breath a sweet or “fruity” odor. Occasionally, diabetic coma is the initial symptom of the disease. The diagnosis of diabetes is not difficult when the symptoms of polydipsia, polyuria, polyphagia, weight loss, and hyperglycemia are present in fasting and postprandial states. C-peptide, a component of proinsulin released during insulin production, can be measured in the serum as a surrogate for insulin levels and is indicative of residual
beta-cell mass and function. The zinc transporter 8 autoantibody (ZnT8Ab) test has been approved for diagnosis of type 1 diabetes.\textsuperscript{52} Other important aspects of evaluation include looking for evidence of the chronic complications of type 1 diabetes, including renal, nervous system, cardiac, peripheral vascular, retinal, and bony tissue damage.

Currently, treatment regimens are designed to achieve optimal glucose level control (as measured by the HbA\textsubscript{1C} value) without causing episodes of significant hypoglycemia.\textsuperscript{49} Management requires individual planning according to type of disease, age, and activity level, but all individuals require some combination of insulin therapy, meal planning, and exercise regimen. There are several different types of insulin preparations available and there are new technologies for more physiologic insulin delivery systems.\textsuperscript{53} Many different kinds of therapies are being tested to prevent the autoimmune destruction of beta cells, including immunosuppression with antirejection drugs (see \textit{Health Alert: Immunotherapy for the Prevention and Treatment of Type 1 Diabetes}). Finally, islet cell, stem cell, and whole pancreas transplantation has been successful in selected individuals.\textsuperscript{50,54}

\textbf{Health Alert}

\textbf{Immunotherapy for the Prevention and Treatment of Type 1 Diabetes}

Many different kinds of immunologic approaches are being tested to prevent the autoimmune destruction of beta cells in type 1 diabetes. These treatments are aimed at preserving insulin synthesis early in the course of disease. Some of these interventions create generalized immunosuppression, including mycophenolate mofetil, monoclonal antibodies to B cells (rituximab), monoclonal antibodies to T cells (otelixizumab, teplizumab), interleukin-1 blockade, and cyclosporine. Studies document their effectiveness in stabilizing beta-cell function but, unfortunately, they also cause many side effects. More focused immunologic therapies are “antigen specific,” which means they suppress only the parts of the immune response that are attacking the beta cells. One approach that has shown promising (but mixed) results has been the use of vaccines to induce T-regulatory cells that suppress the immune attack on specific antigens. Vaccines that have currently been tested include dendritic cells, insulin, glutamic acid decarboxylase 65 (GAD-Alum), and heatshock proteins (DiaPep277). Another ambitious new approach to preserving beta-cell function is through the introduction of stem cells, which decrease autoimmune responses and may engraft and become insulin-producing beta cells.
Clinical trials are needed to evaluate long term remission.

**Type 2 Diabetes Mellitus**

Type 2 diabetes mellitus (non–insulin-dependent diabetes mellitus) affects 9.3% of adults in the United States.48 Prevalence is highest among American Indians and Alaska Natives (16%) and lowest among non-Hispanic whites (7.6%). There also is an increased prevalence of type 2 diabetes in children, especially in obese children (see Table 19-3).

A genetic-environmental interaction appears to be responsible for type 2 diabetes.55 The most well-recognized risk factors are age, obesity, hypertension, physical inactivity, and family history. More than 60 genes have been identified that are associated with type 2 diabetes, including those that code for beta-cell mass, beta-cell function (ability to sense blood glucose levels, insulin synthesis, and insulin secretion), proinsulin and insulin molecular structures, insulin receptors, hepatic synthesis of glucose, glucagon synthesis, and cellular responsiveness to insulin stimulation.56 These genetic abnormalities combined with environmental influences, such as obesity, result in the basic pathophysiologic mechanisms of type 2 diabetes, which are insulin resistance and decreased insulin secretion by beta cells (Figure 19-11).
There is increasing evidence that diet, including diet during pregnancy, influences the long-term risk of type 2 diabetes in children and adults. Metabolic syndrome is a constellation of disorders (central obesity, dyslipidemia, prehypertension, and an elevated fasting blood glucose level) that together confer a high risk of developing type 2 diabetes and associated cardiovascular complications (Box 19-2). The metabolic syndrome often develops during childhood and is prevalent among overweight children and adolescents. Metabolic syndrome is characterized by many of the same genetic and environmental risks as type 2 diabetes and individuals should be screened on a regular basis (see Box 19-2). Early recognition and treatment, including vigorous lifestyle changes, are critical to reducing cardiovascular events and improving clinical outcomes for individuals with prediabetes and metabolic syndrome.

**Box 19-2**

**Criteria for the Diagnosis of Metabolic Syndrome**

Three of the following five traits:

1. Increased waist circumference (>40 inches in men; >35 inches in women)—may be adjusted for ethnic groups
2. Plasma triglycerides $\geq 150$ mg/dl

3. Plasma high-density lipoprotein (HDL) cholesterol $< 40$ mg/dl (men) or $< 50$ mg/dl (women)

4. Blood pressure $\geq 130/85$ mm Hg

5. Fasting plasma glucose $\geq 100$ mg/dl*

*Criterion decreased from 110 to 100 mg/dl based on 2010 diagnostic category for persons at risk for diabetes mellitus (see Box 19-1).

**Pathophysiology**

Many organs contribute to insulin resistance, chronic hyperglycemia, and the consequences of type 2 diabetes (Figure 19-12). **Insulin resistance** is defined as a suboptimal response of insulin-sensitive tissues (especially liver, muscle, and adipose tissue) to insulin and is associated with obesity. Several mechanisms are involved in abnormalities of the insulin signaling pathway and contribute to insulin resistance. These include an abnormality of the insulin molecule, high amounts of insulin antagonists, down-regulation of the insulin receptor, and alteration of glucose transporter (GLUT) proteins.
Obesity is one of the most important contributors to insulin resistance and diabetes and acts through several important mechanisms:

1. Adipokines (leptin and adiponectin) are hormones produced in adipose tissue. Obesity results in increased serum levels of leptin and decreased levels of adiponectin. These changes are associated with inflammation and decreased insulin sensitivity.\(^{60}\)

2. Elevated levels of serum free fatty acids (FFAs) and intracellular deposits of triglycerides and cholesterol are also found in obese individuals. These changes interfere with intracellular insulin signaling, decrease tissue responses to insulin,
alter incretin actions, and promote inflammation.

3. Inflammatory cytokines are released from intra-abdominal adipocytes or adipocyte-associated mononuclear cells and induce insulin resistance and are cytotoxic to beta cells.\(^{61}\)

4. Obesity is correlated with hyperinsulinemia and decreased insulin receptor density.

   Compensatory hyperinsulinemia prevents the clinical appearance of diabetes for many years. Eventually, however, **beta-cell dysfunction** develops and leads to a relative deficiency of insulin activity.\(^{55}\) The islet dysfunction is caused by a combination of a decrease in beta-cell mass and a reduction in normal beta-cell function.\(^{62}\) A progressive decrease in the weight and number of beta cells occurs and many of the remaining cells develop “exhaustion” from increased demand for insulin biosynthesis.

   Glucagon concentration is increased in type 2 diabetes because pancreatic alpha cells become less responsive to glucose inhibition, resulting in an increase in glucagon secretion. These abnormally high levels of glucagon increase blood glucose level by stimulating glycogenolysis and gluconeogenesis. As was discussed under type 1 diabetes, type 2 diabetes also is associated with a deficiency in amylin, further increasing glucagon levels.

   Amylin (islet amyloid polypeptide) is another beta-cell hormone that is decreased in both type 1 and type 2 diabetes. Amylin increases satiety and suppresses glucagon release from the alpha cells. It also contributes to islet cell destruction through the deposition of abnormal (misfolded) amyloid polypeptide in the pancreas.\(^{63}\) Pramlintide, a synthetic analog of amylin, is used for treatment in type 2 diabetes.

   Hormones released from the gastrointestinal (GI) tract play a role in insulin resistance, beta-cell function, and diabetes. **Ghrelin** is a peptide produced in the stomach and pancreatic islets that regulates food intake, energy balance, and hormonal secretion.\(^{64}\) Decreased levels of circulating ghrelin have been associated with insulin resistance and increased fasting insulin levels. The **incretins** are a class of peptides that are released from the GI tract in response to food intake and function to increase the secretion of insulin and have many other positive effects on metabolism. The most studied incretin is called glucagon-like peptide 1 (GLP-1), and studies have demonstrated that beta-cell responsiveness to GLP-1 is reduced both in prediabetes and in type 2 diabetes.\(^{65}\) (see *Health Alert: Incretin Hormones for Type 2 Diabetes Mellitus Therapy*).
**Health Alert**

**Incretin Hormones for Type 2 Diabetes Mellitus Therapy**

The incretin hormones are secreted from endocrine intestinal cells in the presence of carbohydrates, proteins, and fats and have many functions including suppressing appetite. The major incretin hormone is glucagon-like peptide-1 (GLP-1). It controls postprandial glucose levels by promoting glucose-dependent insulin secretion, stimulating insulin gene expression, inhibiting glucagon synthesis, and delaying gastric emptying. GLP-1 also reduces beta-cell apoptosis and induces pancreatic acinar cells to differentiate into new beta cells, thus enhancing beta-cell mass and replenishing intracellular stores of insulin. Incretins are inactivated by the enzyme dipeptidyl peptidase IV (DPP-IV). The many positive effects on glucose metabolism without hypoglycemia have led to the use of incretin hormones and incretin enhancers for the treatment of type 2 diabetes. There are two classes of incretin-related therapies: GLP-1 receptor agonists (GLP-1 RAs) and dipeptidyl peptidase IV (DPP-IV) inhibitors. In addition to improving glucose control, many people taking these medications experience weight loss and improvements in measurements of blood pressure, serum lipids, and myocardial function. There also is increasing interest in the use of incretin therapy to reduce the risk of diabetes in individuals with prediabetes.

The kidneys also influence the pathophysiology of type 2 diabetes. Renal reabsorption of glucose through the sodium-glucose cotransporter 2 (SGLT2) is an important controller of serum glucose levels and new medications aimed at blocking it have resulted in decreased measurements for blood glucose level, weight, and blood pressure.66

**Clinical manifestations**

The clinical manifestations of type 2 diabetes are nonspecific. The affected individual is often overweight, dyslipidemic, hyperinsulinemic, and hypertensive. The individual with type 2 diabetes may show some classic symptoms of diabetes, such as polyuria and polydipsia, but more often will have nonspecific symptoms such as fatigue, pruritus, recurrent infections, visual changes, or symptoms of neuropathy (paresthesias or weakness). In those whose diabetes has progressed
without treatment, symptoms related to coronary artery, peripheral artery, and cerebrovascular disease may develop.

**Evaluation and treatment**

The diagnostic criteria for type 2 diabetes are the same as those for type 1 (see Box 19-1). Prevention of type 2 diabetes, especially in those individuals with prediabetes, hinges on diet and exercise, although there is increasing support for the use of some diabetes medications in high-risk individuals.

As with type 1 diabetes, the goal of treatment for individuals with type 2 diabetes is the restoration of near-euglycemia (a normal blood glucose level) and correction of related metabolic disorders. The first approach to treatment of the individual with type 2 diabetes is maintaining an appropriate diet and exercise program. Diet should match activity levels and include more complex carbohydrates (rather than simple sugars), foods low in fats, adequate protein, and fiber. Weight loss results in improved glucose tolerance. Bariatric surgery improves glycemic control, decreases risk of cardiovascular disease, and promotes weight loss in those morbidly obese. For individuals who require further intervention, oral hypoglycemic agents are indicated. Currently, metformin is considered the primary pharmacologic choice for the treatment of type 2 diabetes and a second oral agent, a GLP-1 receptor agonist, or basal insulin is added if the A1C target is not maintained over 3 months. An increasing number of persons are being treated with incretins (see *Health Alert: Incretin Hormones for Type 2 Diabetes Mellitus Therapy*). A combination of drugs may be required. Insulin therapy may be needed in the later stage of type 2 diabetes because of loss of beta-cell function, which is progressive over time.

**Other Specific Types of Diabetes Mellitus and Gestational Diabetes Mellitus**

As listed in Table 19-3, the American Diabetes Association classification of diabetes mellitus not only includes the most common forms of diabetes (type 1 and type 2) but also encompasses “other specific types of diabetes mellitus” and “gestational diabetes mellitus.” Other specific types of diabetes include genetic defects in beta-cell function, genetic defects in insulin action, diseases of the exocrine pancreas, endocrinopathies, drug- or chemical-induced beta-cell dysfunction, infections, and other uncommon autoimmune and inherited disorders that are associated with diabetes. The best-described of these other specific types of diabetes is termed maturity-onset diabetes of youth (MODY). MODY includes six specific autosomal dominant mutations that affect critical enzymes involved in beta-cell
function or insulin action. It is estimated that only 1% of cases of diabetes are monogenic and, therefore, are classified as MODY. Diagnosis and management are similar to those techniques used for type 2 diabetes.

**Gestational diabetes mellitus (GDM)** has been defined as any degree of glucose intolerance with onset or first recognition during pregnancy. However, this definition meant that many women with previously undiagnosed type 1 or type 2 diabetes were diagnosed with GDM, and many of them had progressive disease after delivery. Therefore the ADA recently recommended that high-risk women found to have diabetes at their initial prenatal visit receive a diagnosis of type 1 or type 2 diabetes, not gestational diabetes. GDM complicates approximately 7% of all pregnancies. Screening for GDM is recommended in asymptomatic, pregnant women after 24 weeks of gestation. An OGTT is used to confirm the diagnosis. Careful glucose control prenatally, during pregnancy, and after delivery is essential to the short- and long-term health of both mother and baby. Women who have GDM have a greatly increased subsequent diabetes risk, making consistent follow-up important.

**Acute Complications of Diabetes Mellitus**

The major acute complications of diabetes mellitus are hypoglycemia, diabetic ketoacidosis, and hyperosmolar hyperglycemic nonketotic syndrome (see comparison in Table 19-5). The **Somogyi effect** (low blood glucose level during night that may lead to morning rise in blood glucose level) and **dawn phenomenon** (early morning rise in blood glucose level related to release of growth hormone, cortisol, and catecholamines without preceding hypoglycemia) also may be seen.

**Hypoglycemia** in diabetes is sometimes called *insulin shock* or *insulin reaction*. Individuals with type 2 diabetes are at less risk for hypoglycemia than those with type 1 diabetes because they retain relatively intact glucose counterregulatory mechanisms. However, hypoglycemia does occur in type 2 diabetes when treatment involves insulin secretagogues (e.g., sulfonylureas) or exogenous insulin.

Symptoms include pallor, tremor, anxiety, tachycardia, palpitations, diaphoresis, headache, dizziness, irritability, fatigue, poor judgment, confusion, visual disturbances, hunger, seizures, and coma. Treatment requires immediate replacement of glucose either orally or intravenously. Glucagon for home use can be prescribed for individuals who are at high risk. Prevention is achieved with individualized management of medications and diet, monitoring of blood glucose levels, and education.

**Diabetic ketoacidosis (DKA)** is a serious complication related to a deficiency of insulin and an increase in the levels of insulin counterregulatory hormones (catecholamines, cortisol, glucagon, growth hormone) (Figure 19-13). DKA occurs in approximately 30% of children with type 1 diabetes, and 5% of children with type 2 diabetes. DKA is much more common in type 1 diabetes because insulin is more deficient (see Table 19-5). It is characterized by hyperglycemia, acidosis, and ketonuria. Insulin normally stimulates lipogenesis and inhibits lipolysis, thus
preventing fat catabolism. With insulin deficiency, lipolysis is enhanced and there is an increase in the amount of nonesterified fatty acids delivered to the liver. The consequence is increased gluconeogenesis contributing to hyperglycemia and production of ketone bodies (acetoacetate, hydroxybutyrate, and acetone) by the mitochondria of the liver at a rate that exceeds peripheral use. Accumulation of ketone bodies causes a drop in pH, resulting in metabolic acidosis. Symptoms of diabetic ketoacidosis include Kussmaul respirations (hyperventilation in an attempt to compensate for the acidosis), postural dizziness, central nervous system depression, ketonuria, anorexia, nausea, abdominal pain, thirst, and polyuria. DKA is managed with a combination of fluids, insulin, and electrolyte replacement.

**Hyperosmolar hyperglycemic nonketotic syndrome (HHNKS)** is an uncommon but significant complication of type 2 diabetes mellitus with a high overall mortality. It occurs more often in elderly individuals who have other comorbidities, including infections or cardiovascular or renal disease. HHNKS differs from DKA in the degree of insulin deficiency (which is more profound in DKA) and the degree of fluid deficiency (which is more marked in HHNKS). The clinical features of HHNKS include a very high serum glucose concentration and osmolarity and a near-normal serum bicarbonate level and pH. Glucose levels are considerably higher in HHNKS than in DKA because of volume depletion. Because the amount of insulin required to inhibit fat breakdown is less than that needed for effective

**FIGURE 19-13** Pathophysiology of DKA and HHNKS in Diabetes Mellitus.
glucose transport, insulin levels are sufficient to prevent excessive lipolysis and ketosis (see Figure 19-13). Clinical manifestations include severe dehydration; loss of electrolytes, including potassium; and neurologic changes, such as stupor. Management includes fluid, insulin, and electrolyte replacement.

**Chronic Complications of Diabetes Mellitus**

A number of serious complications are associated with any type of poorly controlled diabetes mellitus. Most complications are associated with insulin resistance or deficit, chronic hyperglycemia (also known as glucose toxicity), accumulation of advanced glycation end products, and activation of metabolic pathways that cause tissue damage and the chronic complications of diabetes mellitus. These complications include microvascular (damage to capillaries; retinopathies, nephropathies, and neuropathies) and macrovascular (damage to larger vessels; coronary artery, peripheral vascular, and cerebral vascular) disease (Table 19-6). Strict control of blood glucose level reduces some complications, particularly nonfatal myocardial infarction, but increases 5-year mortality. Strict control is not recommended for high-risk individuals with type 2 diabetes mellitus (DM), but the individual risk/benefit profile should be considered.\(^{71,72}\)

**Microvascular Disease**

Diabetic microvascular complications (disease in capillaries) are a leading cause of blindness, end-stage kidney failure, and various neuropathies. Occlusion of capillaries is characteristic of diabetic microvascular disease. The frequency and severity of lesions appear to be proportional to the duration of the disease (more or less than 10 years) and the status of glycemic control. Hypoxia and ischemia accompany microvascular disease, especially in the eye, kidney, and nerves. Many individuals with type 2 diabetes will present with microvascular complications because of the long duration of asymptomatic hyperglycemia that generally precedes diagnosis. This underscores the need to screen for diabetes.
**Diabetic retinopathy.**

*Diabetic retinopathy* is a leading cause of blindness worldwide and in U.S. adults less than 60 years of age.\(^73\) Compared with that in type 1 diabetes, retinopathy seems to develop more rapidly in individuals with type 2 diabetes because of the likelihood of long-standing hyperglycemia before diagnosis. Most individuals with diabetes will eventually develop retinopathy and they are also more likely to develop cataracts and glaucoma (see Chapter 14).

Diabetic retinopathy results from relative hypoxemia, damage to retinal blood vessels, red blood cell (RBC) aggregation, and hypertension (Figure 19-14). The three stages of retinopathy that lead to loss of vision are *nonproliferative* (stage I), characterized by an increase in retinal capillary permeability, vein dilation, microaneurysm formation, and superficial (flame-shaped) and deep (blot) hemorrhages; *preproliferative* (stage II), a progression of retinal ischemia with areas of poor perfusion that culminate in infarcts; and *proliferative* (stage III), the result of neovascularization (angiogenesis) and fibrous tissue formation within the retina or optic disc. Traction of the new vessels on the vitreous humor may cause retinal detachment or hemorrhage into the vitreous humor with severe blurring or loss of vision. *Macular edema* is the leading cause of blurred vision among persons with diabetes. Blurring of vision also can be a consequence of hyperglycemia and sorbitol accumulation in the lens. Dehydration of the lens, aqueous humor, and vitreous humor also reduces visual acuity.
**Diabetic nephropathy.**

Diabetes is the most common cause of chronic kidney disease and end stage kidney disease. Approximately 50% of individuals with diabetes mellitus develop diabetic kidney disease.⁷⁴

Hyperglycemia, advanced glycation end products (AGEs), activation of metabolic pathways, and inflammation all contribute to kidney tissue injury; yet the exact process responsible for destruction of kidneys in diabetes is unknown. Renal glomerular changes occur early in diabetes mellitus, occasionally preceding the overt manifestation of the disease. The glomeruli are injured by hyperglycemia with high renal blood flow (hyperfiltration), by increases in proximal tubular reabsorption, and by intraglomerular hypertension exacerbated by systemic hypertension. There is progressive glomerulosclerosis and decreased glomerular blood flow and glomerular filtration. Alterations in glomerular membrane permeability occur with loss of negative charge and albuminuria. Ultimately, there
can be tubular and interstitial fibrosis contributing to loss of function. Microalbuminuria is the first manifestation of diabetic kidney dysfunction. Before proteinuria, no clinical signs or symptoms of progressive glomerulosclerosis are likely to be evident. Later, hypoproteinemia, reduction in plasma oncotic pressure, fluid overload, anasarca (generalized body edema), and hypertension may occur. As renal function continues to deteriorate, individuals with type 1 diabetes may experience hypoglycemia (because of loss of renal insulin metabolism), which necessitates a decrease in insulin therapy. As the glomerular filtration rate drops below 10 ml/min, uremic signs, such as nausea, lethargy, acidosis, anemia, and uncontrolled hypertension, occur (see Chapter 30 for a discussion of renal failure). Proteinuria is strongly correlated with morbidity and mortality from cardiovascular disease. Early diagnosis and control of hypertension and hyperglycemia decreases the severity of nephropathy and delays the onset of end-stage kidney disease.

Diabetic neuropathies. 

Diabetic neuropathy is the most common cause of neuropathy in the Western world and is the most common complication of diabetes. The underlying pathologic mechanism includes both metabolic and vascular factors related to chronic hyperglycemia with ischemia and demyelination contributing to neural changes and delayed conduction. Both somatic and peripheral nerve cells show diffuse or focal damage, resulting in polyneuropathy. Sensory neuropathies include distal symmetric polyneuropathy, focal neuropathy (wristdrop, footdrop), and diabetic amyotrophy (muscle atrophy; weakness; and pain in the muscles of the hip, thigh, and buttocks). Loss of pain, temperature, and vibration sensation is more common than motor involvement and often involves the extremities first in the hands and feet. Motor neuropathies can affect muscle groups, particularly of the feet, contributing to deformity and unstable balance. Peripheral neuropathy can cause Charcot arthropathy, a progressive deterioration of weight-bearing joints, typically in the foot and ankle. Distal neuropathies combined with vascular complications, infection, or injury can lead to amputation (Figure 19-15).
Autonomic neuropathies include delayed gastric emptying, diabetic diarrhea, altered bladder function (e.g., decreased sensation of bladder fullness, urge or overflow incontinence), impotence, orthostatic hypotension, and heart rate variability with both tachycardia and bradycardia. Neuropathy may occur during periods of “good” glucose control and may be the initial clinical manifestation of type 2 diabetes. Chronic hyperglycemia also can cause cognitive dysfunction with alterations in learning and memory.

**Macrovascular Disease**
Macrovascular disease (lesions in large- and medium-sized arteries) increases morbidity and mortality and increases risk for hypertension, accelerated atherosclerosis, cardiovascular disease, stroke, and peripheral vascular disease, particularly among individuals with type 2 diabetes mellitus. (Atherosclerosis is discussed in Chapter 24.) Children with poorly controlled diabetes have higher risk for macrovascular complications within 1 to 2 decades\(^1\) (Figure 19-16). The process tends to be more severe and accelerated in the presence of other risk factors, including obesity, hyperlipidemia, and smoking.\(^2\)
Diabetes Mellitus and Atherosclerosis. Diabetes with its associated hyperglycemia, relative hypoinsulinemia, oxidative stress, and proinflammatory state contributes to atherogenesis by causing arterial endothelial dysfunction (impaired vasodilation).
Cardiovascular disease.

Cardiovascular disease is the ultimate cause of death in up to 68% of people with diabetes, with higher risk for women. Hypertension often coexists with diabetes mellitus, is more prevalent than in the nondiabetic population, and can have many causes. In type 1 diabetes hypertension is associated with the development of microalbuminuria. In type 2 diabetes hypertension is associated with metabolic syndrome (see p. 475). Hypertension increases the risk for coronary artery disease and stroke. Coronary artery disease (CAD) is the most common cause of morbidity and mortality in individuals with diabetes mellitus. Mechanisms of disease include vessel injury related to insulin resistance and hyperglycemia oxidative stress, accelerated atherosclerosis associated with high levels of triglycerides, high levels of small low-density lipoproteins (LDLs), and low levels of high-density lipoproteins (HDLs); platelet activation and prothrombosis; and endothelial cell dysfunction. In general, the prevalence of CAD increases with the duration but not the severity of diabetes and the onset can be silent.

The incidence of congestive heart failure is higher in individuals with diabetes, even without myocardial infarction. This may be related to cardiomyopathy and the presence of increased amounts of collagen in the ventricular wall and ventricular hypertrophy. There is reduced mechanical compliance of the heart during filling with diastolic and, eventually, systolic failure. (Heart disease is described in Chapter 24.) Guidelines have been developed to reduce the risk and improve treatment of cardiovascular and coronary artery disease in individuals with diabetes.

Stroke.

Stroke is twice as common in those with diabetes (particularly type 2 diabetes) as in the nondiabetic population. The survival rate for individuals with diabetes after a massive stroke is typically shorter than that for nondiabetic individuals. Hypertension, hyperglycemia, hyperlipidemia, and thrombosis are definite risk factors.

Peripheral vascular disease.

Diabetes mellitus increases the incidence of peripheral vascular disease (PVD), with
claudication (pain from reduced blood flow during exercise), ulcers, gangrene, and amputation. Age, duration of diabetes, genetics, and additional risk factors (smoking, hyperlipidemia, hypertension) influence the development and management of PVD. Peripheral vascular disease in those with diabetes is more diffuse and often involves arteries below the knee. Occlusions of the small arteries and arterioles cause most of the gangrenous changes of the lower extremities and occur in patchy areas of the feet and toes. The lesions begin as ulcers and progress to osteomyelitis or gangrene requiring amputation. Peripheral neuropathies and increased risk for infection advance the disease (see Figure 19-15). Significant morbidity and mortality are associated with major amputation.

Infection

The individual with diabetes is at an increased risk for infection throughout the body for several reasons:

1. The senses. Impaired vision caused by retinal changes and impaired touch caused by neuropathy lead to loss of protection with injury and repeated trauma, open wounds, and soft tissue or osseous infection, particularly in the legs and feet.

2. Hypoxia. Once skin integrity is compromised, susceptibility to infection increases as a result of hypoxia. In addition, the glycosylated hemoglobin in the RBCs impedes the release of oxygen to tissues.

3. Pathogens. Some pathogens proliferate rapidly because of increased glucose in body fluids, which provides an excellent source of energy.

4. Blood supply. Decreased blood supply results from vascular changes and reduces the supply of white blood cells to the affected area.

5. Suppressed immune response. Chronic hyperglycemia impairs both innate and adaptive immune responses, including abnormal chemotaxis and vasoactive responses, and defective phagocytosis. Clinical signs of infection may be absent.

Quick Check 19-4

1. What are the major differences between type 1 and type 2 diabetes in relation to insulin?

2. How does obesity contribute to the development of type 2 diabetes?
3. What are three metabolic alterations related to hyperglycemia that contribute to diabetic complications?

4. What is the single most important factor in the management of diabetes mellitus?
Alterations of Adrenal Function

Disorders of the Adrenal Cortex

Disorders of the adrenal cortex are related either to hyperfunction or to hypofunction. Hyperfunction that causes increased secretion of cortisol (hypercortisolism) leads to Cushing disease or Cushing syndrome. Hyperfunction that causes increased secretion of adrenal androgens or estrogens leads to virilization or feminization. Hyperfunction that causes increased levels of aldosterone leads to hyperaldosteronism, which may be primary or secondary. These syndromes often have overlapping features. Hypofunction of the adrenal cortex leads to Addison disease.

Hypercortical Function (Cushing Syndrome, Cushing Disease)

Cushing syndrome refers to the clinical manifestations resulting from chronic exposure to excess cortisol regardless of cause. Cushing disease refers to excess endogenous secretion of ACTH. It is more common in women but men may have more severe symptoms.\(^{90}\) ACTH-dependent hypercortisolism results from overproduction of pituitary ACTH by a pituitary adenoma (which can occur at any age) or by an ectopic secreting nonpituitary tumor, such as a small cell carcinoma of the lung (more common in older adults). ACTH-independent hypercortisolism is caused by cortisol secretion from a rare benign or malignant tumor of one or both adrenal glands (more common in children). A Cushing-like syndrome may develop as a side effect of long-term pharmacologic administration of glucocorticoids.\(^{91}\)

Pathophysiology

Whatever the cause, two observations consistently apply to individuals with hypercortisolism: (1) the normal diurnal or circadian secretion patterns of ACTH and cortisol are lost, and (2) there is no increase in ACTH and cortisol secretion in response to a stressor.\(^{92}\) With ACTH-dependent hypercortisolism, the excess ACTH stimulates excess production of cortisol and there is loss of feedback control of ACTH secretion. In individuals with ACTH-dependent hypercortisolism, secretion of both cortisol and adrenal androgens is increased, and cortisol-releasing hormone is inhibited. ACTH-independent secreting tumors of the adrenal cortex, however, generally secrete only cortisol. When the secretion of cortisol by the tumor exceeds normal cortisol levels, symptoms of hypercortisolism develop.

Clinical manifestations

Weight gain is the most common feature and results from the accumulation of
adipose tissue in the trunk, facial, and cervical areas. These characteristic patterns of fat deposition have been respectively described as “truncal obesity,” “moon face,” and “buffalo hump” (Figures 19-17 and 19-18).
FIGURE 19-17  Symptoms of Addison and Cushing Diseases.  (From Goodman CC, Kelly/Snyder TE: Differential diagnosis for physical therapists, ed 5, Philadelphia, 2013, Saunders.)
Glucose intolerance occurs because of cortisol-induced insulin resistance and increased gluconeogenesis and glycogen storage by the liver. Overt diabetes mellitus develops in approximately 20% of individuals with hypercortisolism. Polyuria is a manifestation of hyperglycemia and resultant glycosuria.

Protein wasting is caused by the catabolic effects of cortisol on peripheral tissues. Muscle wasting leads to muscle weakness. In bone, loss of the protein matrix leads to osteoporosis, with pathologic fractures, vertebral compression fractures, bone and back pain, kyphosis, and reduced height. Cortisol interferes with the action of GH in long bones; thus children who present with short stature may be experiencing growth retardation related to Cushing syndrome rather than GH deficiency. Bone disease may contribute to hypercalcuiuria and resulting renal stones.

In the skin, loss of collagen leads to thin, weakened integumentary tissues through which capillaries are more visible and are easily stretched by adipose deposits. Together, these changes account for the characteristic purple striae seen in the trunk area. Loss of collagenous support around small vessels makes them susceptible to rupture, leading to easy bruising, even with minor trauma. Thin, atrophied skin is also easily damaged, leading to skin breaks and ulcerations. Bronze or brownish hyperpigmentation of the skin, mucous membranes, and hair occurs when there are very high levels of ACTH.

With elevated cortisol levels, vascular sensitivity to catecholamines increases significantly, leading to vasoconstriction and hypertension. Mineralocorticoid effects promote hypokalemia and sodium and water retention with transient weight gain. Suppression of the immune system and increased susceptibility to infections also occur. Approximately 50% of individuals with Cushing syndrome experience irritability and depression, disturbed sleep, difficulty concentrating, memory loss, and, rarely, schizophrenia-like psychosis. Females with ACTH-dependent hypercortisolism may experience symptoms of increased adrenal androgen levels (virilism), with increased hair growth (especially facial hair), acne, and oligomenorrhea.Rarely, unless an adrenal carcinoma is involved, do androgen levels become high enough to cause changes of the voice, recession of the hairline, and hypertrophy of the clitoris.

**Evaluation and treatment**

Routine laboratory examinations may reveal hyperglycemia, glycosuria, hypokalemia, and metabolic alkalosis. A variety of laboratory tests are used to confirm the diagnosis of hypercortisolism and to determine the underlying disorder. These include urinary free cortisol level higher than 50 mcg in 24 hours, abnormal dexamethasone suppressibility of either urinary or serum cortisol, and simultaneous measurement of ACTH and cortisol levels. Late evening salivary
Cortisol levels are used as a screening test and to document alterations in the diurnal variation of cortisol level.\textsuperscript{94} Tumors are diagnosed using imaging procedures.

Treatment is specific for the cause of hypercorticoadrenalism and includes surgery, medication, and radiation. Differentiation between pituitary ectopic and adrenal causes is essential for effective treatment. Without treatment, approximately 50\% of individuals with Cushing syndrome die within 5 years of onset as a result of overwhelming infection, suicide, complications from generalized arteriosclerosis, and hypertensive disease.

**Congenital Adrenal Hyperplasia**

**Congenital adrenal hyperplasia** results from an inherited deficiency of an enzyme that is critical in cortisol biosynthesis. Because cortisol is not produced efficiently, the concentration of ACTH increases and causes adrenal hyperplasia, which results in the overproduction of mineralocorticoids or androgens, or both. The most common form is a 21-hydroxylase deficiency, which involves both mineralocorticoid and cortisol synthesis. Affected female children are virilized and may have genital ambiguity. Infants of both genders exhibit salt wasting. Prenatal diagnosis is available and treatment guidelines have been developed. Disease management requires lifelong treatment with glucocorticoids and mineralocorticoids.\textsuperscript{95,96}

**Hyperaldosteronism**

**Hyperaldosteronism** is characterized by excessive adrenal secretion of aldosterone. Both primary and secondary forms of hyperaldosteronism can occur.

Primary hyperaldosteronism (Conn syndrome, primary aldosteronism) is caused by excessive secretion of aldosterone from an abnormality of the adrenal cortex, usually a single benign aldosterone-producing adrenal adenoma. Bilateral adrenal nodular hyperplasia and adrenal carcinomas account for the remainder of cases. The incidence is estimated to be about 10\% of all hypertensive individuals; however, approximately 33\% of people with resistant hypertension will have evidence of primary hyperaldosteronism.\textsuperscript{97}

Secondary hyperaldosteronism results from an extra-adrenal stimulus of aldosterone secretion, most often by angiotensin II through a renin-dependent mechanism. Examples include decreased circulating blood volume (e.g., in dehydration, shock, or hypoalbuminemia) and decreased delivery of blood to the kidneys (e.g., renal artery stenosis, heart failure, or hepatic cirrhosis). Here, the activation of the renin-angiotensin system and subsequent aldosterone secretion may be seen as compensatory, although in some instances (e.g., congestive heart failure)
the increased circulating volume further worsens the condition. Other causes of secondary hyperaldosteronism are Bartter syndrome, a renal tubular defect causing hypokalemia, and renin-secreting tumors of the kidney.

**Pathophysiology**

In *primary hyperaldosteronism*, pathophysiologic alterations are caused by excessive aldosterone secretion and the fluid and electrolyte imbalances that ensue. Hyperaldosteronism promotes (1) increased renal sodium and water reabsorption with corresponding hypervolemia (see Chapter 5) and hypertension and (2) renal excretion of hydrogen and potassium (see Chapter 5). The extracellular fluid volume overload, hypertension, and suppression of renin secretion are characteristic of primary disorders. Edema may not occur with primary aldosteronism because hypervolemia-induced atrial natriuretic factor release results in loss of sodium and water. Hypokalemic alkalosis, changes in myocardial conduction, and skeletal muscle weakness may be seen, particularly with severe potassium depletion.

In *secondary hyperaldosteronism*, the effect of increased extracellular volume on renin secretion may vary. If renin secretion is being stimulated by variables other than pressure-initiated cellular changes at the juxtaglomerular apparatus (see Chapter 29), increased circulating blood volume may not decrease renin secretion through feedback mechanisms. This process occurs, for instance, in states of increased estrogen levels.

**Clinical manifestations**

Hypertension, hypokalemia, and neuromuscular manifestations are the hallmarks of primary hyperaldosteronism. Hypertension is resistant to treatment and can lead to the development of left ventricular dilation and hypertrophy, vascular disease, and kidney disease.

**Evaluation and treatment**

Various clinical and laboratory evaluations are useful in assessing hyperaldosteronism and include the following:

1. Measurement of blood pressure—hypertension is usually present.

2. Serum and urinary electrolyte levels: serum sodium level is normal or elevated and serum potassium level is depressed, but urinary potassium level is elevated; metabolic alkalosis may be present.
3. Plasma aldosterone-to-renin ratio increases.

4. Aldosterone suppression testing is performed using either salt loading or fludrocortisone acetate (Florinef) if the aldosterone-to-renin ratio is increased.

5. Imaging techniques may be used to localize an aldosterone-secreting adenoma.

   Treatment includes management of hypertension and hypokalemia, as well as correction of any underlying causal abnormalities. If an aldosterone-secreting adenoma is present, it must be surgically removed. Medical management with aldosterone receptor antagonists, such as spironolactone or eplerenone (a drug without the side effects of spironolactone), is a viable option in selected cases.

**Hypersecretion of Adrenal Androgens and Estrogens**

Hypersecretion of adrenal androgens and estrogens may be caused by adrenal tumors, either adenomas or carcinomas; Cushing syndrome; or defects in steroid synthesis. The clinical syndrome that is manifested depends on the hormone secreted, the gender of the individual, and the age at which the hypersecretion is initiated. Hypersecretion of estrogens causes **feminization**, the development of female secondary sex characteristics. Hypersecretion of androgens causes **virilization**, the development of male secondary sex characteristics (Figure 19-19).
The effects of an estrogen-secreting tumor are most evident in males and result in gynecomastia (98% of cases), testicular atrophy, and decreased libido. In female children, such tumors may lead to early development of secondary sex characteristics. The changes caused by an androgen-secreting tumor are more easily observed in females and include excessive face and body hair growth (hirsutism), clitoral enlargement, deepening of the voice, amenorrhea, acne, and breast atrophy. In children, virilizing tumors promote precocious sexual development and bone aging. Treatment of androgen-secreting tumors usually involves surgical excision.

**Adrenocortical Hypofunction**

**Hypocortisolism** (low levels of cortisol secretion) develops either because of inadequate stimulation of the adrenal glands by ACTH or because of a primary inability of the adrenals to produce and secrete the adrenocortical hormones.
Sometimes there is partial dysfunction of the adrenal cortex, so only synthesis of cortisol and aldosterone or the adrenal androgens is affected. Hypofunction of the adrenal cortex may affect glucocorticoid or mineralocorticoid secretion, or both.

**Addison disease.**

Primary adrenal insufficiency is termed Addison disease. It is relatively rare, occurring most often in adults aged 30 to 60 years, although it may appear at any time. Addison disease is caused by autoimmune mechanisms that destroy adrenal cortical cells and is more common in women. Chronic infections, such as tuberculosis, account for the majority of cases of primary adrenal insufficiency in underdeveloped countries.

**Pathophysiology**

Addison disease is characterized by inadequate corticosteroid and mineralocorticoid synthesis and elevated levels of serum ACTH (loss of negative feedback). Before clinical manifestations of hypocortisolism are evident, more than 90% of total adrenocortical tissue must be destroyed.

**Idiopathic Addison disease (organ-specific autoimmune adrenalitis)** causes adrenal atrophy and hypofunction and is an organ-specific autoimmune disease. It may occur in childhood (type 1) or adulthood (type 2). 21-Hydroxylase autoantibodies and autoreactive T cells specific to adrenal cortical cells are present in 50% to 70% of individuals with idiopathic Addison disease, and this percentage increases in younger persons and in those with other autoimmune diseases. This deficiency allows the proliferation of immunocytes directed against specific antigens within the adrenocortical cells. The adrenal glands in idiopathic Addison disease are smaller than normal and may be misshapen. Idiopathic Addison disease is often associated with other autoimmune diseases, especially Hashimoto thyroiditis, pernicious anemia, and idiopathic hypoparathyroidism. In these cases, Addison disease may be inherited as an autosomal recessive trait. (Mechanisms of inheritance are described in Chapter 2.)

**Clinical manifestations**

The symptoms of Addison disease are primarily a result of hypocortisolism and hypoaldosteronism and are often nonspecific. With mild to moderate hypocortisolism, symptoms begin with weakness and easy fatigability. Skin changes, including hyperpigmentation and vitiligo, may occur. As the condition progresses, anorexia, nausea, vomiting, and diarrhea may develop. Of greatest
Concern is the development of hypotension that can progress to complete vascular collapse and shock. This is known as adrenal crisis, or addisonian crisis, and develops with undiagnosed disease or acute withdrawal of glucocorticoid therapy.

**Evaluation and treatment**

Serum and urine levels of cortisol are depressed with primary hypocortisolism and ACTH levels are increased. Because of dehydration, blood urea nitrogen levels may increase. Serum glucose level is low. Eosinophil and lymphocyte counts often are elevated. Hyperkalemia is seen in Addison disease and may cause mild alkalosis (see *Chapter 5*). The ACTH stimulation test may be used to evaluate serum cortisol levels.

The treatment of Addison disease involves lifetime glucocorticoid and possibly mineralocorticoid replacement therapy, together with dietary modifications and correction of any underlying disorders. With acute stressors (e.g., infection, surgery, or trauma), additional cortisol must be administered to approximate the amount of cortisol that might be expected if normal adrenal function were present (approximately 100 to 300 mg/day). The individual's diet should include at least 150 mEq of sodium per day, and sodium intake should be increased if the individual experiences excessive sweating or diarrhea.

**Secondary hypocortisolism.**

Secondary hypocortisolism commonly results from prolonged administration of exogenous glucocorticoids; they suppress ACTH secretion and cause adrenal atrophy, resulting in inadequate corticosteroidogenesis once the exogenous glucocorticoids are withdrawn. Decreased ACTH secretion also can result from pituitary infarction, pituitary tumors that compress ACTH-secreting cells, or hypophysectomy. In all instances of low ACTH levels, adrenal atrophy occurs and endogenous adrenal steroidogenesis is depressed. Clinical manifestations of secondary hypocortisolism are similar to those of Addison disease, although hyperpigmentation usually does not occur. The renin-angiotensin system usually is normal, so aldosterone and potassium levels also tend to be normal.

**Tumors of the Adrenal Medulla**

Hyperfunction of the adrenal medulla is caused by pheochromocytomas (chromaffin cell tumors) or sympathetic paragangliomas of the adrenal medulla. They are rare, and about 10% are malignant and metastasize to the lungs, liver, bones, or paraaortic lymph nodes. The tumors are usually sporadic although up to 40% of them can be inherited.
Pathophysiology

Pheochromocytomas and sympathetic paragangliomas cause excessive production of norepinephrine, although large tumors secrete epinephrine and norepinephrine because of autonomous secretion of the tumor. Approximately 5% of people with these tumors have no symptoms, apparently because the tumor is nonfunctioning. Such tumors can, however, release catecholamines, especially in response to a stressor, such as surgery.

Clinical manifestations

The clinical manifestations of a pheochromocytoma and sympathetic paragangliomas are related to the chronic effects of catecholamine secretion and include persistent hypertension, headache, pallor, diaphoresis, tachycardia, and palpitations. Hypertension results from increased peripheral vascular resistance and may be sustained or paroxysmal. An acute episode of hypertension related to hypersecretion of catecholamines may follow specific events, such as exercise, excessive ingestion of tyrosine-containing foods (aged cheese, red wine, beer, yogurt), ingestion of caffeine-containing foods, external pressure on the tumor, and induction of anesthesia. Hypertension unresponsive to drug therapy is often the first indication of a pheochromocytoma. Headaches appear because of sudden changes in catecholamine levels in the blood, affecting cerebral blood flow. Hypermetabolism and sweating are related to chronic activation of sympathetic receptors in adipocytes, hepatocytes, and other tissues. Glucose intolerance may occur because of catecholamine-induced inhibition of insulin release by the pancreas. These tumors tend to be extremely vascular and can rupture, causing massive and potentially fatal hemorrhage.

Evaluation and treatment

Symptoms of pheochromocytoma can be insidious or intermittent and difficult to diagnose. A diagnosis is made when increased catecholamine production is found in the blood or urine. The site of the tumor is then determined using abdominal imaging techniques. Because of the possibility of metastasis, whole-body scanning may be done.

Management of catecholamine excess is essential to prevent hypertensive emergencies and requires the use of α- and β-adrenergic blockers. The usual treatment of pheochromocytoma is laparoscopic surgical excision of the tumor, although open resection is still completed for large tumors or when metastasis is suspected. Medical therapy is continued to stabilize blood pressure before, during, or after surgery. Malignant pheochromocytoma is rarely curable and is usually
managed by a combination of surgical debulking of the tumor combined with chemotherapy.\textsuperscript{104}

Did You Understand?

Mechanisms of Hormonal Alterations

1. Abnormalities in endocrine function may be caused by elevated or depressed hormone levels that result from (1) faulty feedback systems, (2) dysfunction of the gland, (3) altered metabolism of hormones, (4) dysfunction of carrier proteins, or (5) production of hormones from nonendocrine tissues.

2. Target cells may fail to respond to hormones because of (1) cell surface receptor–associated disorders, (2) intracellular disorders, or (3) circulating inhibitors.

Alterations of the Hypothalamic-Pituitary System

1. Dysfunction in the action of hypothalamic hormones is most commonly related to interruption of the connection between the hypothalamus and pituitary—the pituitary stalk.

2. Disorders of the posterior pituitary include syndrome of inappropriate ADH secretion (SIADH) and diabetes insipidus. SIADH is characterized by abnormally high ADH secretion; diabetes insipidus is characterized by abnormally low ADH secretion.

3. In SIADH, high ADH levels interfere with renal free water clearance, leading to hyponatremia and hypoosmolality, and are associated with brain injury, surgical procedures with certain forms of cancer related to ectopic secretion of ADH by tumor cells, and medications.

4. Diabetes insipidus may be neurogenic (caused by insufficient amounts of ADH) or nephrogenic (caused by an inadequate response to ADH). Its principal clinical features are polyuria and polydipsia.

5. Hypopituitarism can be primary (dysfunction of the pituitary) or secondary (dysfunction of the hypothalamus). Primary hypopituitarism can result from a pituitary tumor, trauma, infections, stroke, or surgical removal.

6. Hypopituitarism can affect any or all of the pituitary hormones and symptoms may range from mild to life-threatening.
7. Hyperpituitarism is caused by pituitary adenomas. These are usually benign, slow-growing tumors that arise from cells of the anterior pituitary.

8. Expansion of a pituitary adenoma causes both neurologic and secretory effects. Pressure from the expanding tumor causes hyposecretion of cells, dysfunction of the optic chiasma (leading to visual disturbances), and dysfunction of the hypothalamus and some cranial nerves.

9. Growth hormone deficiency causes increased body fat, decreased muscle mass, and psychologic problems in adults; and hypopituitary dwarfism in children.

10. Hypersecretion of growth hormone (GH) in adults causes acromegaly, in which GH secretion becomes high and unpredictable. Pituitary adenoma is the most common cause of acromegaly. Excessive GH secretion in children with open epiphyseal plates causes giantism.

11. Prolonged, abnormally high levels of GH lead to proliferation of body and connective tissue and slowly developing renal, thyroid, and reproductive dysfunction.

12. Prolactinomas result in galactorrhea, hirsutism, amenorrhea, hypogonadism, and osteopenia.

**Alterations of Thyroid Function**

1. Thyrotoxicosis is a general condition in which elevated thyroid hormone (TH) levels cause greater than normal physiologic responses. The condition can be caused by a variety of specific diseases, each of which has its own pathophysiology and course of treatment.

2. In general, hyperthyroidism has a range of endocrine, reproductive, gastrointestinal, integumentary, and ocular manifestations. These are caused by increased circulating levels of TH and by stimulation of the sympathetic division of the autonomic nervous system.

3. Graves disease, the most common form of hyperthyroidism, is caused by an autoimmune mechanism that overrides normal mechanisms for control of TH secretion and is characterized by thyrotoxicosis, ophthalmopathy, and circulating thyroid-stimulating immunoglobulins.
4. Toxic nodular goiter and toxic multinodular goiter occur when TH-regulating mechanisms and abnormal hypertrophy of the thyroid gland cause hyperthyroidism. Toxic multinodular goiter is caused by independently functioning follicular cell adenomas.

5. Thyrotoxic crisis is a severe form of hyperthyroidism that is often associated with physiologic or psychologic stress. Without treatment, death occurs quickly.

6. Primary hypothyroidism is caused by deficient production of TH by the thyroid gland. Secondary hypothyroidism is caused by hypothalamic or pituitary dysfunction. Symptoms depend on the degree of TH deficiency. Common manifestations include decreased energy metabolism, decreased heat production, and myxedema.

7. Primary hypothyroidism is characterized by an increased level of TSH, which stimulates goiter formation.

8. Autoimmune thyroiditis (Hashimoto disease) is associated with humoral (antibodies) and cellular autoimmune destruction of the thyroid gland and gradual loss of thyroid function. Autoimmune thyroiditis occurs in those individuals with genetic susceptibility to an autoimmune mechanism that causes thyroid damage and eventual hypothyroidism.

9. Subacute thyroiditis is a self-limiting nonbacterial inflammation of the thyroid gland that damages follicular cells, causing leakage of $T_3$ and $T_4$. Hyperthyroidism then is followed by transient hypothyroidism, which is corrected by cellular repair and a return to normal levels in the thyroid.

10. Myxedema is a sign of hypothyroidism caused by alterations in connective tissue with water-binding proteins that lead to edema and thickened mucous membranes.

11. Myxedema coma is a severe form of hypothyroidism that may be life-threatening without emergency medical treatment.

12. Congenital hypothyroidism is the absence of thyroid tissue during fetal development or defects in hormone synthesis.

13. Thyroid carcinoma is a relatively rare cancer associated with exposure to ionizing radiation, especially in childhood.
Alterations of Parathyroid Function

1. Hyperparathyroidism, which may be primary or secondary, is characterized by greater than normal secretion of parathyroid hormone (PTH).

2. Primary hyperparathyroidism is caused by an interruption of the normal mechanisms that regulate calcium and PTH levels. Manifestations include chronic hypercalcemia, increased bone resorption, and hypercalciuria.

3. Secondary hyperparathyroidism is a compensatory response to hypocalcemia and often occurs with chronic renal failure and vitamin D deficiency.

4. Tertiary hyperparathyroidism is persistent secretion of PTH after treatment of secondary hyperparathyroidism.

5. Hypoparathyroidism, defined by abnormally low PTH levels, is caused by thyroid surgery, autoimmunity, or genetic mechanisms.

6. The lack of circulating PTH in hypoparathyroidism causes hypocalcemia, hyperphosphatemia, decreased bone resorption, and hypocalciuria.

Dysfunction of the Endocrine Pancreas: Diabetes Mellitus

1. Diabetes mellitus is a group of disorders characterized by glucose intolerance, chronic hyperglycemia, and disturbances of carbohydrate, protein, and fat metabolism.

2. A diagnosis of diabetes mellitus is based on elevated plasma glucose concentrations and measurement of glycosylated hemoglobin. Classic signs and symptoms are often present as well.

3. The two most common types of diabetes mellitus are type 1 and type 2.

4. Type 1 diabetes mellitus is characterized by loss of beta cells, presence of islet cell antibody, lack of insulin, excess of glucagon, and altered metabolism of fat, protein, and carbohydrates.

5. Type 1 diabetes mellitus is caused by a gradual process of autoimmune
destruction of beta cells in genetically susceptible individuals.

6. In type 1 diabetes mellitus, hyperglycemia causes polyuria and polydipsia resulting from osmotic diuresis.

7. Ketoacidosis is caused by increased levels of circulating ketones without the inhibiting effects of insulin. Increased levels of circulating fatty acids and weight loss are both manifestations of type 1 uncontrolled diabetes mellitus.

8. Type 2 diabetes mellitus is caused by genetic susceptibility that is triggered by environmental factors. The most compelling environmental risk factor is obesity.

9. In the obese, many factors, including metabolic syndrome, altered adipokines, increased fatty acids, inflammation, and hyperinsulinemia, contribute to the development of insulin resistance and hyperglycemia.

10. Some insulin production continues in type 2 diabetes mellitus, but the weight and number of beta cells decrease. There are decreased levels of insulin, amylin, ghrelin, and incretins and glucagon concentration is increased. All contribute to chronic hyperglycemia.

11. A rare monogenetic form of diabetes is called maturity-onset diabetes of youth (MODY).

12. Gestational diabetes is glucose intolerance during pregnancy.

13. Acute complications of diabetes mellitus include hypoglycemia, diabetic ketoacidosis, and hyperosmolar hyperglycemic nonketotic syndrome.

15. Diabetic ketoacidosis (DKA) develops when there is an absolute or relative deficiency of insulin and an increase in the insulin counterregulatory hormones of catecholamines—cortisol, glucagon, and growth hormone. DKA presents with hyperglycemia, acidosis, and ketonuria.

16. Hyperosmolar hyperglycemic nonketotic syndrome is pathophysiologically similar to diabetic ketoacidosis, although levels of free fatty acids are lower in hyperosmolar nonacidotic diabetes and lack of ketosis indicates some level of insulin action. Severe dehydration and electrolyte imbalance are present.
17. Chronic complications of diabetes mellitus include microvascular disease (e.g., neuropathy, retinopathy, nephropathy), macrovascular disease (e.g., coronary artery disease, stroke, peripheral vascular disease), and infection.

18. Microvascular disease is characterized by thickening of the capillary basement membrane, disruption of the microcirculation, and decreased tissue perfusion.

19. Macrovascular disease associated with diabetes mellitus is most often related to the proliferation of atherosclerotic plaques in the arterial wall and coagulation defects.

20. The incidence of coronary heart disease, peripheral vascular disease, and stroke is greater in those with diabetes than in nondiabetic individuals.

21. Individuals with diabetes are at risk for a variety of infections. Infection may be related to sensory impairment and resulting injury, hypoxia, increased proliferation of pathogens in elevated concentrations of glucose, decreased blood supply associated with vascular damage, and impaired immune protection.

**Alterations of Adrenal Function**

1. Disorders of the adrenal cortex are related to hyperfunction or hypofunction. No known disorders are associated with hypofunction of the adrenal medulla, but medullary hyperfunction causes clinically defined syndromes.

2. Cortical hyperfunction, or hypercortisolism, causes Cushing syndrome, which does not involve the pituitary gland, and Cushing disease, which is hypercortisolism with pituitary involvement. Congenital adrenal hyperplasia is a genetic disorder with deficient steroidogenesis and excess androgen synthesis.

3. Hypercortisolism is usually caused by Cushing disease (pituitary-dependent) and very rarely can be caused by ectopic production of ACTH. Complications include obesity, diabetes, protein wasting, immune suppression, and mental status changes.

4. Excessive aldosterone secretion causes hyperaldosteronism, which may be primary or secondary. Primary hyperaldosteronism is caused by an abnormality of the adrenal cortex. Secondary hyperaldosteronism involves an extra-adrenal stimulus, often angiotensin.

5. Hyperaldosteronism promotes increased sodium reabsorption (with
corresponding hypervolemia), increased extracellular volume (which is variable), hypokalemia related to renal reabsorption of sodium, and excretion of potassium.

6. Hypersecretion of adrenal androgens and estrogens can be a result of adrenal tumors, either adenomas or carcinomas. Hypersecretion of estrogens causes feminization, the development of female secondary sexual characteristics. Hypersecretion of androgens causes virilization, the development of male secondary sexual characteristics.

7. Hypofunction of the adrenal cortex can affect glucocorticoid or mineralocorticoid secretion, or both. Hypofunction can be caused by a deficiency of ACTH or by a primary deficiency in the gland itself.

8. Hypocortisolism, or low levels of cortisol, is caused by inadequate adrenal stimulation by ACTH or by primary cortisol hyposecretion. Primary adrenal insufficiency is termed Addison disease.

9. Addison disease is characterized by elevated ACTH levels with inadequate corticosteroid synthesis and output.

10. Manifestations of Addison disease are related to hypocortisolism and hypoaldosteronism. Symptoms include weakness, fatigability, hypoglycemia and related metabolic problems, lowered response to stressors, hyperpigmentation, vitiligo, and manifestations of hypovolemia and hyperkalemia.

11. Hyperfunction of the adrenal medulla is usually caused by a pheochromocytoma, a catecholamine-producing tumor. Symptoms of catecholamine excess are related to their sympathetic nervous system effects and include hypertension, palpitations, tachycardia, glucose intolerance, excessive sweating, and constipation.

All the body's tissues and organs require oxygen and nutrients to survive. These essential needs are provided by the blood that flows through miles of vessels throughout the human body. The red blood cells provide the oxygen, and the fluid portion of the blood carries the nutrients. The blood also cleans discarded waste from the tissues and transports cells (white blood cells) and other ingredients that are necessary for protecting the entire body from injury and infection.
Components of the Hematologic System

Composition of Blood

Blood consists of various cells that circulate suspended in a solution of protein and inorganic materials (plasma), which is approximately 91% water and 9% dissolved substances (solutes). The blood volume amounts to about 6 quarts (5.5 L) in adults. The continuous movement of blood guarantees that critical components are available to all parts of the body to carry out their chief functions: (1) delivery of substances needed for cellular metabolism in the tissues, (2) removal of the wastes of cellular metabolism, (3) defense against invading microorganisms and injury, and (4) maintenance of acid-base balance.

Plasma and Plasma Proteins

In adults, plasma accounts for 50% to 55% of blood volume (Figure 20-1). Plasma is a complex aqueous liquid containing a variety of organic and inorganic elements (Table 20-1). The concentration of these elements varies depending on diet, metabolic demand, hormones, and vitamins. Plasma differs from serum in that serum is plasma that has been allowed to clot in the laboratory in order to remove fibrinogen and other clotting factors that may interfere with some diagnostic tests.
FIGURE 20-1 Composition of Whole Blood. Approximate values for the components of blood in a normal adult. (From Patton KT, Thibodeau GA: Structure & function of the body, ed 15, St Louis, 2016, Mosby.)
The plasma contains a large number of proteins (plasma proteins). These vary in structure and function and can be classified into two major groups—albumin and globulins. Most plasma proteins are produced by the liver. The major exception is antibody, which is produced by plasma cells in the lymph nodes and other lymphoid tissues (see Chapter 7).

**Albumin** (about 60% of total plasma protein) serves as a carrier molecule for...
both normal components of blood and drugs. Its most essential role is regulation of the passage of water and solutes through the capillaries. Albumin molecules are large and do not diffuse freely through the vascular endothelium, and thus they maintain the critical colloidal osmotic pressure (or oncotic pressure) that regulates the passage of fluids and electrolytes into the surrounding tissues (see Chapters 1 and 5). Water and solute particles tend to diffuse out of the arterial portions of the capillaries because blood pressure is greater in arterial than in venous blood vessels. Water and solutes move from tissues into the venous portions of the capillaries where the pressures are reversed, oncotic pressure being greater than intravascular pressure or hydrostatic pressure. In the case of decreased production (e.g., cirrhosis, other diffuse liver diseases, protein malnutrition) or excessive loss of albumin (e.g., certain kidney diseases), the reduced oncotic pressure leads to excessive movement of fluid and solutes into the tissue and decreased blood volume.

The remaining plasma proteins, or globulins, are often classified by their properties in an electric field (serum electrophoresis). Under the normal conditions used to perform serum electrophoresis, albumin is the most rapidly moving protein. The globulins are classified by their movement relative to albumin: alpha globulins (those moving most closely to albumin), beta globulins, and gamma globulins (those with the least movement). The alpha and beta globulins may be subdivided into subregions (alpha-1, alpha-2, beta-1, or beta-2 globulins). Fibrinogen is a major plasma protein (about 4% of total plasma protein) that would move between the beta and gamma regions but is removed during the formation of serum. The gamma-globulin region consists primarily of antibodies (see Chapter 7).

Plasma proteins can also be classified by function: clotting, defense, transport, or regulation. The clotting factors promote coagulation and stop bleeding from damaged blood vessels. Fibrinogen is the most plentiful of the clotting factors and is the precursor of the fibrin clot (see Figure 20-18). Proteins involved in defense, or protection, against infection include antibodies and complement proteins (see Chapters 6 and 7). Transport proteins specifically bind and carry a variety of inorganic and organic molecules, including iron (transferrin), copper (ceruloplasmin), lipids and steroid hormones (lipoproteins) (see Chapters 1 and 23), and vitamins (e.g., retinol-binding protein). Regulatory proteins include a variety of enzymatic inhibitors (e.g., \( \alpha_1 \)-antitrypsin) that protect the tissues from damage, precursor molecules (e.g., kininogen) that are converted into active biologic molecules when needed, and protein hormones (e.g., cytokines) that communicate between cells.

Plasma also contains several inorganic ions that regulate cell function, osmotic pressure, and blood pH. These include electrolytes, sodium, potassium, calcium,
chloride, and phosphate. (Electrolytes are described in Chapters 1 and 4.)

**Cellular Components of the Blood**

The cellular elements of the blood are broadly classified as red blood cells (i.e., erythrocytes), white blood cells (i.e., leukocytes), and platelets. The components of the blood are listed in Table 20-2. Pathways of blood differentiation or maturation are shown in Figure 20-2.

**Erythrocytes.**

Erythrocytes (red blood cells) are the most abundant cells of the blood, occupying approximately 48% of the blood volume in men and about 42% in women. Erythrocytes are primarily responsible for tissue oxygenation. Hemoglobin (Hb) carries the gases, and electrolytes regulate gas diffusion through the cell's plasma membrane. The mature erythrocyte lacks a nucleus and cytoplasmic organelles (e.g.,
Leukocytes.

Leukocytes (white blood cells) defend the body against organisms that cause
infection and also remove debris, including dead or injured host cells of all kinds (Figure 20-4). The leukocytes act primarily in the tissues but are transported in the circulation. The average adult has approximately 5000 to 10,000 leukocytes/mm³ of blood.

Leukocytes are classified according to structure as either granulocytes or agranulocytes and according to function as either phagocytes or immunocytes. The granulocytes, which include neutrophils, basophils, and eosinophils, are all phagocytes. (Phagocytic action is described in Chapter 6.) Of the agranulocytes, the monocytes and macrophages are phagocytes, whereas the lymphocytes are immunocytes (cells that create immunity; see Chapter 7).

Granulocytes.

The granulocytes have many membrane-bound granules in their cytoplasm. These granules contain enzymes capable of killing microorganisms and catabolizing debris ingested during phagocytosis. The granules also contain powerful biochemical mediators with inflammatory and immune functions. These mediators,
along with the digestive enzymes, are released from granulocytes in response to specific stimuli and affect other cells in the circulation. Granulocytes are capable of amoeboid movement, by which they migrate through vessel walls (diapedesis) and then to sites where their action is needed.

The neutrophil (polymorphonuclear neutrophil [PMN]) is the most numerous and best understood of the granulocytes (Figure 20-5). Neutrophils constitute 60% to 70% of the total leukocyte count in adults.

![Figure 20-5](image)

**FIGURE 20-5** Leukocytes. Normal cells in peripheral blood: A, Erythrocyte (red blood cell); B, Neutrophil (segmented); C, Neutrophil (banded); D, Eosinophil; E, Basophil; F, Lymphocyte; G, Monocyte; H, Platelet. (From Keohane E, Smith L, Walenga J: Rodak’s hematology, ed 5, St. Louis, 2016, Saunders).

Neutrophils are the chief phagocytes of early inflammation. Soon after bacterial invasion or tissue injury, neutrophils migrate out of the capillaries and into the damaged tissue, where they ingest and destroy contaminating microorganisms and debris. Neutrophils are sensitive to the environment in damaged tissue (e.g., low pH, enzymes released from damaged cells) and die in 1 or 2 days. The breakdown of dead neutrophils releases digestive enzymes from their cytoplasmic granules. These enzymes dissolve cellular debris and prepare the site for healing.

**Eosinophils**, which have large, coarse granules, constitute only 2% to 4% of the normal leukocyte count in adults. Using a spectrum of pattern-recognition
receptors, eosinophils are capable of amoeboid movement and phagocytosis. Unlike neutrophils, eosinophils ingest antigen-antibody complexes and are induced by immunoglobulin E (IgE)–mediated hypersensitivity reactions to attack parasites (see Chapters 7 and 8). Eosinophil secondary granules contain toxic chemicals (e.g., major basic protein, eosinophil cationic protein, eosinophil peroxidase, eosinophil-derived neurotoxin) that are highly destructive to parasites and viruses. Eosinophil granules also contain a variety of enzymes (e.g., histaminase) that help to control inflammatory processes. Eosinophils also release leukotrienes, prostaglandins, platelet-activating factor (PAF), and a variety of cytokines (e.g., interleukin-1 [IL-1], IL-6, tumor necrosis factor-alpha [TNF-α], granulocyte-macrophage colony-stimulating factor [GM-CSF]) and chemokines (e.g., IL-8) that augment the inflammatory response. During type I hypersensitivity, allergic reactions and asthma are characterized by high eosinophil counts, which may be involved in a dual role of regulation of inflammation and contribute to the destructive inflammatory processes observed in the lungs of persons with asthma.

**Basophils**, which make up less than 1% of leukocytes, are structurally similar to the mast cells (see Figure 20-5). Basophils contain cytoplasmic granules with histamine, chemotactic factors, proteolytic enzymes (e.g., elastase, lysophospholipase), and an anticoagulant (heparin). Stimulation of basophils also induces synthesis of vasoactive lipid molecules (e.g., leukotrienes) and cytokines, including interleukin-6 (IL-6), which affects differentiation of Th1 cells and Th2 cells. Basophils also are a particularly rich source of the cytokine IL-4, which preferentially guides B-cell differentiation toward plasma cells that secrete IgE (see Chapter 7).

**Agranulocytes.**
The agranulocytes—monocytes, macrophages, and lymphocytes—contain relatively fewer granules than granulocytes. Monocytes and macrophages make up the mononuclear phagocyte system (MPS) (see p. 497, and Chapter 6). Both monocytes and macrophages participate in the immune and inflammatory response, being powerful phagocytes. They also ingest dead or defective host cells, particularly blood cells.

**Monocytes** are immature macrophages (see Figure 20-5). Monocytes are formed and released by the bone marrow into the bloodstream. As they mature, monocytes migrate into a variety of tissues (e.g., liver, spleen, lymph nodes, peritoneum, gastrointestinal tract) and fully mature into tissue macrophages. Other monocytes may mature into macrophages and migrate out of the vessels in response to infection or inflammation.

**Lymphocytes** constitute approximately 20% to 25% of the total leukocyte count
and are the primary cells of the immune response (see Figure 20-5 and Chapter 7). Most lymphocytes transiently circulate in the blood and eventually reside in lymphoid tissues as mature T cells, B cells, or plasma cells. (Lymphocyte function and dysfunction are described in detail in Unit 2.)

**Natural killer (NK) cells**, which resemble lymphocytes, kill some types of tumor cells (in vitro) and some virus-infected cells without prior exposure (see Chapters 6 and 7). They develop in the bone marrow and circulate in the blood.

**Platelets.**

**Platelets (thrombocytes)** are not true cells but irregularly-shaped anuclear cytoplasmic fragments that are essential for blood coagulation and control of bleeding. They are formed by fragmentation of very large (40 to 100 µm in diameter) cells known as **megakaryocytes** and contain cytoplasmic granules (discussed later in this chapter) capable of releasing potent mediators when stimulated by injury to a blood vessel (Figure 20-6).

![FIGURE 20-6 Colored Micrograph of Platelets. The platelet on the left is moderately activated, with a generally round shape and the beginning of formation of pseudopodia (foot-like extensions from the membrane). The platelet on the right is fully activated, with extensive pseudopodia. (Copyright Dennis Kunkel Microscopy Inc.)](image)

The normal platelet concentration is approximately 150,000 to 400,000 platelets/mm³ of circulating blood, although the normal ranges may vary slightly from laboratory to laboratory. An additional one third of the body's available
platelets are in a reserve pool in the spleen. A platelet circulates for approximately 8 to 11 days, ages, and is removed by macrophages, mostly in the spleen.

**Quick Check 20-1**

1. What are the unique properties of the erythrocyte's shape?

2. Why are plasma proteins important to blood volume?

3. Which leukocytes are granulocytes?

4. Compare and contrast granulocytes, agranulocytes, phagocytes, and immunocytes.

**Lymphoid Organs**

The lymphoid system is closely integrated with the circulatory system. The lymphoid organs, some of which are merely aggregations of lymphoid tissue, are classified as primary or secondary. The primary lymphoid organs are the thymus and the bone marrow. The secondary lymphoid organs consist of the spleen, lymph nodes, tonsils, and Peyer patches of the small intestine. All of the lymphoid organs link the hematologic and immune systems in that they are sites of residence, proliferation, differentiation, or function of lymphocytes and mononuclear phagocytes (monocytes and macrophages). (The liver, which also has hematologic functions, is primarily a digestive organ and is described in Chapter 35.)

**Spleen**

The spleen is the largest of the lymphoid organs. It serves as a site of fetal hematopoiesis, filters and cleanses the blood by mononuclear phagocytes, initiates an immune responses to blood-borne microorganisms, and serves as a reservoir for blood.

The spleen is a concave, encapsulated organ that weighs about 150 g and is about the size of a fist. Strands of connective tissue (trabeculae) extend throughout the spleen from the splenic capsule, dividing it into compartments that contain masses of lymphoid tissue called splenic pulp. The spleen is interlaced with many blood vessels, some of which can distend to store blood.

Arterial blood that enters the spleen first encounters the white splenic pulp, which consists of masses of lymphoid tissue containing macrophages and lymphocytes,
primarily T lymphocytes in proximity to the arterioles (Figure 20-7). Cellular clumps (lymphoid follicles) are formed in the white pulp around the splenic arterioles. The lymphoid follicles consist primarily of B lymphocytes and are the chief sites of immune function within the spleen. Here blood-borne antigens encounter lymphocytes, initiating the immune response and the conversion of lymphoid follicles into germinal centers (see Chapter 7).
Some of the blood continues through the microcirculation and enters highly distensible storage areas, called *venous sinuses*, in the red pulp of the spleen. The venous sinuses (and the red pulp) can store more than 300 ml of blood. Sudden reductions in blood pressure cause the sympathetic nervous system to stimulate constriction of the sinuses and expel as much as 200 ml of blood into the venous circulation, helping to restore blood volume or pressure in the circulation and increasing the hematocrit by as much as 4%.

The endothelial lining of the venous sinuses is discontinuous (having gaps
between endothelial cells) and therefore extremely permeable so that blood cells are allowed to exit the circulation. The red pulp contains a system of loosely interconnected resident macrophages that provide the principal site of splenic filtration. Because of the slow circulation in the sinuses, the macrophages easily phagocytose old, damaged, or dead blood cells of all kinds (but chiefly erythrocytes), microorganisms, macromolecules, and particles of debris. Hemoglobin from phagocytosed erythrocytes is catabolized, and heme (iron) is stored in the cytoplasm of the macrophages or released back into the blood. Blood that filters through the red pulp then moves through the venous sinuses and into the portal circulation.

The spleen is not absolutely necessary for life or for adequate hematologic function. However, splenic absence from any cause (atrophy, traumatic injury, or removal because of disease) has several secondary effects on the body. For example, leukocytosis (high levels of circulating leukocytes) often occurs after splenectomy, suggesting that the spleen exerts some control over the rate of proliferation of leukocyte stem cells in the bone marrow or their release into the bloodstream. Circulating levels of iron also may decrease, reflecting the spleen's role in the iron cycle. The immune response to encapsulated bacteria (e.g., Streptococcus pneumoniae [pneumococcus], Neisseria meningitidis [meningococcus], Haemophilus influenzae), which is primarily an IgM response, may be severely diminished resulting in increased susceptibility to disseminated infections. Loss of the spleen results in an increase in morphologically defective blood cells in the circulation, confirming the spleen's role in removing old or damaged cells.

**Lymph Nodes**

Structurally, lymph nodes are part of the lymphatic system. Lymphatic vessels collect interstitial fluid from the tissues and transport it, as lymph, through vessels of increasing size to the thoracic duct, which drains into the superior vena cava, returning the lymph to the circulation. Lymph nodes are distributed throughout the body and provide filtration of the lymph during its journey through the lymphatics. Each lymph node is enclosed in a fibrous capsule, branches of which (trabeculae) extend inward to partition the node into several compartments (Figure 20-8). Reticular fibers of connective tissue divide the compartments into a meshwork throughout the lymph node. The node consists of outer (cortex) and inner (paracortex) cortical areas and an inner medulla. Lymph enters through multiple small afferent lymphatic vessels into the subcapsular sinus, just beneath the capsule, and drains into the cortical sinuses to the medullary sinuses, from which the lymph
is collected and leaves the node by way of the efferent lymphatic vessel. Blood flows into the lymph nodes through the lymphatic artery, which ends in groups of postcapillary venules distributed throughout the outer cortex. The blood is drained through the lymphatic vein.

Functionally, lymph nodes are part of the hematologic and immune systems and are the primary site for the first encounter between antigen and lymphocytes. Lymphocytes enter the lymph node from the blood through the postcapillary venules by means of diapedesis across the endothelial lining. B lymphocytes tend to
migrate preferentially to the cortex and medulla of the nodes, whereas T lymphocytes predominantly migrate to the paracortex. Macrophages reside in the lymph node; help filter the lymph of debris, foreign substances, and microorganisms; and provide antigen-processing functions. The dendritic cells encounter and process antigens and microorganisms in other tissues, enter the lymph node through the afferent lymph vessels, and migrate throughout the nodes (see Chapter 6). The reticular network provides adhesive surfaces for trapping large numbers of phagocytes and lymphocytes and facilitates their organization into follicles or primary nodules. The presence of antigen, either removed from the lymph by macrophages or presented on the surface of dendritic cells, results in the production of secondary nodules containing germinal centers. In the germinal centers lymphocytes, particularly B cells, respond to antigenic stimulation by undergoing proliferation and further differentiation into memory cells and plasma cells (see Chapter 7). Plasma cells migrate to the medullary cords. The B-lymphocyte proliferation in response to a great deal of antigen (e.g., during infection) may result in lymph node enlargement and tenderness (reactive lymph node).

**The Mononuclear Phagocyte System**

The **mononuclear phagocyte system (MPS)** consists of monocytes that differentiate without dividing and reside in the tissues for months or perhaps years. Table 20-3 lists the various names given to macrophages localized in specific tissues.

Cells of the MPS ingest and destroy (by phagocytosis) unwanted materials, such
as foreign protein particles, circulating immune complexes, microorganisms, debris from dead or injured cells, defective or injured erythrocytes, and dead neutrophils. Recently, the osteoclast was classified as a true member of the MPS. Osteoclasts are multinucleated cells that originate from the monocyte cell lineage (see Figure 20-2) and are specialized for the function of lacunar bone resorption; however, they are also known to have phagocytic abilities.

Development of Blood Cells

Hematopoiesis

The typical human requires about 100 billion new blood cells per day. Blood cell production, termed **hematopoiesis**, is constantly ongoing, occurring in the liver and spleen of the fetus and only in bone marrow (**medullary hematopoiesis**) after birth. This process involves the biochemical stimulation of populations of relatively undifferentiated cells to undergo mitotic division (i.e., proliferation) and maturation (i.e., differentiation) into mature hematologic cells. Although proliferation and differentiation are usually sequential, certain blood cells proliferate and differentiate simultaneously. Erythrocytes and neutrophils generally differentiate fully before entering the blood, but monocytes and lymphocytes continue to mature in the blood and in secondary lymphatic organs.

Hematopoiesis continues throughout life, increasing in response to a need to replenish destroyed circulating cells (e.g., during hemorrhage, hemolytic anemia [peripheral destruction of erythrocytes], consumptive thrombocytopenia) or in response to infection. In general, long-term stimuli, such as chronic diseases, cause a greater increase in hematopoiesis than acute conditions, such as hemorrhage.

Various abnormalities in medullary hematopoiesis have been identified and are discussed in Chapter 21. **Extramedullary hematopoiesis**—blood cell production in tissues other than bone marrow—of apparently normal blood cells has been reported in the spleen, liver, and, less frequently, lymph nodes, adrenal glands, cartilage, adipose tissue, intrathoracic areas, and kidneys. Extramedullary hematopoiesis, however, is usually a sign of disease, occurring in pernicious anemia, sickle cell anemia, thalassemia, hemolytic disease of the newborn (erythroblastosis fetalis), hereditary spherocytosis, and certain leukemias.

Bone Marrow

**Bone marrow** is confined to the cavities of bone and is the primary residence of hematopoietic stem cells. It consists of blood vessels, nerves, mononuclear phagocytes, stromal cells, and blood cells in various stages of differentiation. Adults have two kinds of bone marrow: red, or active (hematopoietic), marrow (also called **myeloid tissue**); and yellow, or inactive, marrow. The large quantities of fat in inactive marrow make it yellow. Not all bones contain active marrow. In adults, active marrow is found primarily in the flat bones of the pelvis (34%), vertebrae (28%), cranium and mandible (13%), sternum and ribs (10%), and in the extreme proximal portions of the humerus and femur (4% to 8%). Inactive marrow predominates in cavities of other bones. (Bones are discussed further in Chapter 38.)
Hematopoietic marrow is vascularized by the primary arteries of the bones, which terminate in a capillary network forming large venous sinuses. Hematopoietic marrow and fat fill the spaces surrounding the network of venous sinuses. Newly produced blood cells traverse narrow openings between endothelial cells in the venous sinus walls and thus enter the circulation. Normally, cells do not enter the circulation until they have differentiated (e.g., developed appropriate surface receptors to interact with the endothelium and enter the circulation), but premature release occurs in certain diseases.

The hematologic compartment of the bone marrow consists of cellular microenvironments or niches that control differentiation of hematopoietic progenitor cells. The cellular composition of niches includes osteoclasts, osteoblasts, sinusoidal endothelial cells, fibroblasts, megakaryocytes, macrophages, and nerve cells. Osteoblasts are derived from fibroblasts and are responsible for construction of bone. Osteoclasts are multinucleate cells of monocytic origin that remodel bone by resorption. Both cells produce cytokines that affect proliferation of hematopoietic cells. At least two populations of stem cells are found in bone marrow niches. Mesenchymal stem cells (MSCs) are stromal cells that can differentiate into a variety of cells, including osteoblasts, adipocytes, and chondrocytes (produce cartilage). Hematopoietic stem cells (HSCs) are progenitors of all hematologic cells. Both populations of stem cells undergo self-renewal in the bone marrow, so that additional MSCs and HSCs are produced to replace those undergoing differentiation.

Two distinct types of niches have been identified—the osteoblastic (also called endosteal) niche and the vascular niche (Figure 20-9). The osteoblastic niche is centralized around osteoblasts, which line the surface of bone, whereas the vascular niche is organized around sinusoidal endothelial cells. In both niches, HSCs are affected by direct cell-to-cell signaling and soluble mediators produced by cells within each niche. Each niche also contains two specialized cells derived from MSCs: CXCL12-abundant reticular (CAR) cells and nestin-expressing cells.
Bone Marrow Stem Cell Niches. Stem cell niches are microenvironments where stem cells undergo hematopoiesis into all forms of blood cells. Stem cell niches retain and maintain adult resting hematopoietic stem cells (HSCs) and are activated after cell injury to promote cell renewal or differentiation to form new tissues. The fate of individual HSCs is determined by interactions (intercellular adherence, cytokines, chemokines) with specialized cells within the niches. Within osteoblastic niches the HSC interacts primarily with the osteoblasts and specialized mesenchymal stem cells (MSCs) that include nestin-expressing (Nestin+) MSCs and CXCL12-abundant reticular (CAR) cells. Within the vascular niches, the HSC interacts with vascular endothelial cells, Nestin+ MSC, and a more abundant population of CAR cells.

CAR cells resemble reticular cells with long cellular processes and closely interact with HSCs to provide important intercellular signaling through HSC regulatory molecules, including chemokine ligand 12 (CXCL12), stem cell factor (SCF, also called steel factor), vascular cell adhesion molecule 1 (VCAM-1), and angiopoietin 1 (ANG1). CXCL12 is a chemokine that reacts with a chemokine receptor on HSCs. SCF is expressed as a cell surface transmembrane protein or a soluble protein and reacts with the HSC KIT receptor (named stem cell growth factor receptor, proto-oncogene c-Kit, or CD117). VCAM-1 mediates intercellular adhesion through its receptor, integrin α4β1. ANG1 is secreted and reacts with a tyrosine kinase receptor. Nestin-expressing cells express large amounts of the intermediate filament protein, nestin, and particularly SCF and VCAM-1. Although both MSC-derived cells are present in the osteoblastic niche and vascular niche, the CAR cell is the predominant cell in the vascular niche.

Each bone marrow niche affects HSCs differently. In the osteoblastic niche, HSCs
are in direct contact with osteoblasts, CAR cells, and nestin-expressing cells. The effect is retention of HSCs in the bone marrow in a quiescent (dormant) state. HSCs that traffic to the vascular niche directly contact endothelial cells, as well as nestin-expressing cells and larger numbers of perivascular CAR cells. The cumulative signaling events induce HSC proliferation and hematopoietic differentiation.

**Cellular Differentiation**

All humans originate from a single cell (the fertilized egg) that has the capacity to proliferate and eventually differentiate into the huge diversity of cells of the human body. After fertilization, the egg divides over a 5-day period to form a hollow ball (blastocyst) that implants on the uterus. Until about 3 days after fertilization, each cell (blastomere) is undifferentiated and retains the capacity to differentiate into any cell type. In the 5-day blastocyst, the outer layer of cells has undergone differentiation and commitment to become the placenta. Cells of the inner cell mass, however, continue to have unlimited differentiation potential (currently referred to as being pluripotent) and can grow into different kinds of tissue—blood, nerves, heart, bone, and so forth. After implantation, cells of the inner cell mass begin differentiation into other cell types. Differentiation is a multistep process and results in intermediate groups of stem cells with more limited, but still impressive, abilities to differentiate into many different types of cells.

Within the bone marrow niches each type of blood cell originates from hematopoietic stem cells that proliferate and differentiate under control of a variety of cytokines and growth factors⁹ (see Figure 20-2). As with all stem cells, the hematopoietic stem cells are self-renewing (they have the ability to proliferate without further differentiation) so that a relatively constant population of stem cells is available. Some hematopoietic stem cells will continue differentiation into hematopoietic progenitor cells. Progenitor cells retain proliferative capacity but are committed to possible further differentiation into particular types of hematologic cells: lymphoid (lymphocytes, NK cells), granulocyte/monocyte (granulocytes, monocytes, macrophages), and megakaryocyte/erythroid (platelets, erythrocytes) progenitor cells.

Several cytokines participate in hematopoiesis, particularly **colony-stimulating factors (CSFs or hematopoietic growth factors)**, which stimulate the proliferation of progenitor cells and their progeny and initiate the maturation events necessary to produce fully mature cells. Multiple cell types in hematopoietic organs, including endothelial cells, fibroblasts, and lymphocytes, produce the necessary CSFs.

Hematopoiesis in the bone marrow occurs in two separate pools—the stem cell pool and the bone marrow pool—with eventual release of mature cells into the
peripheral circulation (Figure 20-10). The stem cell pool contains pluripotent stem cells and partially committed progenitor cells. The bone marrow pool contains cells that are proliferating and maturing in preparation for release into the circulation and mature cells that are stored for later release into the peripheral blood. The peripheral blood also contains two pools of cells—those circulating and those stored around the walls of the blood vessels (often called the marginating storage pool). The marginating storage pool primarily consists of neutrophils that adhere to the endothelium in vessels where the blood flow is relatively slow. These cells can rapidly move into tissues and mucous membranes when needed.

Under certain conditions, the levels of circulating hematologic cells need to be rapidly replenished. Medullary hematopoiesis can be accelerated by any or all of three mechanisms: (1) conversion of yellow bone marrow, which does not produce blood cells, to red marrow, which does, by the actions of erythropoietin (a hormone that stimulates erythrocyte production); (2) faster differentiation of daughter cells; and, presumably, (3) faster proliferation of stem cells.

Quick Check 20-3

1. Why is the stem cell system important to hematopoiesis?
2. Why are some stem cells called pluripotent?

3. What role do stromal cells play in hematopoiesis?

**Development of Erythrocytes**

For almost 100 years it was thought that erythrocytes developed in the spleen. It was not until the 1950s that the bone marrow was identified as the site of *erythropoiesis*, or development of red blood cells.

**Erythropoiesis**

In the confines of the bone marrow erythroid progenitor cells proliferate and differentiate into large, nucleated *proerythroblasts*, which are committed into producing cells of the erythroid series. The proerythroblast differentiates through several intermediate forms of *erythroblast* (sometimes called *normoblast*) while progressively eliminating most intracellular structures (including the nucleus), synthesizing hemoglobin, and becoming more compact, eventually assuming the shape and characteristics of an erythrocyte.

The last immature form is the *reticulocyte*, which contains a mesh-like (reticular) network of ribosomal RNA that is visible microscopically after staining with certain dyes. Reticulocytes remain in the marrow approximately 1 day and are released into the venous sinuses. They continue to mature in the bloodstream and may travel to the spleen for several days of additional maturation. The normal reticulocyte count is 1% of the total red blood cell count. Approximately 1% of the body's circulating erythrocyte mass normally is generated every 24 hours. Therefore, the reticulocyte count is a useful clinical index of erythropoietic activity and indicates whether new red cells are being produced.

Most steps of erythropoiesis are primarily under the control of a feedback loop involving the glycoprotein erythropoietin. In healthy humans, the total volume of circulating erythrocytes remains surprisingly constant. In conditions of tissue hypoxia, erythropoietin is secreted primarily by the peritubular cells of the kidney (Figure 20-11). Rising levels of erythropoietin causes a compensatory increase in erythrocyte production if the oxygen content of blood decreases because of anemia, high altitude, or pulmonary disease. The normal steady-state rate of production (2.5 million erythrocytes per second) can increase (to 17 million per second) under anemic or low-oxygen states. Thus, the body responds to reduced oxygenation of blood in two ways: (1) by increasing the intake of oxygen through increased respiration and (2) by increasing the oxygen-carrying capacity of the blood through increased erythropoiesis.
Recombinant human erythropoietin (r-HuEPO) is used in individuals with anemia secondary to decreased erythropoietin from chronic renal failure. An immediate effect of erythropoietin administration is an increase in the blood reticulocyte count, followed by increasing levels of erythrocytes. The most significant side effect is increased blood pressure.

**Hemoglobin Synthesis**

**Hemoglobin (Hb)**, the oxygen-carrying protein of the erythrocyte, constitutes approximately 90% of the cell's dry weight. Hemoglobin-packed blood cells take up oxygen in the lungs and exchange it for carbon dioxide in the tissues. Hemoglobin increases the oxygen-carrying capacity of blood by 100-fold. Each hemoglobin molecule is composed of two pairs of polypeptide chains (the globins) and four colorful complexes of iron plus protoporphyrin (the hemes), which is responsible for the blood's ruby-red color (Figure 20-12).
Several variants of hemoglobin exist, but they differ only slightly in primary structure based on the use of different polypeptide chains: alpha, beta, gamma, delta, epsilon, or zeta (α, β, γ, δ, ε, or ζ).\(^\text{10}\) Hemoglobin A, the most common type in adults, is composed of two α- and two β-polypeptide chains (α\(_2\)β\(_2\)). A normal variant, fetal hemoglobin (hemoglobin F), is a complex of two α- and two γ-polypeptide chains (α\(_2\)γ\(_2\)) that binds oxygen with a much greater affinity than adult hemoglobin.

**Heme** is a large, flat, iron-protoporphyrin disk that is synthesized in the mitochondria and can carry one molecule of oxygen (O\(_2\)).\(^\text{11}\) Thus, an individual hemoglobin molecule with its four hemes can carry four oxygen molecules. If all four oxygen-binding sites are occupied by oxygen, the molecule is said to be saturated. Through a series of biochemical reactions, **protoporphyrin**, a complex four-ringed molecule, is produced and bound with ferrous iron. It is crucial that the iron be correctly charged; reduced ferrous iron (Fe\(^{2+}\)) can bind oxygen, whereas ferric iron (Fe\(^{3+}\)) cannot. Binding of oxygen to ferrous iron temporarily oxidizes Fe\(^{2+}\) to Fe\(^{3+}\) (**oxyhemoglobin**), but after the release of oxygen the body reduces the iron to Fe\(^{2+}\) and reactivates the hemoglobin (**deoxyhemoglobin** [reduced hemoglobin]). Without reactivation, the Fe\(^{3+}\)-containing hemoglobin
(methemoglobin) cannot bind oxygen. An excess of ferric iron occurs with certain drugs and chemicals, such as nitrates and sulfonamides.

Several other molecules can competitively bind to deoxyhemoglobin. Carbon monoxide (CO) directly competes with oxygen for binding to ferrous ion with an affinity that is about 200-fold greater than that of oxygen. Thus, even a small amount of CO can dramatically decrease the ability of hemoglobin to bind and transport oxygen. Hemoglobin also binds carbon dioxide (CO$_2$), but at a binding site separate from where oxygen binds. In the lungs, CO$_2$ is released, allowing hemoglobin to bind oxygen.

Erythrocytes may play a role in the maintenance of vascular relaxation. Nitric oxide (NO) produced by blood vessels is a major mediator of relaxation and dilation of the vessel walls. In the lungs, hemoglobin can concurrently bind oxygen to the ferrous ion and NO to cysteine residues in the globins (Figure 20-13). As hemoglobin transfers its oxygen to tissue, it may also shed small amounts of nitric oxide, contributing to dilation of the blood vessels and helping transfer of the oxygen into tissues.
Nutritional Requirements for Erythropoiesis

Normal development of erythrocytes and synthesis of hemoglobin depend on an optimal biochemical state and adequate supplies of the necessary building blocks, including protein, vitamins, and minerals (Table 20-4). If these components are lacking for a prolonged time, erythrocyte production slows and anemia (insufficient numbers of functional erythrocytes) may result (see Chapter 21).

*Although pantothenic acid is important for optimal synthesis of heme, experimentally induced deficiency failed to produce anemia or other hematopoietic disturbances.

DNA, Deoxyribonucleic acid; RNA, ribonucleic acid.

Erythropoiesis cannot proceed in the absence of vitamins, especially $B_{12}$, folate (folic acid), $B_6$, riboflavin, pantothenic acid, niacin, ascorbic acid, and vitamin E. Dietary vitamin $B_{12}$ is a large molecule that requires a protein secreted by parietal cells into the stomach (intrinsic factor [IF]) for transport across the ileum. Vitamin $B_{12}$ is stored in the liver and used as needed in erythropoiesis. Decreased $B_{12}$ absorption may lead to pernicious anemia. Folate is necessary for DNA and RNA synthesis. Folate absorption occurs principally in the upper small intestine and is stored in the liver. Folate deficiency occurs more rapidly. Folate supplements are prescribed for pregnant women because pregnancy increases the demand for folate. Supplements can protect against neural tube defects and may prevent anemia.

**Normal Destruction of Senescent Erythrocytes**

Mature erythrocytes have cytoplasmic enzymes capable of glycolysis (anaerobic glucose metabolism) and production of small quantities of adenosine triphosphate (ATP). ATP provides the energy needed to maintain cell function and keep its
plasma membrane pliable\textsuperscript{12} (see Figure 1-1). Metabolic processes diminish as the erythrocyte ages, so less ATP is available to maintain plasma membrane function. The aged or senescent red cell becomes increasingly fragile and loses its reversible deformability, becoming susceptible to rupture while passing through narrowed regions of the microcirculation.

Additionally, the plasma membrane of senescent red cells undergoes phospholipid rearrangement with enrichment of surface phosphatidylserine that is recognized by receptors on macrophages (primarily in the spleen), which selectively remove and sequester the red cells. If the spleen is dysfunctional or absent, macrophages in the liver (Kupffer cells) assume control. During digestion of hemoglobin in the macrophage, porphyrin reduces to bilirubin, which is transported to the liver, conjugated, and finally excreted in the bile as glucuronide (Figure 20-14). Bacteria in the intestinal lumen transform conjugated bilirubin into urobilinogen. Although a small portion is reabsorbed, most urobilinogen is excreted in feces. Conditions causing accelerated erythrocyte destruction increase the load of bilirubin for hepatic clearance, leading to increased serum levels of unconjugated bilirubin and increased urinary excretion of urobilinogen. Gallstones (cholelithiasis) can result from a chronically elevated rate of bilirubin excretion.

\textbf{FIGURE 20-14} Metabolism of Bilirubin Released by Heme Breakdown. MPS, Mononuclear phagocyte system.
Iron cycle.

Approximately 67% of total body iron is bound to heme in erythrocytes (hemoglobin) and muscle cells (myoglobin), and approximately 30% is stored in mononuclear phagocytes (i.e., macrophages) and hepatic parenchymal cells as either ferritin or hemosiderin. The remaining 3% (less than 1 mg) is lost daily in urine, sweat, bile, sloughing of epithelial cells from the skin and intestinal mucosa, and minor bleeding. Approximately 25 mg of iron is required daily for erythropoiesis; only 1 to 2 mg of iron is dietary and the remainder is obtained from continual recycling of iron from erythrocytes.

The methemoglobin released from the breakdown of senescent or damaged erythrocytes is dissociated by the enzyme heme oxygenase, and the iron is released into the bloodstream where it is free to bind again to transferrin or be stored in the macrophage's cytoplasm as ferritin or hemosiderin (Figure 20-15). A minute amount of iron is stored in muscle cells by the heme-containing protein myoglobin. Unavailable stores of iron are present in cytochromes, catalases, and peroxidase enzymes.

**FIGURE 20-15  Iron Cycle.** Iron released from gastrointestinal epithelial cells circulates in the bloodstream associated with its plasma carrier, transferrin. It is delivered to erythroblasts in bone marrow, where most of it is incorporated into hemoglobin. Mature erythrocytes circulate for approximately 120 days, after which they become senescent and are removed by the mononuclear phagocyte system (MPS). Macrophages of MPS (mostly in spleen) break down ingested erythrocytes and return iron to the bloodstream directly or after storing it as ferritin or hemosiderin.
The protein ferritin is the major intracellular iron storage protein. Apoferritin, which is ferritin without attached iron, can store thousands of atoms of iron. Several apoferritin complexes combine to form the micelle ferritin. Large aggregates of micelles (if a large amount of iron is present) produce large iron storage complexes, known as hemosiderin. Under a light microscope, hemosiderin is visible as an iron-based pigment in cell inclusions. The iron within deposits of hemosiderin is poorly available to supply iron when needed. The most common cause of hemosiderin deposition is simple bruising. Hemosiderin in small amounts within iron-rich tissues (i.e., spleen, liver, bone marrow) is considered normal. Large aggregates or its presence in tissue, such as the lungs or subcutaneous tissue, suggest a pathologic condition.

Iron from either dietary sources, release of iron stores, or erythrocyte catabolism is transported in the blood bound to apotransferrin, thus becoming transferrin. Apotransferrin is a glycoprotein synthesized primarily by hepatocytes in the liver but also produced in small quantities by tissue macrophages, submaxillary and mammary glands, and ovaries or testes (see Figure 20-15). Transferrin is transported to the bone marrow, where it binds to transferrin receptors on erythroblasts. Transferrin receptors are on the plasma membrane of all nucleated cells, but at particularly high levels on erythroid precursors and rapidly proliferating cells (e.g., lymphocytes), and are thought to be the only route of cellular entry for transferrin-attached iron. Transferrin is recycled (transferrin cycle) by intracellular dissociation of the iron and secretion of the resultant apotransferrin to the bloodstream.

The iron is transported to the erythroblast's mitochondria (the site of hemoglobin production), where the enzyme heme synthetase inserts ferrous iron into protoporphyrin to form heme. Heme then is bound to globin to form hemoglobin. Iron not used in erythropoiesis is stored temporarily as ferritin or hemosiderin and later excreted.

The body's iron homeostasis is primarily controlled by the hormone hepcidin. Hepcidin is a 25 amino acid peptide synthesized in the liver and released into the plasma, where it is bound with high affinity to $\alpha_2$-macroglobulin and with relatively lower affinity to albumin. Hepatocellular hepcidin production is regulated physiologically by the levels of iron in the body, rate of erythropoiesis, and percentage of oxygen saturation. Hepatocytes (liver cells) sense levels of circulating iron by means of receptors for transferrin. Excess iron is stored in hepatocytes and macrophages, and hepatocytes sense these levels by means of receptors for bone morphogenetic protein (BMP), most likely BMP-6, which is a growth factor produced to a large extent by bone marrow sinusoid endothelial cells. Hepcidin production also can be induced by inflammation via IL-6.
Hepcidin regulates iron levels through its binding capacity to ferroportin, which is a transmembrane iron exporter found in the plasma membrane of cells that transport or store iron, including macrophages, hepatocytes, and enterocytes (intestinal cells). The body's total iron balance is maintained through controlled absorption rather than excretion. Dietary iron (primarily as Fe\(^{2+}\)) is transported directly across the membranes of enterocytes in the duodenum and proximal jejunum. (Transport mechanisms are described in Chapter 1.) Hepcidin induces internalization and degradation of ferroportin, thus leading to increased intracellular iron stores, decreased dietary iron absorption, and decreased levels of circulating iron. Decreased production of hepcidin leads to release of stored iron and increased dietary absorption. Thus, if the body's iron stores are low or the demand for erythropoiesis increases, dietary iron is transported rapidly through the epithelial cell and into the plasma. If body stores are high and erythropoiesis is not increased, iron transport is stopped, although iron can cross the epithelial cells' plasma membrane passively and is stored as ferritin.

**Quick Check 20-4**

1. Why is the reticulocyte count important?
2. Why is iron important to erythropoiesis?
3. What happens to aging erythrocytes?

**Development of Leukocytes**

Leukocytes consist of lymphocytes, granulocytes, and monocytes. Most leukocytes arise from hematopoietic stem cells in the bone marrow that differentiate into common lymphoid progenitors and common myeloid progenitors (their pathways of differentiation are shown in Figure 20-2). Lymphoid progenitor cells develop into lymphocytes, which are released into the bloodstream to undergo further maturation in the primary and secondary lymphoid organs (see Chapter 7). Common myeloid progenitors further differentiate into progenitors for erythrocytes, megakaryocytes, and mast cells, and into granulocyte/monocyte progenitors. The granulocyte/monocyte progenitors further differentiate into monocyte progenitors and granulocyte progenitors, which develop into monocytes/macrophages and granulocytes (neutrophils, basophils, eosinophils), respectively. Development from hematopoietic stem cell to common granulocyte/monocyte progenitor primarily is under the control of stem cell factor,
IL-3, and GM-CSF, whereas further differentiation into granulocytic and monocytic progenitors is controlled by G-CSF and M-CSF, respectively. The ultimate granulocytic phenotype is determined in the bone marrow by relative local concentrations of early and late-acting cytokines, including GM-CSF, G-CSF, IL-3, IL-5, stem cell factor, and others. Granulocytes are released into the blood within 14 days of development. The bone marrow selectively retains immature granulocytes as a reserve pool that can be rapidly mobilized in response to the body's needs.

Monocytic progenitors differentiate into monocytes within 24 hours and are released into the circulation. Monocytes mature into various forms of macrophages, a process that is usually complete within 1 or 2 days after release.

Most leukocytes exist in the body from days to years, depending on type. Maintenance of optimal levels of granulocytes and monocytes in the blood depends on the availability of pluripotent stem cells in the marrow, induction of these into committed stem cells, timely release of new cells from the marrow, and mobilization of the granulocyte reserve pool. Leukocyte production increases in response to infection, to the presence of steroids, and to reduction or depletion of reserves in the marrow. It also is associated with strenuous exercise, convulsive seizures, heat, intense radiation, paroxysmal tachycardias (outbursts of rapid heart rate), pain, nausea and vomiting, and anxiety.

### Development of Platelets

Platelets (thrombocytes) are derived from stem cells and progenitor cells that differentiate into megakaryocytes. During thrombopoiesis, the megakaryocyte progenitor is programmed to undergo an endomitotic cell cycle (endomitosis) during which DNA replication occurs, but anaphase and cytokinesis are blocked16 (see Figures 20-2 and 20-6, and Chapter 1). Thus, the megakaryocyte nucleus enlarges and becomes extremely polyploid (up to 100-fold or more of the normal amount of DNA) without cellular division. Concurrently, the numbers of cytoplasmic organelles (e.g., internal membranes, granules) increase, and the cell develops cellular surface elongations and branches that progressively fragment into platelets. A single large (up to 100 µm) megakaryocyte may produce thousands of smaller platelets (2 to 3 µm). Like erythrocytes, platelets released from the bone marrow lack nuclei.

About two thirds of platelets enter the circulation, and the remainder resides in the splenic pool. Platelets circulate in the bloodstream for about 10 days before beginning to lose their ability to carry out biochemical reactions. Senescent platelets are sequestered and destroyed in the spleen by mononuclear cell phagocytosis. **Thrombopoietin (TPO)**, a hormone growth factor, is the main regulator of the
circulating platelet numbers. TPO is primarily produced by the liver and induces platelet production in the bone marrow.\textsuperscript{17} Platelets express receptors for TPO and, when circulating platelet levels are normal, TPO is adsorbed onto the platelet surface and prevented from accessing the bone marrow and initiating further platelet production.\textsuperscript{18} When platelet levels are low, however, the amount of TPO exceeds the number of available platelet TPO receptors, and free TPO can enter the bone marrow. During inflammation IL-6 induces increased production of TPO, which increases production of newly formed platelets, which are more thrombogenic.
Mechanisms of Hemostasis

Hemostasis means arrest of bleeding. As a result of hemostasis, damaged blood vessels may maintain a relatively steady state of blood volume, pressure, and flow. Three equally important components of hemostasis are platelets, clotting factors, and the vasculature (endothelial cells and subendothelial matrix). The following list is the general sequence of events in hemostasis: (1) vascular injury leads to a transient arteriolar vasoconstriction to limit blood flow to the affected site; (2) damage to the endothelial cell lining of the vessel exposes prothrombogenic subendothelial connective tissue matrix leading to platelet adherence and activation and formation of a hemostatic plug to prevent further bleeding (primary hemostasis); (3) tissue factor, produced by the endothelium, collaborates with secreted platelet factors and activated platelets to activate the clotting (coagulation) system to form fibrin clots and further prevent bleeding (secondary hemostasis); and (4) the fibrin/platelet clot contracts to form a more permanent plug, and regulatory pathways are activated (fibrinolysis) to limit the size of the plug and begin the healing process. The relative importance of the hemostatic mechanisms clearly varies with vessel size. Damage to large vessels cannot easily be controlled by hemostasis but requires vascular contraction and dramatically decreased blood flow into the damaged vessels (Table 20-5).

Function of Platelets and Blood Vessels
Platelets normally circulate freely, suspended in plasma, in an unactivated state. Endothelial cells lining the vessels produce nitric oxide (NO) and the prostaglandin derivative prostacyclin I$_2$ (PGI$_2$), which help maintain blood flow and pressure and platelets in an inactive state. NO and PGI$_2$ are highly synergistic; PGI$_2$ production varies a great deal in response to stimuli, whereas NO is released continually to regulate vascular tone. Endothelium also produces adenosine diphosphatase, which degrades ADP (a potent activator of platelets).

The endothelial cell surface contains antithrombotic molecules, such as glycosaminoglycans (e.g., heparan sulfate), thrombomodulin, and plasminogen activators. These limit platelet activation and fibrin deposition. Although thrombomodulin and plasminogen activators help control hemostasis in normal vessels, their effects are magnified during vascular damage and clot formation; therefore, further information is provided on these molecules in the following text describing control of hemostatic mechanisms.

When a vessel is damaged, platelet activation may be initiated. The role of platelet activation is to (1) contribute to regulation of blood flow into a damaged site through induction of vasoconstriction (vasospasm), (2) initiate platelet-to-platelet interactions resulting in formation of a platelet plug to stop further bleeding, (3) activate the coagulation (or clotting) cascade to stabilize the platelet plug, and (4) initiate repair processes including clot retraction and clot dissolution. The normal platelet count ranges from 150,000 to 400,000/mm$^3$, and a count below 150,000/mm$^3$ is defined as thrombocytopenia. However, the thrombocytopenia is usually asymptomatic unless the count drops below 100,000/mm$^3$, at which time the number of platelets may be inadequate and abnormal bleeding may occur in response to trauma. Spontaneous major bleeding episodes do not generally occur unless the platelet count falls below 20,000/mm$^3$. However, these values are not absolute and their clinical significance will vary among individuals.

Platelet activation proceeds through a process of (1) increased adhesion to the damaged vascular wall; (2) platelet degranulation, which stimulates changes in platelet shape; (3) aggregation as platelet–vascular wall and platelet-platelet adherence increases; and (4) activation of the clotting system and development of an immobilizing meshwork of platelets and fibrin (Figure 20-16, and see Health Alert: Sticky Platelets, Genetic Variations, and Cardiovascular Complications).

**Health Alert**

**Sticky Platelets, Genetic Variations, and Cardiovascular Complications**
Investigators report that a genetic trait induces some people to make sticky platelets. People with platelets that tend to stick together have an increased risk of suffering complications from heart procedures. After individuals received angioplasty, in which a balloon-tipped catheter opens a blocked artery, investigators compared complications in the group with more sticky, or reactive, platelets with those with less reactive platelets. Of 112 participants, 3 months after the procedure, 15 individuals with sticky platelets experienced chest pain or a heart attack; 4 individuals with less reactive platelets experienced such complications. In addition, 10 people with sticky platelets needed another angioplasty, compared with only 2 from the less reactive platelet group.

In another study, investigators analyzed the receptor glycoprotein GP11b/111a for weaknesses that might direct attempts to prevent clotting, heart attack, and stroke. Blood samples from 1340 people revealed that 72% had inherited from both parents a gene for a version of GP11b/111a called \( P1^{A1} \), whereas 28% had inherited 1 or 2 copies of a gene encoding a version called \( P1^{A2} \). The blood from the group with two copies of \( P1^{A1} \) clotted less readily than did the blood of the other group. The degree of clotting also depended on fibrinogen levels in the blood. In individuals with unusually high fibrinogen levels, the presence of \( P1^{A1} \) glycoprotein seemed to increase clotting more than the presence of \( P1^{A2} \). Thus, testing for platelet stickiness and GP11b/111a status could determine which people need anticlotting drugs and also the duration of treatment.

This process can begin in several ways. If the vessel lining remains intact in an area of inflammation, the endothelial cells may become activated by cytokines and
express new proteins on their surface. Several of these, particularly P-selectin, bind specifically yet weakly with receptors on the surface of inactive platelets (e.g., GPIb) (Figure 20-17). As inflammation progresses, the platelets adhere more avidly through additional receptors that bind through a fibrinogen bridge with the endothelial cell surface. The principal fibrinogen receptor on platelets is the integrin αIIbβ3 (also known as GPIIb/IIIa).
During vessel damage, the endothelial layer is frequently compromised, resulting in exposure of the underlying matrix that contains collagen, fibronectin, and other components. The matrix also contains von Willebrand factor (vWF), and the
exposed collagen can bind additional vWF from the circulation (see Figure 20-17). Platelets adhere strongly to collagen through the receptor GPα/IIα (as well as other receptors not shown); GPVI and integrin α₂β₁) and to vWF through the receptor complex of platelet receptor GPIb and clotting factors IX and V. Progressively the platelets undergo further aggregation through platelet-to-platelet adhesion involving further fibrinogen bridging between receptors (particularly GPIIb/IIIa) on adjacent platelets.

As a result of interactions with the endothelium or the subendothelial matrix, as well as exposure to inflammatory mediators produced by the endothelium and other cells, the platelets are activated. Activation causes reorganization of the platelet cytoskeleton, leading to dynamic changes in platelet shape from smooth spheres to those with spiny projections and degranulation (also called the platelet-release reaction) and resulting in the release of various potent biochemicals.

Platelets contain three types of granules—lysosomes, dense bodies, and alpha granules. The contents of the dense bodies and alpha granules are particularly important in hemostasis. Dense bodies are generally proinflammatory (e.g., adenosine diphosphate [ADP], calcium, and serotonin). ADP recruits and activates other platelets through specific receptors. ADP also induces the platelet plasma membrane to undergo several important changes, including becoming ruffled and sticky; undergoing cellular spreading to make tight contacts between neighboring platelets, causing the platelet plug to seal the injured endothelium; and undergoing externalization of the phospholipid phosphatidylserine, which provides a matrix for activation of clotting factors. Serotonin is a vasoactive amine with histamine-like properties to increase vasodilation and vascular permeability (see Chapter 6). Calcium is necessary for many of the intracellular signaling mechanisms that control platelet activation.

Alpha granules contain a mixture of clotting factors (fibrinogen, factor V), growth and angiogenic factors (e.g., platelet-derived growth factor [PDGF], vascular endothelial growth factor [VEGF], basic fibroblast growth factor), and angiogenesis inhibitors (e.g., platelet factor 4, thrombospondin, inhibitors of metalloproteinases). Platelet factor 4 also is a heparin-binding protein. Depending upon the particular stimulus platelets may selectively release promoters or inhibitors of angiogenesis. Many of these mediators also either promote or inhibit platelet activity and the eventual process of clot formation (see Figure 20-17). PDGF stimulates smooth muscle cells and promotes tissue repair. Heparin-binding proteins enhance clot formation at the site of injury.

Platelets also begin producing the prostaglandin derivative thromboxane A₂ (TXA₂), which counters the effects of prostacyclin I₂ (PGI₂), produced by
endothelial cells (see Figure 20-17). TXA₂ causes vasoconstriction and promotes the
degranulation of platelets, whereas PGI₂ promotes vasodilation and inhibits platelet
degranulation. In platelets, an isoform of cyclooxygenase (COX-1) converts
arachidonic acid to TXA₂. Aspirin, particularly at low doses, specifically and
irreversibly inhibits COX-1, decreasing production of TXA₂ and decreasing platelet
activation. Daily intake of low doses of aspirin leads to more than 95% inhibition of
TXA₂ in just a few days.

If blood vessel injury is minor, hemostasis is achieved temporarily by formation
of the platelet plug, which usually forms within 3 to 5 minutes of injury. Platelet
plugs seal the many minute ruptures that occur daily in the microcirculation,
particularly in capillaries. With too few platelets, numerous small hemorrhagic
areas called purpuras develop under the skin and throughout the tissues (see Chapter
21).

**Function of Clotting Factors**

A blood clot is a meshwork of protein strands that stabilizes the platelet plug and
traps other cells, such as erythrocytes, phagocytes, and microorganisms (Figure 20-
18). The strands are made of fibrin, which is produced by the clotting
(coagulation) system. The clotting system was described in Chapter 6 and consists
of a family of proteins that circulate in the blood in inactive forms. Initiation of the
system results in sequential activation (cascade) of multiple members of the system
until a fibrin clot is created.
The clotting system is usually presented as two pathways of initiation (intrinsic and extrinsic pathways) that join in a common pathway. The intrinsic pathway is activated when Hageman factor (factor XII) in plasma contacts negatively charged subendothelial substances exposed by vascular injury. The extrinsic pathway is activated when tissue thromboplastin, a substance released by damaged endothelial cells, reacts with clotting factors, particularly factor VII. Both pathways lead to the common pathway and activation of factor X, which proceeds to clot formation.

The extrinsic pathway is clearly predominant; individuals with deficiencies in intrinsic pathway components (i.e., factor XI, factor XII), surprisingly, do not have prolonged bleeding because these factors do not seem to be important for clotting. As with the complement cascade, the clotting system is complex with a large number of alternative activators and inhibitors, and the relative importance of particular factors may differ between in vivo hemostasis and in vitro testing of clotting or may depend on the particular mechanism by which the pathway is activated. There also is interaction between components of the intrinsic and extrinsic pathways so that an activated member of one pathway may activate a member of the other pathway (e.g., factor VIIa of the extrinsic pathway can directly activate factor IX of the intrinsic pathway).

Activated platelets are important participants in clotting. The phosphatidylserine-rich surface produced during platelet activation provides a matrix on which several important complexes of clotting factors are formed. These include the intrinsic pathway's tenase complex (factor X and activated factors VIII and IX) that activates factor X and the prothrombinase complex (prothrombin and activated factors X and...
V) that activates prothrombin into thrombin. Thrombin then converts fibrinogen into fibrin, which polymerizes into a fibrin clot. Thrombin has broad activity in the inflammatory response. In addition to producing fibrin, thrombin is an activator of other coagulation proteins (e.g., factors V, VIII, XI, XIII), platelets (e.g., aggregation, degranulation), endothelial cells (e.g., up-regulation of adhesion molecules for leukocytes, increased NO, PGI$_2$, PDGF), and monocytes (e.g., cytokine secretion, increased receptors for endothelial cells).

Under normal conditions, spontaneous activation of hemostasis is prevented by factors residing on the endothelial cell surface. These include thrombin inhibitors (e.g., antithrombin III), tissue factor inhibitors (e.g., tissue factor pathway inhibitor), and mechanisms for degrading activated clotting factors (e.g., protein C). **Antithrombin III (AT-III)** is a circulating inhibitor of plasma serine proteases. AT-III is produced by the liver and binds to heparin sulfate found naturally on the surface of endothelial cells, or with heparin administered clinically to prevent thrombosis. Heparin induces a change in AT-III that greatly enhances its capacity to inhibit thrombin and other activated clotting factors. **Tissue factor pathway inhibitor (TFPI)** is produced by endothelial cells and platelets; complexes to, and reversibly inhibits, factor Xa in the prothrombinase complex; and also inhibits other activated clotting factors.

**Thrombomodulin** is a thrombin-binding protein on the surface of endothelial cells. **Protein C** in the circulation binds to thrombomodulin in a thrombin-dependent manner and is converted to activated protein C.$^{19}$ Activated protein C, in association with a cofactor (protein S), degrades factors Va and VIIIa. Deficiencies of AT-III, protein C, or protein S are important causes of hypercoagulation (increased clotting). Expression of thrombomodulin and the endothelial cell protein C receptor is down-regulated by cytokines and other products of inflammation (e.g., IL-1α, tumor necrosis factor-alpha [TNF-α], endotoxin), thereby enhancing clot formation.

**Retraction and Lysis of Blood Clots**

After a clot is formed, it retracts, or “solidifies.” Fibrin strands shorten, becoming denser and stronger, which approximates the edges of the injured vessel wall and seals the site of injury. Retraction is facilitated by the large numbers of platelets trapped within the fibrin meshwork. The platelets contract and “pull” the fibrin threads closer together while releasing a factor that stabilizes the fibrin. Contraction expels serum from the fibrin meshwork (see Figure 20-18). This process usually begins within a few minutes after a clot has formed, and most of the serum is expelled within 20 to 60 minutes.
Lysis (breakdown) of blood clots is carried out by the **fibrinolytic system** (Figure 20-19). Another plasma protein, plasminogen, is converted to **plasmin** by several products of coagulation and inflammation, especially by the enzymatic action of **tissue plasminogen activator (t-PA)**. Endothelial cells express t-PA, which is activated maximally after binding to fibrin. Another activator of plasminogen is **urokinase-like plasminogen activator (u-PA)**. The u-PA binds to a specific cellular u-PA receptor (u-PAR), causing activation of plasminogen. This urokinase is the major activator of fibrinolysis in the extravascular or tissue compartment, whereas t-PA is largely involved in intravascular fibrinolysis. Several cancers appear to use membrane-bound u-PA to digest intercellular matrix and greatly facilitate tumor invasion and metastasis. Both t-PA and u-PA have been used clinically to treat diseases associated with a blood clot (e.g., pulmonary embolism, myocardial infarction, stroke).²⁰

![Figure 20-19](image)

**FIGURE 20-19**  The Fibrinolytic System. Fibrinolysis is initiated by the binding of plasminogen to fibrin. Although tissue plasminogen activator (t-PA) initiates intravascular fibrinolysis, urokinase plasminogen activator (u-PA) is the major activator of fibrinolysis in tissue (extravascular). Plasmin digests the fibrin into smaller soluble pieces (fibrin degradation products). *u-PAR*, urokinase-like plasminogen activator receptor.

Plasmin is an enzyme that dissolves clots (**fibrinolysis**) by degrading fibrin and fibrinogen into **fibrin degradation products (FDPs)**. A major FDP is D-dimer. D-dimer is two D domains from adjacent fibrin monomers that are cross-linked by factor XIIIa and released as a result of enzymatic cleavage by plasmin. Measurement of levels of circulating D-dimer has been used for diagnosis of deep venous
thrombosis (DVT) or pulmonary embolism (PE). Blood tests for evaluating the hematologic system are listed in Table 20-6.

**Quick Check 20-5**

1. What specific cells are involved in development of leukocytes?
2. Why are platelets necessary to stop bleeding?
3. Briefly describe the steps of platelet adhesion and aggregation.
4. How does plasminogen initiate fibrinolysis?

Pediatrics & Hematologic Value Changes

Blood cell counts tend to rise above adult levels at birth and then decline gradually throughout childhood. Table 20-7 lists normal ranges during infancy and childhood. The immediate rise in values is the result of accelerated hematopoiesis during fetal life and the increased numbers of cells that result from the trauma of birth and cutting of the umbilical cord.

Average blood volume in the full-term neonate is 85 ml/kg of body weight. The premature infant has a slightly larger blood volume of 90 ml/kg of body weight. In both full-term and premature infants, blood volume decreases during the first few months. Thereafter the average blood volume is 75 to 77 ml/kg, which is similar to that of older children and adults.

The hypoxic intrauterine environment stimulates erythropoietin production in the fetus and accelerates fetal erythropoiesis, producing polycythemia (excessive proliferation of erythrocyte precursors) in the newborn. After birth, the oxygen from the lungs saturates arterial blood, and more oxygen is delivered to the tissues. In response to the change from a placental to a pulmonary oxygen supply during the first few days of life, levels of erythropoietin and the rate of blood cell formation decrease. The active rate of fetal erythropoiesis is reflected by the large numbers of immature erythrocytes (reticulocytes) in the peripheral blood of full-term neonates. After birth, the number of reticulocytes decreases by 50% every 12 hours, so it is rare to find an elevated reticulocyte count after the first week of life. During this period of rapid growth, the rate of erythrocyte destruction is greater than that in later childhood and adulthood. In full-term infants, the normal erythrocyte life span is 60 to 80 days; in premature infants, it may be as short as 20 to 30 days; and in children and adolescents, it is the same as that in adults—120 days.

The postnatal fall in hemoglobin and hematocrit values is more marked in
premature infants than it is in full-term infants. In preschool and school-aged children, hemoglobin, hematocrit, and red blood cell counts gradually rise. Metabolic processes within the erythrocytes of neonates differ significantly from those found in erythrocytes of normal adults. The relatively young population of erythrocytes in newborns consumes greater quantities of glucose than do erythrocytes in adults.

The lymphocytes of children tend to have more cytoplasm and less compact nuclear chromatin than do the lymphocytes of adults. A possible explanation is that children tend to have more frequent viral infections, which are associated with atypical lymphocytes. Minor infections, in which the child fails to exhibit clinical manifestations of illness, and the administration of immunizations also may account for the lymphocyte changes.

At birth the lymphocyte count is high, and it continues to rise during the first year of life. Then it steadily declines until the lower value seen in adults is reached. It is unknown whether these developmental variations are physiologic or a response to frequent viral infection and immunizations in children.

The neutrophil count, like the lymphocyte count, is high at birth and rises during the first days of life. After 2 weeks, the neutrophil count falls to within or below the normal adult range. Although the exact age can vary by approximately 7 years of age, the neutrophil count is the same as that of an adult.

The eosinophil count is higher in the first year of life and higher in children than in teenagers or adults. Monocyte counts also are high in the first year of life but then decrease to adult levels. Platelet counts in full-term neonates are comparable with those in adults and remain so throughout infancy and childhood.
Aging & Hematologic Value Changes

Blood composition changes little with age, although some components may be altered by iron deficiency. Total serum iron level, total iron-binding capacity, and intestinal iron absorption are all decreased somewhat in elderly persons. The erythrocyte life span is normal, although the erythrocytes are replenished more slowly after bleeding. Hemoglobin levels may be low, and the plasma membranes of erythrocytes become increasingly fragile, with portions being lost, presumably because of physical trauma inflicted during circulation.

Lymphocyte function decreases with age (see Chapters 7 and 8), causing changes in cellular immunity and some decline in T-cell function. The humoral immune system is less able to respond to antigenic challenge.

No changes in platelet numbers or structure have been observed in elderly persons, yet platelet adhesiveness probably increases. Although fibrinogen levels and levels of factors V, VII, and IX tend to be increased, no major hypercoagulability has been confirmed.
Did You Understand?

Components of the Hematologic System

1. Blood consists of a variety of components—about 92% water and 8% solutes. In adults, the total blood volume is approximately 5.5 L.

2. Plasma, a complex aqueous liquid, contains two major groups of plasma proteins: albumins and globulins.

3. The cellular elements of blood are the red blood cells (erythrocytes), white blood cells (leukocytes), and platelets.

4. Erythrocytes are the most abundant cells of the blood, occupying approximately 48% of the blood volume in men and approximately 42% in women. Erythrocytes are responsible for tissue oxygenation.

5. Leukocytes are fewer in number than erythrocytes and constitute approximately 5000 to 10,000 cells/mm$^3$ of blood. Leukocytes defend the body against infection and remove dead or injured host cells.

6. Leukocytes are classified as either granulocytes (neutrophils, basophils, eosinophils) or agranulocytes (monocytes/macrophages, lymphocytes).

7. Platelets are anuclear disk-shaped cytoplasmic fragments. Platelets are essential for blood coagulation and control of bleeding.

8. The lymphoid organs are sites of residence, proliferation, differentiation, or function of lymphocytes and mononuclear phagocytes.

9. The spleen is the largest lymphoid organ and functions as the site of fetal hematopoiesis, filters and cleanses the blood, and acts as a reservoir for lymphocytes and other blood cells.

10. The lymph nodes are the site of development or activity of large numbers of lymphocytes, monocytes, and macrophages.

11. The mononuclear phagocyte system (MPS) is composed of monocytes in bone marrow and peripheral blood and macrophages in tissue.
12. The MPS is the main line of defense against bacteria in the bloodstream and cleanses the blood by removing old, injured, or dead blood cells; antigen-antibody complexes; and macromolecules.

**Development of Blood Cells**

1. Hematopoiesis, or blood cell production, occurs in the liver and spleen of the fetus and in the bone marrow after birth.

2. Hematopoiesis involves two stages: proliferation and differentiation, or maturation. Each type of blood cell has parent cells called stem cells.

3. Hematopoiesis continues throughout life to replace blood cells that grow old and die, are killed by disease, or are lost through bleeding.

4. Bone marrow consists of red (hematopoietic) marrow (blood vessels, mononuclear phagocytes, stem cells, blood cells in various stages of differentiation, stromal cells) and yellow marrow (fatty tissue).

5. The bone marrow contains multiple populations of stem cells; mesenchymal stem cells develop into fibroblasts, osteoclasts, and adipocytes; and hematopoietic stem cells develop into blood cells.

6. Regulation of hematopoiesis occurs in bone marrow niches in which hematopoietic stem cells differentiate and are controlled by multiple cytokines and chemokines and through direct contact with osteoblasts (osteoblastic niche) or vascular endothelial cells (vascular niche), as well as several other specialized cells, including CAR cells and nestin-expressing cells.

7. Specific hematopoietic growth factors (e.g., colony-stimulating factors) are necessary for the adequate production of myeloid, erythroid, lymphoid, and megakaryocytic lineages.

8. Hemoglobin, the oxygen-carrying protein of the erythrocyte, enables the blood to transport 100 times more oxygen than could be transported dissolved in plasma alone.

9. Erythropoiesis depends on the presence of vitamins (especially vitamin B$_{12}$, folate vitamin, vitamin B$_{6}$, riboflavin, pantothenic acid, niacin, ascorbic acid, and vitamin
10. Regulation of erythropoiesis is mediated by erythropoietin, which is secreted by the kidneys in response to tissue hypoxia and causes a compensatory increase in erythrocyte production if the oxygen content of the blood decreases because of anemia, high altitude, or pulmonary disease.

11. The iron cycle reutilizes iron released from old or damaged erythrocytes. Iron binds to transferrin in the blood, is transported to macrophages of the MPS, and is stored in the cytoplasm as ferritin.

12. Iron homeostasis is controlled by hepcidin, a small hormone produced by hepatocytes, which regulates ferroportin, the principal transporter of iron from stores in hepatocytes and macrophages and from intestinal cells that absorb dietary iron.

13. Maintenance of optimal levels of granulocytes and monocytes in the blood depends on the availability of pluripotential stem cells in the marrow, induction of these into committed stem cells, and timely release of new cells from the marrow.

14. Granulocytes and monocytes in the blood develop from common myeloid progenitor cells in the bone marrow under the direction of several growth factors, including stem cell factor, IL-3, and GM-CSF.

15. Specific humoral colony-stimulating factors (CSFs) are necessary for the adequate growth of myeloid, erythroid, lymphoid, and megakaryocytic lineages.

16. Platelets develop from megakaryocytes by a process called endomitosis, which is controlled by thrombopoietin. During endomitosis the megakaryocytes undergo mitosis but not cell division and the cytoplasm and plasma membrane fragment into platelets.

**Mechanisms of Hemostasis**

1. Hemostasis, or arrest of bleeding, involves (1) vasoconstriction (vasospasm), (2) formation of a platelet plug, (3) activation of the clotting cascade, (4) formation of a blood clot, and (5) clot retraction and clot dissolution.

2. The normal vascular endothelium prevents spontaneous clotting by producing factors such as nitric oxide (NO) and prostacyclin $I_2$ ($PGL_2$) that relax the vessels and
prevent platelet activation.

3. Lysis of blood clots is the function of the fibrinolytic system. Plasmin, a proteolytic enzyme, splits fibrin and fibrinogen into fibrin degradation products that dissolve the clot.

**Pediatrics & Hematologic Value Changes**

1. Blood cell counts tend to rise above adult levels at birth and then decline gradually throughout childhood.

2. The lymphocytes of children tend to have more cytoplasm and less compact nuclear chromatin than do the lymphocytes of adults.

**Aging & Hematologic Value Changes**

1. Blood composition changes little with age. Erythrocyte replenishment may be delayed after bleeding, presumably because of iron deficiency.

2. Lymphocyte function appears to decrease with age. Particularly affected is a decrease in cellular immunity.

3. Platelet adhesiveness probably increases with age.

  Disorders of Coagulation, 544
Alterations of erythrocyte function involve either insufficient or excessive numbers of erythrocytes in the circulation or normal numbers of cells with abnormal components. Anemias are conditions in which there are too few erythrocytes or an insufficient volume of erythrocytes in the blood. Polycythemias are conditions in which erythrocyte numbers or volume is excessive. All of these conditions have many causes and are pathophysiologic manifestations of a variety of disease states.

Many disorders involving leukocytes range from increased numbers of leukocytes (i.e., leukocytosis) in response to infections to proliferative disorders (such as leukemia). Many hematologic disorders are malignancies, and many nonhematologic malignancies metastasize to bone marrow, affecting leukocyte production. Thus a large portion of this chapter is devoted to malignant disease.

The primary role of clotting (hemostasis) is to stop bleeding through an interaction of endothelium lining the vessels, platelets, and clotting factors. A large number of disease states may be associated with a clinically significant increase or decrease in clotting resulting from alterations in any of the three main components of the clotting process.
Alterations of Erythrocyte Function

Classification of Anemias

Anemia is a reduction in the total number of erythrocytes in the circulating blood or a decrease in the quality or quantity of hemoglobin. Anemias commonly result from (1) impaired erythrocyte production, (2) blood loss (acute or chronic), (3) increased erythrocyte destruction, or (4) a combination of these three factors. Anemias are classified by their causes (e.g., anemia of chronic disease) or by the changes that affect the size, shape, or substance of the erythrocyte. The most common classification of anemias is based on the changes that affect the cell's size and hemoglobin content (Table 21-1). Terms used to identify anemias reflect these characteristics. Terms that end with -cytic refer to cell size, and those that end with -chromic refer to hemoglobin content. Additional terms describing erythrocytes found in some anemias are anisocytosis (assuming various sizes) and poikilocytosis (assuming various shapes).

**Clinical manifestations**

The main alteration of anemia is a reduced oxygen-carrying capacity of the blood resulting in tissue hypoxia. Symptoms of anemia vary, depending on the body's
ability to compensate for the reduced oxygen-carrying capacity. Anemia that is mild and starts gradually is usually easier to compensate and may cause problems for the individual only during physical exertion. As red cell reduction continues, symptoms become more pronounced and alterations in specific organs and compensation effects are more apparent. Compensation generally involves the cardiovascular, respiratory, and hematologic systems (Figure 21-1).

A reduction in the number of blood cells in the blood causes a reduction in the consistency and volume of blood. Initial compensation for cellular loss is movement of interstitial fluid into the blood, causing an increase in plasma volume. This movement maintains an adequate blood volume, but the viscosity (thickness) of the blood decreases. The “thinner” blood flows faster and more turbulently than
normal blood, causing a hyperdynamic circulatory state. This hyperdynamic state creates cardiovascular changes—increased stroke volume and heart rate. These changes may lead to cardiac dilation and heart valve insufficiency if the underlying anemic condition is not corrected.

**Hypoxemia**, reduced oxygen level in the blood, further contributes to cardiovascular dysfunction by causing dilation of arterioles, capillaries, and venules, thus increasing flow through them. Increased peripheral blood flow and venous return further contributes to an increase in heart rate and stroke volume in a continuing effort to meet normal oxygen demand and prevent cardiopulmonary congestion. These compensatory mechanisms may lead to heart failure.

Tissue hypoxia creates additional demands and effects on the pulmonary and hematologic systems. The rate and depth of breathing increase in an effort to increase oxygen availability accompanied by an increase in the release of oxygen from hemoglobin. All of these compensatory mechanisms may cause individuals to experience shortness of breath (dyspnea), a rapid and pounding heartbeat, dizziness, and fatigue. In mild chronic cases, these symptoms may be present only when there is an increased demand for oxygen (e.g., during physical exertion), but in severe cases, symptoms may be experienced even at rest.

Manifestations of anemia may be seen in other parts of the body. The skin, mucous membranes, lips, nail beds, and conjunctivae become either pale because of reduced hemoglobin concentration or yellowish (jaundiced) because of accumulation of end products of red cell destruction (hemolysis) if that is the cause of the anemia. Tissue hypoxia of the skin results in impaired healing and loss of elasticity, as well as thinning and early graying of the hair. Nervous system manifestations may occur where the cause of anemia is a deficiency of vitamin B\textsubscript{12}. Myelin degeneration occurs, causing a loss of nerve fibers in the spinal cord, resulting in paresthesias (numbness), gait disturbances, extreme weakness, spasticity, and reflex abnormalities. Decreased oxygen supply to the gastrointestinal (GI) tract often produces abdominal pain, nausea, vomiting, and anorexia. Low-grade fever (<101° F [38.3° C]) occurs in some anemic individuals and may result from the release of leukocyte pyrogens from ischemic tissues.

When the anemia is severe or acute in onset (e.g., hemorrhage), the initial compensatory mechanism is peripheral blood vessel constriction, diverting blood flow to essential vital organs. Decreased blood flow detected by the kidneys activates the renin-angiotensin response, causing salt and water retention in an attempt to increase blood volume. These situations are considered to be emergencies and require immediate intervention to correct the underlying problem that caused the acute blood loss; therefore, long-term compensatory mechanisms do not develop.
Therapeutic interventions for slowly developing anemic conditions require treatment of the underlying condition and palliation of associated symptoms.\(^1\) Therapies include transfusion, dietary correction, and administration of supplemental vitamins or iron.

**Macrocytic-Normochromic Anemias**

The **macrocytic (megaloblastic) anemias** are characterized by unusually large stem cells (megaloblasts) in the marrow that mature into erythrocytes that are unusually large in size (macrocytic), thickness, and volume.\(^2\) The hemoglobin content is normal, thus allowing them to be classified as normochromic. These anemias are the result of ineffective erythrocyte deoxyribonucleic acid (DNA) synthesis, commonly caused by deficiencies of vitamin B\(_{12}\) (cobalamin) or folate (folic acid). These defective erythrocytes die prematurely, which decreases their numbers in the circulation, causing anemia. Premature death of damaged erythrocytes, **eryptosis**, is a common mechanism of cellular loss in individuals with anemia secondary to deficiencies of iron, infections (e.g., malaria, mycoplasma), chronic diseases (e.g., diabetes, renal disease), genetic diseases (e.g., beta-thalassemia, glucose-6-phosphate dehydrogenase [G6PD] deficiency, sickle cell trait), and myelodysplastic syndrome.\(^3\)

Defective DNA synthesis in megaloblastic anemias causes red cell growth and development to proceed at unequal rates. DNA synthesis and cell division are blocked or delayed. However, ribonucleic acid (RNA) replication and protein (hemoglobin) synthesis proceed normally. Asynchronous development leads to an overproduction of hemoglobin during prolonged cellular division, creating a larger than normal erythrocyte with a disproportionately small nucleus. With each cell division, the disproportion between RNA and DNA becomes more apparent.

**Pernicious Anemia**

**Pernicious anemia (PA)**, the most common type of macrocytic anemia, is caused by vitamin B\(_{12}\) deficiency, which is often associated with the end stage of type A chronic atrophic (autoimmune) gastritis (Figure 21-2, C).\(^4\) **Pernicious** means highly injurious or destructive and reflects the fact that this condition was once fatal. It most commonly affects individuals older than age 30 who are of Northern European descent; however, it has now been recognized in all populations and ethnic groups.
Pathophysiology

The underlying alteration in PA is the absence of *intrinsic factor* (IF), a transporter required for gastric absorption of dietary vitamin $B_{12}$, a vitamin essential for nuclear maturation and DNA synthesis in red blood cells. Deficiency of IF may be congenital or, more often, an autoimmune process directed against gastric parietal cells. Congenital IF deficiency is a genetic disorder with an autosomal recessive inheritance pattern. The autoimmune form of the disease also has a genetic component. Family clusters have been identified; 20% to 30% of individuals related to persons with PA also have PA. These relatives, particularly first-degree female relatives, also demonstrate a higher frequency of the presence of gastric autoantibodies. PA also is frequently a component of autoimmune polyendocrinopathy, which is a cluster of autoimmune diseases of endocrine organs (e.g., chronic autoimmune thyroiditis [Hashimoto thyroiditis], type 1 diabetes mellitus, Addison disease, primary hypoparathyroidism, Graves disease, and myasthenia gravis) that frequently present as comorbidities. Autoimmune thyroiditis and type 1 diabetes mellitus, in particular, are associated with PA.

Most cases of PA result from an autoimmune gastritis (type A chronic gastritis) in which gastric atrophy results from destruction of parietal and zymogenic (relating to an enzyme) cells. Individuals with PA commonly have autoantibodies against the gastric $H^+\cdot K^+$ ATPase, which is the major protein constituent of parietal cell membranes. Gastric mucosal atrophy, in which gastric parietal cells are destroyed, results in a deficiency of all secretions of the stomach—hydrochloric acid, pepsin, and IF. A direct correlation exists between the severity of the gastric lesion and the degree of malabsorption of vitamin $B_{12}$. Additionally, autoantibodies against IF prevent the formation of the $B_{12}$-IF complex. Thus, PA is secondary to autoimmune destruction of parietal cells, diminishing the production of IF and the presence of autoantibodies that neutralize the capacity of remaining IF to transport vitamin $B_{12}$.

Initiation of the autoimmune process may be secondary to a past infection with *Helicobacter pylori*. Although active infection with *H. pylori* is rare in individuals with PA, more than half of these individuals possess circulating antibodies against this microorganism, suggesting a history of infection. The current opinion is that in genetically prone individuals, antigens expressed by *H. pylori* mimic the parietal cell $H^+\cdot K^+$ ATPase, resulting in production of an antibody that binds and damages the parietal cell (see Chapter 8 for a discussion of antigenic mimicry and autoimmune disease).

Environmental factors that may contribute to chronic gastritis include excessive alcohol or hot tea ingestion and smoking. Complete or partial removal of the stomach (gastrectomy) causes IF deficiency. Drugs known as proton pump...
inhibitors (PPIs) are used to decrease gastric acidity and may decrease vitamin B\textsubscript{12} absorption, but it is not thought that they actually cause PA. Although PA is a benign disorder, people with type A chronic gastritis also are at risk for developing gastric adenocarcinoma and gastric carcinoid type I. The incidence rate of carcinoma in these individuals is 2% to 3%.

**Clinical manifestations**

Pernicious anemia develops slowly (over 20 to 30 years), so by the time an individual seeks treatment, it is usually severe. Early symptoms are often ignored because they are nonspecific and vague and include infections, mood swings, and gastrointestinal, cardiac, or kidney ailments. When the hemoglobin level has decreased to 7 to 8 g/dl, the individual experiences classic symptoms of pernicious anemia: weakness, fatigue, paresthesias of feet and fingers, difficulty walking, loss of appetite, abdominal pain, weight loss, and a sore tongue that is smooth and beefy red. The skin may become “lemon yellow” (sallow), caused by a combination of pallor and jaundice. Hepatomegaly, indicating right-sided heart failure, may be present in the elderly along with splenomegaly, which is nonpalpable.

Neurologic manifestations result from nerve demyelination that may produce neuronal death. The posterior and lateral columns of the spinal cord also may be affected, causing a loss of position and vibration sense, ataxia, and spasticity. These complications pose a serious threat because they are not reversible, even with appropriate treatment. The cerebrum also may be involved with manifestations of affective disorders, most commonly of the depressive types. Low levels of vitamin B\textsubscript{12} have been associated with neurocognitive disorders. An increased prevalence of serum vitamin B\textsubscript{12} deficiency has been reported among individuals with Alzheimer disease.

**Evaluation and treatment**

Evaluation is based on blood tests, bone marrow aspiration, serologic studies, gastric biopsy, and clinical manifestations. The Schilling test (no longer offered in most laboratories) indirectly evaluated vitamin B\textsubscript{12} absorption by administering radioactive B\textsubscript{12} and measuring excretion in the urine. Low urinary excretion was significant for PA. The Schilling test has been replaced with serologic studies that measure methylmalonic acid and homocysteine levels, which are elevated early in PA; and this test is more sensitive. The presence of circulating antibodies against parietal cells and intrinsic factor also is useful in diagnosis.\textsuperscript{9} Autoimmune gastritis is a chronic progressive inflammatory disorder resulting in replacement of the parietal cell mass by atropic and metaplastic mucosa.\textsuperscript{7} The interactions are very
complex because of autoantibodies against intrinsic factor that impair the absorption of vitamin $B_{12}$ (cobalamin). The resulting cobalamin deficiency manifests with neurologic and systemic symptoms of PA. The complexity increases with the underappreciated overlap with *Helicobacter pylori* infection. The risk of gastric cancer has not been adequately studied. Gastric biopsy reveals total achlorhydria (absence of hydrochloric acid), which is diagnostic for PA because it occurs only in the presence of this gastric lesion.

Replacement of vitamin $B_{12}$ (cobalamin) is the treatment of choice. Initial injections of vitamin $B_{12}$ are administered weekly until the deficiency is corrected, followed by monthly injections for the remainder of the individual's life. The effectiveness of cobalamin replacement therapy is determined by a rising reticulocyte count. Blood counts return to normal within 5 to 6 weeks. PA cannot be cured so maintenance therapy is lifelong. Conventional wisdom and practice assumed that oral preparations were ineffective because there was no IF to facilitate absorption of vitamin $B_{12}$. However, recent experience has shown that higher doses of orally administered vitamin $B_{12}$ will be absorbed across the small bowel and that this treatment is beneficial.

Untreated PA is fatal, usually because of heart failure. With replacement therapy of vitamin $B_{12}$, mortality has decreased significantly. Death from PA is now rare and relapses are often the result of noncompliance with therapy.

**Folate Deficiency Anemias**

Folate (folic acid) is an essential vitamin required for RNA and DNA synthesis within the maturing erythrocyte. Folates are coenzymes required for the synthesis of thymine and purines (adenine and guanine) and the conversion of homocysteine to methionine. Deficient production of thymine, in particular, affects cells undergoing rapid division (e.g., bone marrow cells undergoing erythropoiesis). Humans are totally dependent on dietary intake to meet the daily requirement of 50 to 200 mg/day. Increased amounts are required for lactating and pregnant females. Folate is absorbed from the upper small intestine and does not require any other element (i.e., IF) to facilitate absorption. After absorption, folate circulates through the liver, where it is stored. Folate deficiency occurs more often than $B_{12}$ deficiency, particularly in alcoholics and individuals with chronic malnourishment. It is estimated that at least 10% of North Americans are folate deficient but the incidence has been decreasing in the United States since the fortification of foods with folate and the increased use of folate supplements.

Clinical manifestations are similar to the malnourished appearance of individuals with PA. Specific manifestations include cheilosis (scales and fissures of the mouth),
stomatitis (inflammation of the mouth), and painful ulcerations of the buccal mucosa and tongue characteristic of burning mouth syndrome. Burning mouth syndrome may be secondary to a large number of disorders (e.g., extremely dry mouth, infection, autoimmune disease, nutritional deficiencies, and other conditions). Dysphagia, flatulence, and watery diarrhea also may be present, as well as histologic changes in the GI tract suggestive of sprue (chronic absorption disorder). Undiagnosed inflammatory bowel disease (e.g., Crohn disease, ulcerative colitis) may be the underlying cause of folate malabsorption in some individuals, and folate deficiency may suppress proliferation of the intestinal mucosa, leading to an increase of gastrointestinal damage. Neurologic manifestations, if present, may be caused by thiamine deficiency, which often accompanies folate deficiency.

Evaluation of folate deficiency is based on blood tests, measurement of serum folate levels, and clinical manifestations. Treatment requires administration of oral folate preparations until adequate blood levels are obtained and manifestations are reduced or eliminated. Long-term therapy is not necessary if the appropriate dietary adjustments are made to maintain adequate intake. After administration of folate, the manifestations of anemia disappear within 1 to 2 weeks.

**Microcytic-Hypochromic Anemias**

The **microcytic-hypochromic anemias** are characterized by abnormally small erythrocytes that contain abnormally reduced amounts of hemoglobin (see Figure 21-2, B). Hypochromia occurs even in cells of normal size.

Microcytic-hypochromic anemia can result from (1) disorders of iron metabolism, (2) disorders of porphyrin and heme synthesis, or (3) disorders of globin synthesis. Specific conditions include iron deficiency anemia, sideroblastic anemia, and thalassemia.

**Iron Deficiency Anemia**

**Iron deficiency anemia (IDA)** is the most common type of anemia throughout the world, occurring in both developing and developed countries. Certain populations are at high risk for developing hypoferremia and IDA and include individuals living in poverty, women of childbearing age, and children. Iron deficiency in children is associated with numerous adverse health-related manifestations, especially cognitive impairment, which may be irreversible (see Chapter 22, Health Alert: A Significant Number of Children Develop and Suffer from Severe Iron Deficiency Anemia, p. 555). Children in developing countries often are affected by chronic parasite infestations that result in blood and iron loss greater than dietary intake. Treatment of helminth infections results in
improvement in appetite, growth, and in the anemia. Iron deficiency anemia also occurs in individuals with lead poisoning and treatment is associated with a decrease in lead levels. An increased prevalence of iron deficiency has been observed in overweight children.

Females in the United States have a higher incidence than males for both hypoferremia and IDA, with the peak incidence occurring in the reproductive years and decreasing at menopause. Males have a higher incidence during childhood and adolescence.

**Pathophysiology**

IDA can arise from one of two different etiologies or a combination of both—inadequate dietary intake or chronic blood loss. In both instances there is no intrinsic dysfunction in iron metabolism; however, both etiologies deplete iron stores and reduce hemoglobin synthesis. A second category is a metabolic or functional iron deficiency in which various metabolic disorders lead to either insufficient iron delivery to bone marrow or impaired iron use (or absorption) within the marrow. Paradoxically, iron stores may be sufficient but delivery is inadequate to maintain heme synthesis, thus producing a functional or relative iron deficiency.

In developed countries, pregnancy and a continuous loss of blood are the most common causes of IDA. A blood loss of 2 to 4 ml/day (1 to 2 mg of iron) is enough to cause IDA. Menorrhagia (excessive menstrual bleeding) causes primary IDA in females. Males may experience bleeding as a result of ulcers, hiatal hernia, esophageal varices, cirrhosis, hemorrhoids, ulcerative colitis, or cancer. Other causes of blood loss for both genders include: (1) use of medications that cause GI bleeding (such as aspirin or nonsteroidal anti-inflammatory drugs [NSAIDs]); (2) surgical procedures that decrease stomach acidity, intestinal transit time, and absorption (e.g., gastric bypass); (3) insufficient dietary intake of iron; and (4) eating disorders such as pica—the craving and eating of nonnutritional substances, such as dirt, chalk, and paper. *H. pylori* infections also have been found to cause IDA of unknown origin, although *H. pylori* impairs iron uptake.

Iron in the form of hemoglobin is in constant demand by the body. An important attribute of iron is that it can be recycled; therefore, the body maintains a balance between iron that is in use as hemoglobin and iron that is stored and available for future hemoglobin synthesis (see Figure 21-2, *B*). Blood loss disrupts this balance by creating a need for more iron, thus depleting the iron stores more rapidly to replace the iron lost from bleeding. Iron contributes to immune function by regulating immune effector mechanisms (such as cytokine activities). The precise benefits or detriments of iron deficiency and immunity are controversial.
IDA develops slowly through three overlapping stages. In stage I, the body's iron stores for red cell production and hemoglobin synthesis are depleted. Red cell production proceeds normally with the hemoglobin content of red cells also remaining normal. In stage II, insufficient amounts of iron are transported to the marrow, and iron-deficient red cell production begins. Stage III begins when the hemoglobin-deficient red cells enter the circulation to replace normal, aged erythrocytes that have been destroyed. The manifestations of IDA appear in stage III when there is an insufficient iron supply and diminished hemoglobin synthesis.

**Clinical manifestations**

The onset of symptoms is gradual, and individuals usually do not seek medical attention until hemoglobin levels drop to 7 or 8 g/dl. Early symptoms are nonspecific and include fatigue, weakness, shortness of breath, and pale earlobes, palms, and conjunctivae (Figure 21-3).

As the condition progresses and becomes more severe, structural and functional changes occur in epithelial tissue. The fingernails become brittle and “spoon shaped” or concave (*koilonychia*) (Figure 21-4). Tongue papillae atrophy and cause soreness along with redness and burning (Figure 21-5). These changes can be reversed within 1 to 2 weeks of iron replacement therapy. The corners of the mouth become dry and sore (angular stomatitis), and an individual may experience difficulty with swallowing because of a “web” that develops from mucus and inflammatory cells at the opening of the esophagus. These lesions have the potential to become cancerous.
Nonheme iron is a component of many enzymes in the body, and lack of iron may alter other physiologic processes and contribute to the clinical manifestations. Individuals with IDA exhibit gastritis, neuromuscular changes, irritability, headache, numbness, tingling, and vasomotor disturbances. Gait disturbances are rare. In the elderly, mental confusion, memory loss, and disorientation may be wrongly perceived as “normal” events associated with aging.

**Evaluation and treatment**

Evaluation is based on clinical manifestations and laboratory tests. Iron stores are measured directly, by bone marrow biopsy, or indirectly, by tests that measure serum ferritin level, transferrin saturation, or total iron-binding capacity. A
sensitive indicator of heme synthesis is the amount of free erythrocyte protoporphyrin (FEP) within erythrocytes. A test that determines the concentration of soluble fragment transferrin receptor differentiates primary IDA from IDA that is associated with chronic disease.

The first step in treatment of IDA is to find and eliminate, or rule out, sources of blood loss. If this is not done, replacement therapy is ineffective. Iron replacement therapy is required and very effective. Initial doses are 150 to 200 mg/day and are continued until the serum ferritin level reaches 50 mg/L, indicating that adequate replacement has occurred. A rapid decrease in fatigue, lethargy, and other associated symptoms is generally seen within the first month of therapy. Replacement therapy usually continues for 6 to 12 months after the bleeding has stopped but may continue for as long as 24 months. Menstruating females may need daily oral iron replacement therapy (325 mg/day) until menopause.

**Sideroblastic Anemia**

**Sideroblastic anemias (SAs)** are a heterogeneous group of inherited and acquired disorders characterized by anemia of varying severity and the presence of ringed sideroblasts in the bone marrow (see Figure 21-2, K). **Ringed sideroblasts** are erythroblasts that contain iron-laden mitochondria arranged in a circle around one third or more of the nucleus. More simply, these are red cells that contain iron granules that have not been synthesized into hemoglobin but instead are arranged in a circle around the nucleus. Individuals with SA also have increased tissue levels of iron.

**Pathophysiology**

Sideroblastic anemias have various causes but all share the commonality of altered heme synthesis in the erythroid cells in bone marrow. **Acquired sideroblastic anemias (ASAs),** which are the most common, occur as a primary disorder with no known cause (idiopathic) or are associated with other myeloproliferative or myeloplastic disorders, for example, myeloma, polycythemia vera, and leukemias. Another form, described as **reversible sideroblastic anemias (reversible SAs),** is secondary to various conditions such as alcoholism, drug reactions, copper deficiency, and hypothermia. Reversible SA, associated with alcoholism, results from nutritional deficiencies of folate. Some drugs also cause reversible SA and include antituberculous agents (isoniazid [INH], pyrazinamide, cycloserine, and chloramphenicol) that interfere with B₁₂ metabolism or directly injure the mitochondria. Copper deficiency also causes reversible SA by interfering with conversion of ferric iron to ferrous iron. This is extremely rare and is associated
with gastrectomy and prolonged parenteral nutrition without copper supplements. Hypothermia causes decreased heme synthesis and incorporation into hemoglobin.

**Hereditary (congenital) sideroblastic anemias** are rare and occur almost exclusively in males, supporting a recessive X-linked transmission; however, autosomal transmission affecting females has been reported. Other genetic, chromosomal, or enzyme dysfunctions also have been associated with hereditary SA, for example, mutations in TRNT1 (tRNA nucleotidyl transferase) that lead to metabolic defects in both mitochondria and cytosol. In all instances, SA anemia is present in infancy or childhood but may remain undetected until midlife when other conditions, such as diabetes or cardiac failure from iron overload, cause its manifestation.

The leading known cause of primary ASA, **myelodysplastic syndrome (MDS)**, is a group of disorders of hematopoietic stem cells with all three stem cell lines (erythrocytic, granulocytic, and megakaryocytic) demonstrating abnormal growth or cell characteristics. Pure SA, or cellular features limited to the erythrocytic line, requires blood transfusions that may, over time, produce iron overload. With adequate chelation therapy, individuals are able to survive and thrive for many years. MDS, characterized by abnormalities of multiple cell lineages, may include alterations of neutrophils and platelets. Bleeding from thrombocytopenia and platelet dysfunction is prevalent. Of those who survive, 40% develop acute (myeloblastic) leukemia.

**Clinical manifestations**

The anemias of SA are generally moderate to severe, with hemoglobin levels varying from 4 to 10 g/dl. In addition to the cardiovascular and respiratory manifestations common to all anemias, individuals with SA may show signs of iron overload (hemochromatosis) and mild to moderate enlargement of the liver (hepatomegaly) and spleen (splenomegaly). However, liver function remains normal or only mildly affected. Occasionally, the skin may become abnormally colored (bronze-tinted). Neurologic and skin alterations associated with other anemias are absent. Hemosiderosis of cardiac tissue may result in heart rhythm disturbances, which is a significant but uncommon complication and generally occurs late in the course of the disease. Growth and development impairment may occur in infants and young children who are severely affected.

**Evaluation and treatment**

Initially, SA may be mistaken for deficiency of stem cells in the marrow (hypoplastic anemia) or iron deficiency anemia. The diagnosis of SA is established by bone marrow biopsy, which documents the presence of sideroblasts and
confirms the diagnosis. The severity of the anemia is quite variable.

Initial treatment of SA is directed toward identification of a causative agent (i.e., drugs or toxins). Treatment is supportive, with transfusions being the primary intervention. Following removal of the agent, oral pyridoxine (100 mg/day) may be administered on a trial basis. Acquired SA related to alcohol abuse and pyridoxine antagonists often demonstrates a complete response to pyridoxine. SA caused by other etiologies does not demonstrate the same improvement.

Individuals with hereditary SA are initially treated with pyridoxine therapy (50 to 200 mg/day), which is effective in approximately one third of individuals. An optimal response is reticulocytosis with blood hemoglobin levels and low free erythrocyte protoporphyrin levels also returning to normal within 1 to 2 months. Structural abnormalities of cells (microcytosis), however, do not disappear. Hemoglobin levels also may increase in response to therapy but stabilize at less than normal levels. A therapeutic response to pyridoxine may be maintained with lifelong administration of a reduced dosage. Nonresponse to pyridoxine requires blood transfusions for symptom relief and to promote growth and development.

Evidence of iron overload requires iron depletion therapy to prevent or minimize organ damage. Phlebotomy, or removal of blood from the circulation, is used in individuals with mild to moderate anemia without other complications (e.g., heart disease). After iron removal, maintenance phlebotomies are continued. Severely anemic individuals who may require transfusions become extremely iron overloaded, which mandates use of deferoxamine, an iron-chelating agent, to reduce excess iron levels.

Individuals with acquired SA are less likely to respond to pyridoxine, but SA rarely incapacitates them. When SA is secondary to an identifiable cause, treatment or removal of the cause is essential. In the absence of blood cell abnormalities and iron overload, progression takes place over years. Transfusion and chelation therapy is the same as for hereditary SA when indicated.

Recent advances in treatment for SAs include prolonged administration of erythropoietin and stem cell transplant. Treatment with recombinant human erythropoietin improves anemia in 30% of those with myelodysplastic syndrome. Individuals with the subset of MDS identified as refractory anemia have the overall best response rate. Congenital SA has been treated successfully with stem cell transplants; however, this treatment is in the early stages of use and long-term efficacy has not yet been established. Death from SA is rare and often secondary to complications, such as infection, bone marrow failure, liver failure, or cardiac failure or arrhythmias, or both.
Normocytic-Normochromic Anemias

Normocytic-normochromic anemias (NNAs) are characterized by erythrocytes that are relatively normal in size and hemoglobin content but insufficient in number. These types of anemia do not share any common etiology, pathologic mechanism, or morphologic characteristics. They are less common than the macrocytic-normochromic and the microcytic-hypochromic anemias. The five distinct anemias are aplastic (damage to bone marrow erythropoiesis); posthemorrhagic (acute blood loss); acquired hemolytic (immune destruction of erythrocytes); hereditary hemolytic, such as sickle cell (see Figure 21-2, L) (destruction by eryptosis); and anemia of chronic inflammation (multiple causes). The diversity of the NNAs is summarized in Table 21-2. (Sickle cell anemia is discussed in Chapter 22.)

Quick Check 21-1

1. How do cell size and content determine classification of anemia?

2. Why is iron important to hemoglobin synthesis, and why is iron deficiency related to anemia?

3. Discuss the pathophysiology of iron deficiency anemia.

4. How is anemia diagnosed?
### TABLE 21-2
**Normocytic-Normochromic Anemias**

<table>
<thead>
<tr>
<th>Anemia</th>
<th>Pathophysiology</th>
<th>Clinical Manifestations</th>
<th>Evaluation and Treatment</th>
</tr>
</thead>
<tbody>
<tr>
<td>Aplastic</td>
<td>Rare; may result from infiltrative disorders of bone marrow, autoimmune diseases, renal failure, splenic dysfunction, vitamin B&lt;sub&gt;12&lt;/sub&gt; or folate deficiency, parvovirus infection, or exposure to radiation, drugs, and toxins; also may be congenital Common stem cell population may be altered so it cannot proliferate or differentiate, or stem cell environment is altered to inhibit erythropoiesis Outcome ranges from death to minimal manifestations</td>
<td>Classic cardiovascular and respiratory manifestations with thrombocytopenia, hemorrhage into tissues, leukopenia, and infection</td>
<td>Bone marrow biopsy determines whether anemia is caused by pure red cell aplasia or hypoplasia Treat underlying disorder or prevent further exposure to causative agent Blood transfusions, marrow transplant, and pharmacologic stimulation of bone marrow function</td>
</tr>
<tr>
<td>Posthemorrhagic</td>
<td>Caused by sudden blood loss with normal iron stores</td>
<td>Often obscured by cardiovascular manifestations of acute hemorrhage Severe shock, lactic acidosis, and death can occur if blood loss exceeds 40-50% of plasma volume</td>
<td>Restoration of blood volume by intravenous administration of saline, dextran, albumin, or plasma Transfusion of whole blood also required occasionally</td>
</tr>
<tr>
<td>Hemolytic</td>
<td>Acquired: caused by infection, systemic disease, drugs or toxins, liver disease, kidney disease, abnormal immune responses Hereditary: caused by abnormalities of RBC membrane or cytoplasmic contents; present at birth Hemolysis: in blood vessels or lymphoid tissues that filter blood (e.g., spleen, liver) Erythrocytes: rigid, slowing their passage and making them vulnerable to phagocytosis Types: warm antibody disease (mediated by IgG antibody specific for erythrocyte antigens), cold antibody disease (mediated by IgM), and drug induced</td>
<td>Splenomegaly, jaundice, aplastic hemolytic, or megaloblastic crises can develop with viral infection With severe disease, bones become deformed and pathologic fractures occur Cardiovascular and respiratory manifestations correspond with severity of anemia</td>
<td>Blood and bone marrow studies Erythroid hyperplasia is found in marrow and blood smears Treatment of acquired disease involves removing cause or treating underlying disorder Other forms of treatment are transfusions, splenectomy, and steroids or folate</td>
</tr>
<tr>
<td>Anemia of chronic inflammation</td>
<td>Associated with chronic infections (e.g., AIDS), chronic inflammatory diseases (e.g., rheumatoid arthritis, SLE), and malignancies Causes are decreased erythrocyte life span, failure of mechanisms of compensatory erythropoiesis, or disturbance of iron cycle</td>
<td>Manifestations fewer and milder than most other anemias General disability caused by chronic disease limits physical activity so hemoglobin levels adequate; if they drop, signs of iron deficiency anemia develop</td>
<td>Blood tests show iron deficiency in marrow despite normal or increased iron stores elsewhere No treatment is needed unless anemia becomes symptomatic Erythropoietin may be used</td>
</tr>

*AIDS*, Acquired immunodeficiency syndrome; *RBC*, red blood cell; *SLE*, systemic lupus erythematosus.
Myeloproliferative Red Cell Disorders

Hematologic dysfunction results from an overproduction of cells, as well as a deficiency. One or more hematopoietic lines may be overproduced in the marrow in response to exogenous (e.g., exposure to radiation, drugs) or endogenous (e.g., physiologic compensatory response, immune disorder) signals. Excessive red cell production is classified as **polycythemia** (Table 21-3). Polycythemia exists in two forms: relative and absolute. **Relative polycythemia** results from hemoconcentration of the blood associated with dehydration that may be caused by decreased water intake, diarrhea, excessive vomiting, or increased use of diuretics. Its development is usually of minor consequence and resolves with fluid administration or treatment of underlying conditions.

*Nonphysiologic means that there is no obvious physiologic explanation for hypersecretion of erythropoietin. 2,3-DPG, 2,3-Diphosphoglycerate; Hb, hemoglobin.*

**Absolute polycythemia** consists of two forms: primary and secondary. **Secondary polycythemia**, the most common of the two, is a physiologic response resulting from erythropoietin secretion caused by hypoxia. This hypoxia is noted in individuals living at higher altitudes (>10,000 ft), smokers with increased blood levels of CO, and individuals with chronic obstructive pulmonary disease or coronary heart failure, or both. Abnormal types of hemoglobin (e.g., San Diego, Chesapeake), which have a greater affinity for oxygen, also cause secondary polycythemia, as does inappropriate secretion of erythropoietin by certain tumors (e.g., renal cell carcinoma, hepatoma, and cerebellar hemangioblastomas).
**Polycythemia Vera**

**Polycythemia vera (PV)** (also known as **primary polycythemia**) is a stem cell disorder with hyperplastic and neoplastic bone marrow alterations. PV is characterized by an abnormal uncontrolled proliferation of red blood cells (frequently with increased levels of white blood cells [leukocytosis] and platelets [thrombocytosis]). The increase in red cells (polycythemia) is responsible for most of the clinical symptoms including an increase in blood volume and viscosity. PV is one of several disorders collectively known as **myeloproliferative neoplasms (MPNs)** (Box 21-1). These disorders include certain leukemias, essential thrombocytosis, and chronic bone marrow fibrosis. The disorders all result from abnormal regulation of the hematopoietic stem cells. Specifically, the common pathogenic feature is the presence of a mutation in the **Janus kinase 2 gene (JAK2 gene)** resulting in an overproduction of blood cells. Normally, the JAK2 gene makes a protein that helps the body produce blood cells (see Pathophysiology). Because of numerous characteristics (e.g., overproduction of different blood cells, marrow hypercellularity, or fibrosis) shared by these disorders and a lack of specific molecular markers, the diagnosis can be quite challenging. The common features include (1) increased proliferative drive in the bone marrow, (2) hematopoiesis of neoplastic stem cells to secondary hematopoietic organs, (3) marrow fibrosis and peripheral deficiencies in blood cells (cytopenias), and (4) variable transformation to acute leukemia.

---

**Box 21-1**

**World Health Organization (WHO) Classification of Myeloid Malignancies**

1. Acute myeloid leukemia (AML) and related neoplasms

2. Myeloproliferative neoplasms (MPN)

2.1. Chronic myeloid leukemia, **BCR-ABL1** positive (CML)

2.2. **BCR-ABL1**-negative MPN

2.2.1. Polycythemia vera
2.2.2. Primary myelofibrosis (PMF)

2.2.3. Prefibrotic PMF

2.2.4. Essential thrombocythemia (ET)

2.3. Other MPN

2.3.1. Chronic neutrophilic leukemia (CNL)

2.3.2. Chronic eosinophilic leukemia, not otherwise specified (CEL-NOS)

2.3.3. Mastocytosis

2.3.4. Myeloproliferative neoplasm, unclassified (MPN-U)

3. Myelodysplastic syndromes (MDS)

3.1. Refractory cytopenia\textsuperscript{b} with unilineage dysplasia (RCUD)

3.1.1. Refractory anemia (ring sideroblasts <15\% of erythroid precursors)

3.1.2. Refractory neutropenia

3.2. Refractory anemia with ring sideroblasts (RARS; dysplasia limited to erythroid lineage and ring sideroblasts \( \geq 15\% \) of bone marrow erythroid precursors)
3.3. Refractory cytopenia with multilineage dysphasia (RCMD; ring sideroblast count does not matter)

3.4. Refractory anemia with excess blasts (RAEB)

3.4.1. RAEB-1 (2-4% circulating or 5-9% marrow blasts)

3.4.2. RAEB-2 (5-19% circulating or 10-19% marrow blasts or Auer rods present)

3.5. MDS associated with isolated del(5q)

3.6. MDS, unclassified

4. MDS/MPN

4.1. Chronic myelomonocytic leukemia (CMML)

4.2. Atypical chronic myeloid leukemia, BCR-AB1 negative

4.3. Juvenile myelomonocytic leukemia (JMML)

4.4. MDS/MPN, unclassified

4.4.1. Provisional entry: Refractory anemia with ring sideroblastic associated with marked thrombocytosis (RARS-T)

5. Myeloid and lymphoid neoplasms with eosinophilia and abnormalities of PDGFRA, PDGFRB, FGFRI
5.1. Myeloid and lymphoid neoplasms with **PDGFRα** rearrangement

5.2. Myeloid neoplasms with **PDGFRβ** rearrangement

5.3. Myeloid and lymphoid neoplasms with **FGFR1** abnormalities

---

a Acute myeloid leukemia-related precursor neoplasms include “therapy-related myelodysplastic syndrome” and “myeloid sarcoma.”
b Either mono- or bi-cytopenia: hemoglobin <10 g/dl, absolute neutrophil count <1.8 × 10⁹/L, or platelet count <100 × 10⁹/L. However, higher blood counts do not exclude the diagnosis in the presence of unequivocal histologic/cytogenic evidence for myelodysplastic syndrome.
c Genetic rearrangements involving platelet-derived growth factor receptor α/β (**PDFRA/PDFRB**) or fibroblast growth factor receptor 1 (**FGFR1**).

PV is quite rare with an estimated incidence of 2.3 per 100,000 individuals; peak incidence is between the ages of 60 and 80 years with a median incidence of 55 to 60. However, PV has been observed in individuals younger than the age of 40. Males are twice as likely as females to develop PV. It is more common in whites of Eastern European Jewish ancestry than in blacks. PV is rarely seen in children or in multiple members of a single family; however, an autosomal dominant form exists that causes increased secretion of erythropoietin.

**Pathophysiology**

Erythrocytosis is the essential component of PV. Proliferation of erythroid progenitors occurs in the bone marrow independent of the hormone erythropoietin, but the cells express a normal erythropoietin receptor. More than 95% of individuals with PV have an acquired mutation in the tyrosine kinase, Janus kinase 2 (**JAK2**).¹⁷ Normal JAK2 increases the activity of the erythropoietin receptor and is self-regulatory so that JAK2 activity diminishes over time. The mutation associated with PV negates the self-regulatory activity of JAK2 so that the erythropoietin receptor is constantly active regardless of the level of erythropoietin. Overall, the mutated tyrosine kinases bypass normal controls, causing growth factor-independent proliferation and survival of marrow progenitors or precursor cells.
The cause of the mutation is unknown.

**Clinical manifestations**

PV is uncommon and occurs insidiously. Clinical manifestations of PV are a result of the increased red cell mass and hematocrit. Usually there is an increase in blood volume. Together all of these factors cause abnormal blood flow that increases blood viscosity, creating a hypercoagulable state that results in clogging and occlusion of blood vessels. Tissue injury (ischemia) and death (infarction) is the outcome of blood vessel blockage. These outcomes are directly correlated with hematocrit levels. Increases in numbers of thrombocytes, as well as production of dysfunctional platelets, also contribute to this hypercoagulable condition.

Circulatory alterations caused by the thick, sticky blood give rise to other manifestations, such as plethora (ruddy, red color of the face, hands, feet, ears, and mucous membranes) and engorgement of retinal and cerebral veins. Other symptoms may include headache, drowsiness, delirium, mania, psychotic depression, chorea, and visual disturbances. Individuals frequently have an enlarged spleen with abdominal pain and discomfort. Death from cerebral thrombosis is approximately five times greater in individuals with PV.

Cardiovascular function, despite the vascular alterations, remains relatively normal. Cardiac workload and output remain constant; however, increased blood volume does increase blood pressure. Coronary blood flow may be affected, precipitating angina, although cardiovascular infarctions are uncommon. Other cardiovascular manifestations include Raynaud phenomenon and thromboangiitis obliterans.

A unique feature of PV, and helpful in diagnosis, is the development of intense, painful itching that appears to be intensified by heat or exposure to water (*aquagenic pruritus*) so that individuals avoid exposure to water, particularly warm water when bathing or showering. The intensity of itching is related to the concentration of mast cells in the skin and is generally not responsive to antihistamines or topical lotions.

**Evaluation and treatment**

PV is frequently suspected because of clinical features, such as a thrombotic event, splenomegaly, or aquagenic pruritus. Blood and laboratory findings, characterized by an absolute increase in red blood cells and in total blood volume, confirm the diagnosis. Hematocrit levels may range from 18 to 24 g/dl and red blood cell counts may range from $7 \times 10^{12}$ to $7 \times 10^{13}/\mu L$. Erythrocytes appear normal, but anisocytosis may be present. There also may be moderate increases in white blood cells and platelets. A bone marrow examination may be done but is not very valuable unless performed in association with cytogenetic and molecular studies for
relevant mutations in JAK2. The presence of a JAK2 mutation confirms the diagnosis. Treatment of PV consists of reducing red cell proliferation and blood volume, controlling symptoms, and preventing clogging and clotting of the blood vessels. In low-risk individuals (e.g., those younger than age 60 or with no history of thrombosis and without risk factors for cardiovascular disease), the recommended therapy is phlebotomy (300 to 500 ml at a time to reduce erythrocytosis and blood volume) and low-dose aspirin. Frequent phlebotomies also reduce iron levels, a condition that impedes erythropoiesis.

Hydroxyurea, a nonalkylating myelosuppressive, is the drug of choice for myelosuppression because of a reduced incidence to cause leukemia and thrombosis. Radioactive phosphorus ($^{32}$P) also is used as an effective and easily tolerated intervention to suppress erythropoiesis. Its effects may last up to 18 months. Side effects of $^{32}$P include suppression of hematopoiesis resulting in anemia, leukopenia, and thrombocytopenia. Acute leukemia is also a side effect, although most often it occurs only after 7 or more years of treatment, making its use in elderly persons more common. Interferon-alpha has been used when other forms of treatment have failed.

Survival for 10 to 15 years is common. However, without proper treatment, 50% of individuals with PV die within 18 months of the onset of initial symptoms because of thrombosis or hemorrhage. A significant potential outcome of PV is the conversion to acute myeloid leukemia (AML), occurring spontaneously in 10% of individuals and generally being resistant to conventional therapy. Conversion to AML is most likely related to treatment methods associated with cytotoxic myelosuppressive agents. Although PV is a chronic disorder, appropriate therapy results in remissions and prevention of significant pathologic outcomes.

Iron Overload

Iron overload can be primary, as in hereditary hemochromatosis (HH), or secondary. The secondary causes of iron overload include anemias with inefficient erythropoiesis (e.g., sideroblastic anemia, aplastic anemia), dietary iron overload, or conditions that require repeated blood transfusions or iron dextran injections. Iron absorption is regulated by erythropoietin, tissue oxygenation, and iron stores (see Chapter 20).

Hereditary Hemochromatosis

Hemochromatosis is caused by excessive iron absorption. Hereditary hemochromatosis (HH) is a common inherited, autosomal recessive disorder of iron metabolism and is characterized by increased gastrointestinal iron absorption.
with subsequent tissue iron deposition. Excess iron is deposited first in the liver and pancreas, followed by the heart, joints, and endocrine glands. Excess iron causes tissue damage that can lead to diseases such as cirrhosis, diabetes, heart failure, arthropathies, and impotence. HH affects more males than females.

HH is caused by two genetic base-pair alterations, C282Y and H63D. These are mutations in the HFE gene on chromosome 6. Homozygosity of C282Y is the most common genotype and accounts for 82% to 90% of HH cases. The remaining cases appear to be caused by environmental factors or other genotypes. HFE mutations are common in the United States with 1 in 10 white persons heterozygous for HFE C282Y mutation and 4.4 in 1000 homozygous for the C282Y mutation. C282Y homozygosity is much lower among Hispanics (0.27 in 1000), Asian Americans (<0.001 per 1000), Pacific islanders (0.12 per 1000), and black persons (0.14 per 1000).

Pathophysiology

In HH, regulation of intestinal absorption of dietary iron is abnormal, causing iron accumulation. The HFE gene governs intestinal absorption of dietary iron by regulating the liver-derived protein hepcidin. Hepcidin lowers plasma iron level, and a deficiency in hepcidin, caused by genetic mutations, causes iron overload. The gene mutations in HH reduce hepcidin synthesis, thus reducing the level of circulating plasma hepcidin. The decreased hepcidin-ferroportin (iron transporter) interaction eventually leads to more iron outward flow (efflux) from cells in the small intestinal mucosa, causing a rise in iron concentration and a systemic overload. The iron overload leads to excess iron tissue deposits that can eventually result in liver fibrosis, cirrhosis, hepatocellular carcinoma, diabetes, hypothyroidism, arthritis, cardiomyopathies, and skin hyperpigmentation.

With HH there appears to be a long latent period with individual variation in biochemical expression modified by environmental factors, such as blood loss from menstruation or donation, alcohol intake, and diet. Cirrhosis is a late-stage development of HH that can shorten life expectancy. Cirrhosis also is a risk factor for hepatocellular carcinoma that occurs between 40 and 60 years of age. Cirrhosis prevention is a major goal of HH screening and treatment.

Clinical manifestations

Clinical manifestations of HH include symptoms such as fatigue, malaise, abdominal pain, arthralgias, and impotence; and clinical findings of hepatomegaly, abnormal liver enzymes, bronzed skin, diabetes, and cardiomegaly. Many individuals are diagnosed as a result of serum iron studies as part of a health screening panel. Most affected individuals (>75%) are asymptomatic and have a low
frequency (<25%) of cirrhosis, diabetes, or skin pigmentation.

**Evaluation and treatment**

Laboratory findings in individuals with HH show elevations in serum iron levels, transferrin saturation, and ferritin levels. Documentation of iron overload relies on quantitative phlebotomy with calculation of the amount of iron removed or liver biopsy with determination of quantitative hepatic iron. With the advent of genetic testing, individuals who are C282Y homozygous or compound heterozygous, less than 40 years old, and have normal liver functions, no further workup is necessary.

Treatment of HH is simple and consists of phlebotomy of 550 ml of whole blood, which is equivalent to 200 to 250 mg of iron. Frequency of phlebotomy depends on ferritin levels and should continue until the ferritin level is between 20 and 50 ng/ml. Initially, phlebotomy may be needed weekly but once therapeutic ferritin levels are reached, phlebotomy may only be needed every 2 to 3 months. Blood banks now accept blood donations from persons with documented HH. Iron chelating agents are sometimes used in addition to phlebotomy, but this is not the mainstay of treatment. Individuals with HH should be instructed to refrain from taking iron and vitamin C supplements and consuming raw shellfish; in addition, alcohol should be used in moderation. Family screening is recommended and necessary for all first-degree relatives of a person with HH.
Alterations of Leukocyte Function

Leukocyte function is affected if too many or too few white cells are present in the blood or if the cells that are present are structurally or functionally defective. Phagocytic cells (granulocytes, monocytes, macrophages) may lose their ability to act as effective phagocytes, and the lymphocytes may lose their ability to respond to antigens. (Disruptions of inflammatory and immune processes caused by leukocyte disorders are described in Chapter 6.) Other leukocyte alterations include infectious mononucleosis and cancers of the blood—leukemia and multiple myeloma.

Quantitative Alterations of Leukocytes

Quantitative alterations are increases or decreases in numbers and functions of leukocytes in the blood. **Leukocytosis** is present when the count is higher than normal; **leukopenia** is present when the count is lower than normal. Leukocytosis and leukopenia may affect a specific type of white blood cell and may result from a variety of physiologic conditions and alterations. Leukocytosis occurs as a normal protective response to physiologic stressors, such as invading microorganisms, strenuous exercise, emotional changes, temperature changes, anesthesia, surgery, pregnancy, and some drugs, hormones, and toxins. It also is caused by pathologic conditions, such as malignancies and hematologic disorders. Unlike leukocytosis, leukopenia is never normal and is defined as an absolute blood cell count less than 4000 cells/µL. Leukopenia is associated with a decrease in neutrophils, which increases risk for infection. When the neutrophil count falls to less than 1000/µL, the risk of infection increases drastically. With counts below 500/µL, the possibility for life-threatening infections is high. Leukopenia may be caused by radiation, anaphylactic shock, autoimmune disease (e.g., systemic lupus erythematosus), immune deficiencies (see Chapter 8), and certain chemotherapeutic agents.

Granulocyte and Monocyte Alterations

Increased numbers of circulating granulocytes (neutrophils, eosinophils, basophils) and monocytes are chiefly a physiologic response to infection. Increased numbers also occur as a result of myeloproliferative disorders that increase stem cell proliferation in the bone marrow.

Decreased numbers occur when infectious processes deplete the supply of circulating granulocytes and monocytes, drawing them out of the circulation and into infected tissues faster than they can be replaced. Decreases also can be caused by disorders that suppress marrow function, such as severe congenital neutropenia,
or immune-related neutropenia.\textsuperscript{24}

Granulocytosis—an increase in granulocytes (neutrophils, eosinophils, or basophils)—begins when stored blood cells are released. Neutrophilia is another term that may be used to describe granulocytosis because neutrophils are the most numerous of the granulocytes (Table 21-4). Neutrophilia is seen in the early stages of infection or inflammation and is established when the absolute count exceeds 7500/µL. Release and depletion of stored neutrophils stimulates granulopoiesis to replenish neutrophil reserves. Specific conditions associated with neutrophilia and other white blood cells are identified in Table 21-4.

*AIDS, Acquired immunodeficiency syndrome*; *ALL, acute lymphocytic leukemia; CHF, congestive (left) heart failure; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CMV, cytomegalovirus; GI, gastrointestinal; MI, myocardial infarction; SLE, systemic lupus erythematosus; TB, tuberculosis.*

When the demand for circulating mature neutrophils exceeds the supply, immature neutrophils (and other leukocytes) are released from the bone marrow. Premature release of the immature cells is responsible for the phenomenon known as a **shift-to-the-left**, or **leukemoid reaction**. This refers to the microscopic
detection of disproportionate numbers of immature leukocytes in peripheral blood smears. To understand this phenomenon, visualize cellular differentiation, maturation, and release (see Figure 19-7) as progressing from left to right instead of vertically. The early release of immature white cells prevents the completion of the sequence and shifts the distribution of leukocytes in the blood toward those on the left side of the diagram. This phenomenon is also seen in the blood smear of individuals with leukemia, hence the term *leukemoid reaction*. As infection or inflammation diminishes, and granulopoiesis replenishes circulating granulocytes, a *shift-to-the-right*, or return to normal, occurs.

**Neutropenia** is a condition associated with a reduction in circulating neutrophils and exists clinically when the neutrophil count is less than 2000/µL. Reduction in neutrophils occurs in severe prolonged infections when production of granulocytes cannot keep up with demand.\(^{23,24}\)

Other causes of neutropenia, in the absence of infection, may be (1) decreased neutrophil production or ineffective granulopoiesis, (2) reduced neutrophil survival, and (3) abnormal neutrophil distribution and sequestration. Neutropenia also is classified as primary or secondary and primary disorders are further identified as congenital or acquired. Primary acquired neutropenia is associated with multiple conditions, for example, hypoplastic anemia or aplastic anemia, leukemia (acute myelogenous leukemia [AML]/chronic lymphocytic leukemia [CLL]), lymphomas (Hodgkin, non-Hodgkin), and myelodysplastic syndrome (MDS). The megaloblastic anemias (vitamin B\(_{12}\) and folate deficiency) as well as starvation and anorexia nervosa cause neutropenia because of an inadequate supply of vitamins and nutrients for protein production.

Congenital defects in neutrophil production include cyclic neutropenia, neutropenia with congenital immunodeficiencies, and multiple syndromes, such as Kostmann, Shwachman-Diamond, Diamond-Blackfan, and Barth syndromes. Reduced neutrophil survival and abnormal distribution and sequestration are usually secondary to other disorders. Neutropenia occurs in a variety of immunologic disorders, particularly systemic lupus erythematosus, rheumatoid arthritis, Felty and Sjögren syndromes, splenomegaly, and drug-related causes.

Severe neutropenia, **granulocytopenia** (less than 500/µL), or **agranulocytosis** (complete absence of granulocytes in blood) is usually secondary to arrested hematopoiesis in the bone marrow or massive cell destruction in the circulation. Chemotherapeutic agents used to treat hematologic and other malignancies cause bone marrow suppression. Several other drugs cause agranulocytosis, which occurs rarely but carries a high mortality of 10% to 50%. Clinical manifestations of agranulocytosis include severe infection (particularly of the respiratory system) leading to septicemia, general malaise, fever, tachycardia, and ulcers in the mouth.
and colon. If this condition remains untreated, sepsis caused by agranulocytosis results in death within 3 to 6 days. Other conditions associated with neutropenia are identified in Table 21-4.

**Eosinophilia** is an absolute increase (>450/µL) in the total number of circulating eosinophils. Allergic disorders (type 1) associated with asthma, hay fever, parasitic infections, and drug reactions often cause eosinophilia. Hypersensitivity reactions trigger the release of eosinophilic chemotaxic factor of anaphylaxis (ECF-A), and histamine from mast cells attracts eosinophils to the area. Mast cells release interleukin-5 (IL-5), which stimulates the bone marrow to produce more eosinophils into the blood. Areas with abundant mast cells, such as the respiratory and GI tracts, are commonly affected. Eosinophilia also may occur in dermatologic disorders, eosinophilia-myalgia syndrome, and parasitic invasion. Other conditions that cause eosinophilia are detailed in Table 21-4.

**Eosinopenia**, a decrease in the number of circulating eosinophils, generally is caused by migration of eosinophils into inflammatory sites. It may be seen in Cushing syndrome and as a result of stress caused by surgery, shock, trauma, burns, or mental distress. Other conditions that cause eosinopenia are detailed in Table 21-4.

**Basophilia**, an increase in the number of circulating basophils, is rare and generally is a response to inflammation and immediate hypersensitivity reactions. Basophils contain histamine that is released during an allergic reaction. Increased numbers of basophils are seen in myeloproliferative disorders, such as chronic myeloid leukemia and myeloid metaplasia. Other conditions that are associated with basophilia are listed in Table 21-4.

**Basopenia** (also known as *basophilic leukopenia*) is a decrease in circulating numbers of basophils. It is seen in hyperthyroidism, acute infection, ovulation and pregnancy, and long-term therapy with steroids. Other conditions associated with basopenia are listed in Table 21-4.

**Monocytosis** is an increase in numbers of circulating monocytes (generally greater than 800/µL). It is often transient and not related to a dysfunction of monocyte production. If present, it is usually associated with neutropenia during bacterial infections, particularly in the late stages or recovery stage, when monocytes are needed to phagocytize surviving microorganisms and debris. Increased monocytes also may indicate marrow recovery from agranulocytosis. Monocytosis is often seen in chronic infections such as tuberculosis (TB), brucellosis, listeriosis, and subacute bacterial endocarditis (SBE). Monocytosis has been found to correlate with the extent of myocardial damage following myocardial infarctions. Other conditions associated with monocytosis are identified in Table 21-4. **Monocytopenia**, a decrease in the number of circulating monocytes, is rare
but has been identified with hairy cell leukemia and prednisone therapy.

**Lymphocyte Alterations**

Quantitative alterations of lymphocytes occur when lymphocytes are activated by antigenic stimuli, usually microorganisms (see Chapter 7). **Lymphocytosis** is an increase in the number (absolute lymphocytosis) or proportion of lymphocytes in the blood. It is rare in acute bacterial infections and is seen most commonly in acute viral infections, particularly those caused by the Epstein-Barr virus (EBV)—a causative agent in infectious mononucleosis. Other specific disorders associated with lymphocytosis are listed in Table 21-4.

**Lymphocytopenia** is a decrease in the number of circulating lymphocytes in the blood. It may be attributed to (1) abnormalities of lymphocyte production associated with neoplasias and immune deficiencies and (2) destruction by drugs, viruses, or radiation. It is also known to occur without any detectable cause. Conditions associated with lymphocytopenia are identified in Table 21-4. The lymphocytopenia associated with heart failure and other acute illnesses may be caused by elevated cortisol levels. Lymphocytopenia is a major problem in acquired immunodeficiency syndrome (AIDS). AIDS-related lymphocytopenia is caused by human immunodeficiency virus (HIV), which destroys T-helper lymphocytes. (For a detailed discussion of AIDS, see Chapter 8.)

**Infectious Mononucleosis**

**Infectious mononucleosis (IM)** is a benign, acute, self-limiting, lymphoproliferative clinical syndrome characterized by acute infection of B lymphocytes (B cells). The most common cause is Epstein-Barr virus (EBV).\(^{25}\) EBV is a ubiquitous lymphotropic, herpesvirus and accounts for approximately 85% of IM cases. Other viruses that cause symptoms resembling IM include cytomegalovirus (CMV), adenovirus, HIV, hepatitis A, influenza A and B, and rubella, as well as the bacteria *Toxoplasma gondii*, *Corynebacterium diphtheriae*, and *Coxiella burnetii*. The classic symptoms are pharyngitis, lymphadenopathy, and fever. In individuals with immunodeficiency, the proliferation of infected B cells may be uncontrolled and can lead to the development of B-cell lymphomas.\(^{26}\) Individuals who are coinfectected with malaria or HIV are at increased risk of developing EBV-associated lymphomas, including Burkitt lymphoma (BL). EBV also is etiologically linked to subgroups of Hodgkin lymphoma (HL). Approximately 50% to 85% of children are infected with EBV by age 4, and more than 90% of adults have indications of subclinical EBV infections. These early infections are usually asymptomatic and provide immunity to EBV; thus early EBV
infections rarely develop into IM. IM may arise when the initial infection occurs during adolescence or later, but still only results in IM in 35% to 50% of these individuals. Symptomatic IM usually affects young adults between ages 15 and 35 years, with the peak incidences occurring between 15 and 24 years; males have a later peak (18 to 24 years) than females. The overall incidence rate for this age group is 6 to 8 cases per 1000 persons per year. Children from low socioeconomic environments are particularly susceptible to infections with EBV. IM is uncommon in individuals older than age 40; however, if it does occur, it is commonly caused by CMV.

Transmission of EBV is usually through saliva from close personal contact (e.g., kissing, hence the term kissing disease). The virus also may be secreted in other mucosal secretions of the genital, rectal, and respiratory tracts, as well as blood. Transmission through sneezing or coughing has not been documented. The infection begins with widespread invasion of the B lymphocytes, which have receptors for EBV. The virus initially infects the oropharynx, nasopharynx, and salivary epithelial cells with later spread into lymphoid tissues and B cells.

In the immunocompetent individual, unaffected B cells produce antibodies (IgG, IgA, IgM) against the virus. At the same time, there is a massive proliferation of cytotoxic T cells (CD8) that are directed against EBV-infected cells (see Chapter 7). The immune response against EBV-infected cells is largely responsible for the cellular proliferation in the lymphoid tissue (lymph nodes, spleen, tonsils, and, occasionally, liver). Sore throat and fever are caused by inflammation at the site of initial viral entry (the mouth and throat).

**Clinical manifestations**

The incubation period for IM is approximately 30 to 50 days. Early flulike symptoms, such as headache, malaise, joint pain, and fatigue, may appear during the first 3 to 5 days, although some individuals are without symptoms. At the time of diagnosis, the individual commonly presents with the classic group of symptoms: fever, sore throat (pharyngitis), cervical lymph node enlargement, and fatigue. The pharyngitis is usually diffuse with a whitish or grayish green, thick exudate. It can be painful, causing the individual to seek treatment. Characteristics with progression may include a generalized lymphadenopathy, enlarged spleen, and appearance in the blood of atypical activated T lymphocytes (mononucleosis cells). IM is usually self-limiting, and recovery occurs in a few weeks. Fatigue, however, may last for 1 to 2 months after resolution of the infection.

Severe clinical complications are rare. With progression of IM, general lymph node enlargement may develop with enlargement of the spleen and liver. Splenomegaly is clinically evident 50% of the time and is demonstrated
radiologically 100% of the time. Difficulty in detecting splenomegaly with physical examination contributes to the underestimation of actual enlargement. Splenic rupture is rare (only 0.1% to 0.5% of all cases) and can occur spontaneously as a result of mild trauma, arising primarily in men younger than 25 years of age and between days 4 and 21 after the onset of symptoms. It is the most common cause of death related to IM. Other causes of fatalities are hepatic failure, extensive bacterial infection, or viral myocarditis. Other organ systems are rarely involved, but such involvement may be present with characteristic manifestations, such as fulminant hepatitis with jaundice and anemia, encephalitis, meningitis, Guillain-Barré syndrome, and Bell palsy. Eye manifestations may include eyelid and periorbital edema, dry eyes, keratitis, uveitis, and conjunctivitis. Reye syndrome has been known to develop in children with EBV infection. Pulmonary and respiratory failure has been documented, but is more likely to occur in immunocompromised individuals. Approximately 3% to 10% of adults older than 40 years of age have never been infected with EBV and are susceptible to IM later in life. In these individuals, the classic symptoms are not generally present, making diagnosis more difficult.

**Evaluation and treatment**

The blood of affected individuals contains an increased number of white blood cells with many atypical forms. The diagnosis of IM depends on the following specific findings: (1) an increase in the number of lymphocytes, commonly based on Hoagland criteria of at least 50% lymphocytes and at least 10% atypical lymphocytes in the blood; (2) a positive heterophile antibody reaction (Monospot test, see following text); and (3) a rising titer of specific antibodies for EBV antigens. **Heterophilic antibodies** are a heterogeneous group of IgM antibodies that are agglutinins against nonhuman red blood cells (e.g., horse, sheep) and are detected by qualitative (Monospot) or quantitative (heterophile antibody test) methods. Use of the Monospot test is limited because other infections (e.g., CMV, adenovirus) and toxoplasmosis also produce heterophilic antibodies. Thus 5% to 15% of Monospot tests yield false-positive results. Heterophilic antibodies in the blood increase as the condition progresses, although some individuals and children younger than 4 years of age do not produce them. Diagnosis of EBV infection specifically may be increased with newer viral-specific tests that identify EBV-specific antibodies.

Treatment is supportive and consists of rest and alleviation of symptoms with analgesics and antipyretics. Aspirin is avoided with children because of its association with Reye syndrome. Streptococcal pharyngitis, which occurs in 20% to 30% of cases, is treated with penicillin or erythromycin, not ampicillin—ampicillin
is known to cause a rash. Bed rest with avoidance of strenuous activity and contact sports is indicated. Steroids are used when severe complications, such as impending airway obstruction, or other organ involvement (central nervous system [CNS] manifestations, thrombocytopenic purpura, myocarditis, pericarditis) is evident. Acyclovir has been used in immunocompromised individuals but is not considered standard therapy. In the rare event of splenic rupture, the treatment has been removal of the spleen and continues to be the choice in hemodynamically unstable individuals. Current research, however, is suggesting that it may be better to repair the spleen to avoid overwhelming postsplenectomy infection (OPSI).

Quick Check 21-2

1. What condition is manifested chiefly by an increase in the numbers of circulating granulocytes and monocytes?

2. What is the cause of infectious mononucleosis (IM)?

3. What are the classic symptoms of IM?

Leukemias

Leukemia is a clonal malignant disorder of the bone marrow and usually, but not always, of the blood. The common pathologic feature of all forms of leukemia is an uncontrolled proliferation of malignant leukocytes, causing an overcrowding of bone marrow and decreased production and function of normal hematopoietic cells. Chromosomal abnormalities and translocations are common in the majority of leukemias. When genes become mutated, they create genomic aberrations that block cell maturation and activate pro–growth signaling pathways that prevent apoptotic cell death.

The classification of leukemia is based on (1) the predominant cell of origin (either myeloid or lymphoid) and (2) the rate of progression, which usually reflects the degree at which cell differentiation was arrested when the cell became malignant (acute or chronic) (Figure 21-6). Acute leukemia is characterized by undifferentiated or immature cells, usually a blast cell. The onset of disease is abrupt and rapid. Without treatment, disease progression results in a short survival time. In chronic leukemia, the predominant cell is more differentiated but does not function normally, with a relatively slow progression. There are four types of leukemia: acute lymphocytic (ALL), acute myelogenous (AML), chronic lymphocytic (CLL), and chronic myelogenous (CML). Further classification of
 acute leukemias is based on characteristics that may provide significant therapeutic prognostic information, such as structure, number of cells, genetics, identification of surface markers, and histochemical staining (see Figure 21-6).

![Figure 21-6 Origins of Leukemias and Lymphomas](image)

Leukemia occurs with varying frequencies at different ages and is more common in adults than in children. It is estimated that more than 52,380 cases of leukemia were newly diagnosed in 2014, with males having a slightly higher incidence than females (Table 21-5). Leukemia accounts for about 34% of all childhood cancers; ALL accounts for almost 78% of all new cases of leukemia in children. CLL and AML are the most common types in adults. CML is found mostly in adults.

Data from American Cancer Society: Cancer facts and figures—2015, Atlanta, 2015, The Society.

Over the past 2 decades, the rates of induced remission and survival in most forms of leukemia have increased. Current survival rates range from 24% for AML to 81% for CLL, and as high as 91% for children and adolescents younger than 15 years of age with ALL.30

Pathophysiology

Although the exact cause of leukemia is unknown, several risk factors and related genetic aberrations are associated with the onset of malignancy. The leukemias are clonal disorders driven by genetically abnormal stem-like cancer cells (SLCCs).31 Abnormal immature white blood cells, called blasts, fill the bone marrow and spill into the blood. The leukemia blasts literally “crowd out” the marrow and cause cellular proliferation of the other cell lines to cease. Normal granulocytic-monocytic, lymphocytic, erythrocytic, and megakaryocytic progenitor cells cease to function, resulting in pancytopenia (a reduction in all cellular components of the blood). Almost 90% of ALLs have chromosomal changes that correlate with immunophenotyping and sometimes confer prognostic significance. Several genetic translocations (mitotic errors) are observed in leukemic cells. One of these translocations, the Philadelphia chromosome, is observed in 95% of those with CML and 30% of adults with ALL (Figure 21-7). The Philadelphia chromosome results from a reciprocal translocation between the long arms of chromosomes 9 and 22. A unique protein (bcr-abl protein) is encoded from two genes (BCR from chromosome 22 and ABL from chromosome 9) artificially linked at the junction of translocation. The bcr-abl protein affects a variety of cell cycle control genes, leading to an increased rate of cellular division, inhibition of DNA repair, and other dysregulations of cell growth. Over time the original tumor becomes genetically unstable and diverse.
Risk factors for the onset of leukemia include environmental factors as well as other diseases. Increased risk for ALL has been linked to exposure to x-rays before birth, being exposed to ionizing radiation (postnatally), past treatment with chemotherapy, and certain genetic conditions including Down syndrome, neurofibromatosis type 1 (NF1), Schwachman syndrome, Bloom syndrome, and ataxia telangiectasia. There is growing concern about the effect of low-dose radiation on subsequent risk of leukemia. There is a statistically significant tendency for leukemia to reappear in families. A unique characteristic of ALL, unlike other forms, is that ALL develops at different rates in different geographic locations, although the reason for this is unclear. Individuals in developed countries and in higher socioeconomic categories have an increased incidence of ALL. Acute leukemia also may develop secondary to certain acquired disorders, including CML, CLL, polycythemia vera, myelofibrosis, Hodgkin lymphoma, multiple myeloma, ovarian cancer, and sideroblastic anemia.

Potential risk factors for AML include smoking, previous chemotherapy, and exposure to ionizing radiation. AML is the most frequently reported secondary cancer after high doses of chemotherapy for Hodgkin lymphoma, non-Hodgkin lymphoma, multiple myeloma, ovarian cancer, and breast cancer.
Acute leukemias.

Acute leukemias include two types: acute lymphocytic leukemia (ALL) and acute myelogenous leukemia (AML).\(^{32}\) ALL is an aggressive, fast growing leukemia with too many lymphoblasts or immature white blood cells found in blood and bone marrow. It also is called acute lymphoblastic leukemia. AML is an aggressive fast growing leukemia with too many myeloblasts or immature white blood cells that are not lymphoblasts found in the bone marrow and blood. It also is called acute myeloblastic leukemia, acute myeloid leukemia, and acute nonlymphocytic leukemia (ANLL). Acute leukemias are seen in both genders and in all ages with the incidence increasing dramatically in individuals older than 50 years. North American and Scandinavian countries have the highest mortality; Eastern European countries, Asia (except Japan), and Central America have the lowest mortality. Japan's higher mortality is the result of the atomic bombs dropped in World War II. Blacks have consistently shown a lower mortality than whites. More than 6020 new cases of ALL and 18,860 new cases of AML are estimated in 2014, with more than 1440 deaths from ALL and 10,460 deaths from AML.\(^{33}\) As mentioned earlier, risk factors for ALL include being exposed to x-rays before birth, exposure to ionizing radiation (postnatal), and past treatment with chemotherapy.

**Pathophysiology**

ALL presumably progresses from malignant transformation of B- or C-cell progenitor cells (like a stem cell) (Figure 21-8). Most cases of ALL occur in children and often in the first decade. Although adults account for about 20% of all cases, their mortality rate is significantly higher. The significant difference between the incidence of ALL in adults and children may be because of differences in the biology of the disease. Approximately 75% of ALL cases in children originate from transformed precursor B cells, whereas adult ALL is a mixture of cancers of precursor B-cell or precursor T-cell origin. Precursor B-cell ALL can be further divided into different phenotypes depending on their progression through the B-cell maturation process. The T-cell lineage ALL is distinguished by T-cell–associated markers.
B-cell ALL is strongly associated with aneuploidy of various types, with more than 50 chromosomes. T-cell ALL generally has fewer cytogenetic abnormalities, and the majority have genetic deletions. Several other translocations are commonly observed in ALL, including the Philadelphia chromosome (discussed earlier) and translocations involving the *ETV6* (formerly *TEL*) and *MLL* genes.

AML is the most common adult leukemia; the mean age of diagnosis is 67 years of age. AML results from an abnormal proliferation of myeloid precursor cells, a decreased rate of apoptosis, and an arrest in cellular differentiation. Therefore the bone marrow and peripheral blood are characterized by leukocytosis and a predominance of blast cells. As these immature blast cells increase, they replace normal myelocytic cells, megakaryocytes, and erythrocytes. This displacement can
lead to complications of bleeding, anemia, and infection. Several hereditary conditions are known to increase the risk for AML (e.g., Down syndrome, Fanconi aplastic anemia, Bloom syndrome, and others). More than 150 structural chromosomal abnormalities and several duplications or deletions within genes have been identified in AML. Although ALL and AML are clinically very similar they are genetically and immunologically distinct.\textsuperscript{34}

**Clinical manifestations**

Within days to a few weeks of the first symptoms is an abrupt stormy onset, which is more prevalent in ALL. The clinical manifestations of all varieties of acute leukemia are generally similar. Mechanisms associated with common manifestations are summarized in Table 21-6. Signs and symptoms related to bone marrow depression include fatigue caused by anemia, bleeding resulting from thrombocytopenia, and fever caused by infection. Bleeding may occur in the skin, gums, mucous membranes, and GI tract. Visible signs include petechiae and ecchymosis, as well as discoloration of the skin, gingival bleeding, hematuria, and midcycle or heavy menstrual bleeding.

**Table 21-6**

Clinical Manifestations and Related Pathophysiology in Leukemia

\textit{CLL}, Chronic lymphocytic leukemia; \textit{CMA}, chronic myelocytic leukemia; \textit{RBC}, red blood cell.
Infection sites include the mouth, throat, respiratory tract, lower colon, urinary tract, and skin and may be caused by gram-negative bacilli (*Escherichia coli*), *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae*. Fever is an early sign often accompanied by chills.

Anorexia is accompanied by weight loss, diminished sensitivity to sour and sweet tastes, wasting of muscle, and difficulty swallowing. Liver, spleen, and lymph node enlargement occurs more commonly in ALL than in AML. Liver and spleen enlargement commonly occur together. The leukemic individual often experiences abdominal pain and tenderness. Pain in the bones and joints is thought to result from leukemia infiltration with secondary stretching of the periosteum.

Neurologic manifestations are common and may be caused by either leukemic infiltration or cerebral bleeding. Headache, vomiting, papilledema, facial palsy, blurred vision, auditory disturbances, and meningeal irritation can occur if leukemic cells infiltrate the cerebral or spinal meninges.

**Evaluation and treatment**

Because leukemia often is confused with other conditions, early detection may be difficult. Persistent symptoms need intensive medical investigation. The diagnosis is made through blood tests and examination of bone marrow.

Chemotherapy, used in various combinations, is the treatment of choice for leukemia. Supportive measures include blood transfusions, antibiotics, antifungals, and antivirals. Allopurinol is used to prevent uric acid production and elevation that occurs because of cellular death caused by treatment. Stem cell transplantation is now considered standard therapy for selected individuals with leukemia.

Advances in the treatment of AML have substantially improved the complete remission (CR) rates. Attainment of complete remission requires fairly aggressive treatment. With appropriate induction therapy, approximately 60% to 70% of adults with AML will attain CR status. More than 25% of adults with AML (about 45% of those who attain CR) are expected to survive 3 or more years and may be cured. Since the 1970s, 5-year survival rates for those with ALL have increased from 38% to 66% for adults and from 53% to 91% for children. Factors influencing increased survival rate include the use of combined and multimodality treatment methods; improved supportive services, such as blood banking and nutritional support; and antimicrobial treatment. The presence of the Philadelphia chromosome (observed in about 5% of children with ALL, in 30% of adults with ALL, and occasionally in AML) is a poor prognostic indicator.

Myelosuppression is both a consequence of leukemia and a treatment for the disease. Hematologic support with blood products and granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor
Chronic leukemias.

The two main types of chronic leukemia are (1) **chronic myelogenous leukemia (CML)** and (2) **chronic lymphocytic leukemia (CLL)**. CML is also called **chronic granulocytic leukemia** and **chronic myeloid leukemia**. Several forms of CML can occur, depending on the lineage of the malignant cells (e.g., chronic neutrophilic leukemia [CNL], chronic eosinophilic leukemia [CEL]). CML is a slowly progressing disease with too many blood cells (not lymphocytes) made in the bone marrow. CLL is a slow-growing cancer in which too many immature lymphocytes (white blood cells) are found mostly in the blood and bone marrow. Cancer cells also may be found in lymphoid tissues. In later stages of the disease, cancer cells are sometimes found in the lymph nodes and the disease is called **small lymphocytic lymphoma (SLL)**; also known as **CLL/SLL**. SLL cancer cells are found mostly in the lymph nodes; CLL/SLL also is classified as a non-Hodgkin lymphoma. In adults, CLL is the most common leukemia in the Western world. Individuals with chronic leukemia have a longer life expectancy, usually extending several years from the time of diagnosis.

The chronic leukemias account for the majority of cases in adults (see Table 21-5). The incidences of CLL and CML increase significantly in individuals more than 40 years of age, with prevalence in the sixth through eighth decades. CML is one of a group of diseases called **myeloproliferative disorders**—acquired abnormalities in signaling pathways that lead to growth factor–independent proliferation—which also include polycythemia vera, primary thrombocytosis, and idiopathic myelofibrosis (invasion of bone marrow by fibrous tissue).

Pathophysiology

Chronic myelogenous leukemia (CML) is characterized from other myeloproliferative disorders by the presence of a **chimeric** (genetically distinct cells) **BCR-ABL** fusion gene derived from parts of the **BCR** gene on chromosome 22 and parts of the **ABL** gene on chromosome 9 (Figure 21-9). In the majority of cases (i.e., over 90%), **BCR-ABL** is created by a reciprocal translocation of chromosomes (9;22) called the **Philadelphia chromosome** (see Figure 21-7). In the rest of the cases, the **BCR-ABL** fusion gene is made from complex genetic rearrangements and the cell of origin is a hematopoietic stem cell. The **BCR-ABL** gene causes abnormal cell signaling resulting in pro–growth and pro–survival pathways of the leukemic cells. Much is still unknown about these cell-signaling pathways.
abnormalities and why the *BCR-ABL* fusion gene preferentially drives proliferation of granulocytic and megakaryocytic blood cells. The only known cause of CML is exposure to ionizing radiation.

*FIGURE 21-9  Pathogenesis of Chronic Myeloid Leukemia. The breakage and joining of *BCR* and *ABL* creates the chimeric fusion gene *BCR-ABL*. *BCR-ABL* genetically encodes an active *BCR-ABL* intracellular tyrosine kinase (an enzyme that controls intracellular “on-off” switches). The *ABL* kinase in turn induces signaling through the same pro-growth and pro-survival pathways that are activated by normal hematologic growth factors. Altogether the activation of many downstream pathways drives growth factor–independent proliferation and survival of bone marrow progenitors. (From Kumar V et al: Robbins & Cotran pathologic basis of disease, ed 9, St Louis, 2015, Elsevier.)*
Chronic lymphocytic leukemia (CLL) involves transformation and progressive accumulation of monoclonal B lymphocytes; rarely (less than 5%) are CLL malignancies of T-cell origin. CLL is derived from a transformation of a partially mature B cell that has not yet encountered antigen. Investigations from the past 2 decades have classified CLL and predicted the outcome based on the immunoglobulin heavy chain variable region (IGHV) gene mutational status. Recent studies are addressing five epigenetic biomarkers to classify CLL, which could result in the use of more targeted therapies for specific subgroups. Additionally, investigators report novel recurrent mutations in CLL, including SF3B1 and TP53 mutations, that are independent of IGHV mutational status, demanding the need for urgent standardization of detection methods. The notch 1 (NOTCH1) gene also has been found recurrently mutated in a subset of individuals, not independent of IGHV, and these individuals had a shorter survival. Chromosomal translocations (breakpoints) are rare in CLL. The cause of CLL is unknown.

Clinical manifestations

Chronic leukemia advances slowly and insidiously. Approximately 70% of individuals with CLL are asymptomatic at the time of diagnosis. When symptoms do appear, the most common finding is lymphadenopathy. The most significant effect of CLL is suppression of humoral immunity and increased infection with encapsulated bacteria. Frequently, the level of neutrophils is depressed, which adds to the risk of infection. Invasion of most organ cells is uncommon but infiltration does occur in lymph nodes, liver, spleen, and salivary glands. Central nervous system (CNS) involvement is rare. Approximately 10% of individuals develop a more aggressive malignancy, usually a diffuse large B-cell lymphoma. In these individuals, extreme fatigue, weight loss, night sweats, low-grade fever, elevated levels of the enzyme lactic dehydrogenase, hypercalcemia, anemia, and thrombocytopenia are common.

Individuals with CML may progress through three phases of the disease: a chronic phase lasting 2 to 5 years during which symptoms may not be apparent, an accelerated phase of 6 to 18 months during which the primary symptoms develop, and a terminal blast phase (“blast crisis”) with a survival of only 3 to 6 months. The accelerated phase is characterized by excessive proliferation and accumulation of malignant cells. Splenomegaly is prominent and becomes painful, but lymphadenopathy generally is not present. Liver enlargement also occurs, but liver function is rarely altered. Hyperuricemia is common and produces gouty arthritis. Infections, fever, and weight loss also are seen often. The terminal blast phase is characterized by rapid and progressive leukocytosis with an increase in basophils. In the later stages of the terminal phase, which then resembles AML, blast cells or
promyelocytes predominate, and the individual experiences a “blast crisis.”

The acute effects of CML resemble those of acute leukemia but with more prominent and painful splenomegaly. Liver function rarely is altered despite enlargement, and lymphadenopathy generally is found only in the acute phase of the disease. Hyperuricemia invariably is present and produces gouty arthritis. Infections, fever, and weight loss are common findings in individuals with CML.

**Evaluation and treatment**

Diagnosis of chronic leukemia depends on laboratory analyses of peripheral blood and bone marrow. Diagnosis of CLL is based on detection of a monoclonal B-cell lymphocytosis in the blood. The cells must have the characteristic immunophenotype (CD5+, and CD23-positive B cells) at levels in excess of 5000 cells/µL over a sustained period of time (usually 4 weeks). Confusion with other diseases may be avoided by determination of cell surface markers. CLL lymphocytes co-express the B-cell antigens CD19 and CD20 along with the T-cell antigen CD5. This co-expression only occurs in one other disease entity, mantle cell lymphoma. Bone marrow may contain more than 30% lymphocytes and be normocellular or hypercellular. As assays have become more sensitive for detecting monoclonal B-CLL-like cells in peripheral blood, researchers have detected a monoclonal B-cell lymphocytosis (MBL) in 3% of adults older than 40 years and in 6% of adults older than 60 years. Such early detection and diagnosis may falsely suggest improved survival for the group and may unnecessarily worry or result in therapy for some individuals who would have remained undiagnosed in their lifetime, a circumstance known in the literature as overdiagnosis or pseudodisease.

Treatment of CLL ranges from periodic observation with treatment of infection, hemorrhage, or immunologic complications to a variety of options including steroids, alkylating agents, purine analog drugs, combination chemotherapy, monoclonal antibodies, and transplant options. For individuals with progressing CLL, treatment with conventional doses of chemotherapy is not curative; selected individuals treated with allogeneic stem cell transplantation have achieved prolonged disease-free survival. Antileukemic therapy is frequently unnecessary in uncomplicated early disease. From older clinical trials (1970s through the 1990s), the median survival for all individuals ranges from 8 to 12 years. However, a large variation in survival exists, ranging from several months to a normal life expectancy. Treatment must be individualized based on the clinical behavior of the disease. Ongoing clinical trials are testing the concept of T cells directed at specific antigen targets with engineered chimeric antigen receptors. Complications of pancytopenia, including hemorrhage and infection, are a major
cause of death for these individuals.

The development and introduction of the tyrosine kinase inhibitor imatinib mesylate (Gleevec) as a treatment modality have changed current management of CML. Imatinib mesylate is highly specific for CML and suppression of BCR-ABL kinase activity and produces a complete cytogenetic response in more than 80% of newly diagnosed persons. Although the BCR-ABL inhibitors markedly decrease the number of BCR-ABL–positive cells in the marrow and other places, they do not extinguish the CML stem cell, which persists at low levels.\textsuperscript{34}

**Quick Check 21-3**

1. How are leukemias classified?

2. What is the pathogenesis of ALL?

3. What is the significance of the Philadelphia chromosome, and how is it related to leukemia?
Alterations of Lymphoid Function

Lymphadenopathy

Lymphadenopathy is characterized by enlarged lymph nodes (Figure 21-10). Lymph node enlargement occurs because of an increase in the size and number of its germinal centers caused by proliferation of lymphocytes and monocytes (immature phagocytes) or invasion by malignant cells. Normally, lymph nodes are not palpable or are barely palpable. Enlarged lymph nodes are characterized by being palpable and often also may be tender or painful to touch, although not in all situations.
Localized lymphadenopathy usually indicates drainage of an area associated with an inflammatory process or infection (reactive lymph node). Generalized lymphadenopathy occurs less often and is generally seen in the presence of malignant or nonmalignant disease, particularly in adults. Palpable nodes, however, do not always indicate serious disease and may indicate a minor trauma or infection. The location and size of the enlarged nodes are important factors in diagnosing the cause of the lymphadenopathy, as are the individual's age, gender, and geographic location. Generalized lymphadenopathy occurs with non-Hodgkin lymphomas, chronic lymphocytic leukemia, histiocytosis, and disorders that produce
lymphocytosis. In general, lymphadenopathy results from four types of conditions: (1) neoplastic disease, (2) immunologic or inflammatory conditions, (3) endocrine disorders, or (4) lipid storage diseases. Diseases of unknown cause, including autoimmune diseases and reactions to drugs, also may lead to generalized lymphadenopathy.

**Malignant Lymphomas**

Lymphomas consist of a diverse group of neoplasms that develop from the proliferation of malignant lymphocytes in the lymphoid system (immune system). European and American pathologists have proposed a new classification for lymphoid malignancies—the Revised European American Lymphoma (REAL) classification. The World Health Organization (WHO) modification of the REAL classification recognizes three major categories of lymphoid malignancies based on morphology and cell lineage: (1) B-cell neoplasms; (2) T-cell/natural killer (NK)–cell neoplasms; and (3) Hodgkin lymphoma (Box 21-2); two basic categories of lymphomas are Hodgkin lymphoma and non-Hodgkin lymphoma. Non-Hodgkin lymphoma can be further divided into cancers that have an *indolent* or slow-growing course and those with an *aggressive* or fast-growing course. These different subtypes progress and respond to treatment differently. Both Hodgkin lymphoma and non-Hodgkin lymphoma occur in children and adults and the overall treatment and prognosis depend on the stage and type of lymphoma.

**Box 21-2**

**Updated REAL/WHO Classification**

**B-Cell Neoplasms**

1. Precursor B cell: precursor B-acute lymphoblastic leukemia/lymphoblastic lymphoma (LBL)

2. Peripheral B-cell neoplasms

   a. B-cell CLL/small lymphocytic lymphoma

   b. B-cell prolymphocytic leukemia
c. Lymphoplasmacytic lymphoma/immunocytoma

d. Mantle cell lymphoma

e. Follicular lymphoma

f. Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphatic tissue (MALT) type

g. Nodal marginal zone B-cell lymphoma (± monocytoid B cell)

h. Splenic marginal zone lymphoma (± villous lymphocytes)

i. Hairy cell leukemia

j. Plasmacytoma/plasma cell myeloma

k. Diffuse large B-cell lymphoma

l. Burkitt lymphoma

**T-Cell and Putative NK-Cell Neoplasms**

1. Precursor T-cell neoplasm: precursor T-cell acute lymphoblastic leukemia/LBL

2. Peripheral T-cell and NK-cell neoplasms

a. T-cell CLL/prolymphocytic leukemia

b. T-cell granular lymphocytic leukemia
c. Mycosis fungoides/Sézary syndrome

d. Peripheral T-cell lymphoma, not otherwise characterized

e. Hepatosplenic gamma/delta T-cell lymphoma

f. Subcutaneous panniculitis-like T-cell lymphoma

g. Angioimmunoblastic T-cell lymphoma

h. Extranodal T-/NK-cell lymphoma, nasal type

i. Enteropathy-type intestinal T-cell lymphoma

j. Adult T-cell lymphoma/leukemia (human T-lymphotrophic virus type 1 [HTLV-1])

k. Anaplastic large cell lymphoma, primary systemic type

l. Anaplastic large cell lymphoma, primary cutaneous type

m. Aggressive NK-cell leukemia

**Hodgkin Lymphoma**

1. Nodular lymphocyte-predominant Hodgkin lymphoma

2. Classic Hodgkin lymphoma

a. Nodular sclerosis Hodgkin lymphoma
b. Lymphocyte-rich classic Hodgkin lymphoma

c. Mixed cellularity Hodgkin lymphoma

d. Lymphocyte-depleted Hodgkin lymphoma

Lymphoma is the most common blood cancer in the United States. Incidence rates of lymphoma differ with respect to age, gender, geographic location, and socioeconomic class. The estimated new cases of lymphoma include 9190 cases of Hodgkin lymphoma and 70,800 cases of non-Hodgkin lymphoma. It was estimated in 2014 that 18,990 will die from non-Hodgkin lymphoma and 1180 from Hodgkin lymphoma. Since the early 1970s, the incidence of non-Hodgkin lymphoma has nearly doubled. The exact reason for this increase remains a mystery; however, a modest portion of the increase had been attributed to lymphomas developing in association with immune deficiencies, including AIDS and organ transplants. Conversely, the incidence of Hodgkin lymphoma has declined over the same time period, especially among older adults.

In general, lymphomas are the result of genetic mutations or viral infection. Malignant transformation produces a cell with uncontrolled and excessive growth that accumulates in the lymph nodes and other sites, producing tumor masses.

**Hodgkin Lymphoma**

**Hodgkin lymphoma (HL)** is a malignant lymphoma that progresses from one group of lymph nodes to another, including the development of systemic symptoms, and the presence of B cells called **Reed-Sternberg (RS) cells**. In about 70% of cases, RS cells are infected with EBV. The incidence of HL is approximately 3.1/100,000 males and 2.4/100,000 females and peaks at two different times—during the second and third decades of life and later during the sixth and seventh decades. The incidence is greater in whites than in blacks, with Denmark, the Netherlands, and the United States having the highest incidence and Japan and Australia having the lowest.

**Pathophysiology**

It is widely accepted that the Reed-Sternberg (RS) cell represents the malignant transformed lymphocyte (Figure 21-11). The RS cells are often large and binucleate with occasional mononuclear variants. The RS cells are necessary for the diagnosis of HL; however, they are not specific to HL. In rare instances, cells resembling RS
cells can be found in benign illnesses, as well as in other forms of cancer, including non-Hodgkin lymphomas and solid tissue cancers and in infectious mononucleosis.

The triggering mechanism for the malignant transformation of cells remains unknown. Classic HL appears to be derived from a B cell in the germinal center that has not undergone successful immunoglobulin gene rearrangement (see Chapter 7) and would normally be induced to undergo apoptosis. Survival of this cell may be linked to infection with Epstein-Barr virus (EBV). Laboratory and epidemiologic studies have linked HL with EBV infections, and EBV DNA, RNA, and proteins are frequently observed in HL cells. The EBV epigenome poses a variety of viral-encoded and host-cell factors that control epigenetic regulation by expanding tissue growth, evading immune detection, and driving host-cell carcinogenesis. The RS cells secrete and release cytokines (e.g., interleukin-10 [IL-10], transforming growth factor-beta [TGF-β]) that result in the accumulation of inflammatory cells, which produces the local and systemic effects. HL is subcategorized into two main types: classic Hodgkin and nodular lymphocyte–predominant Hodgkin. Classic HL is subclassified into four types (see Box 21-2) based on the morphology of RS cells and the characteristics of the inflammatory cell infiltrate in the tumor. Lymphocyte-predominant disease presents with earlier-stage disease, longer survival, and fewer
treatment failures than classic HL. \(^{45}\) However, despite a more favorable prognosis, lymphocyte-predominant HL has a tendency to histologically transform into diffuse large B-cell lymphoma by 10 years in approximately 10% of people. \(^{46}\)

**Clinical manifestations**

Many clinical features of HL can be explained by the complex action of cytokines and other growth factors that are secreted and released by the malignant cells. These substances induce infiltration and proliferation of inflammatory cells, resulting in an enlarged, painless lymph node in the neck (often the first sign of HL) (Figure 21-12). The discovery of an asymptomatic mediastinal mass on routine chest x-ray is not uncommon. The cervical, axillary, inguinal, and retroperitoneal lymph nodes are commonly affected in HL (Figure 21-13). Local symptoms caused by pressure and obstruction of the lymph nodes are the result of the lymphadenopathy.
About one third of individuals will have some common systemic symptoms, such as intermittent fever, without other symptoms of infection, drenching night sweats, itchy skin (pruritus), and fatigue. These constitutional symptoms accompanied by weight loss are associated with a poor prognosis.

Although HL rarely arises in the lung, mediastinal and hilar node adenopathy can cause secondary involvement of the trachea, bronchi, pleura, or lungs. Retroperitoneal nodes can involve vertebral bodies and nerves and also can cause displacement of ureters. Spinal cord involvement is more common in the dorsal and lumbar regions than in the cervical region. Skin lesions, although uncommon, include psoriasis and eczematoïd lesions, causing itching and scratching.

As a result of direct invasion from mediastinal lymph nodes, pericardial
involvement can cause pericardial friction rub, pericardial effusion, and engorgement of neck veins. The GI tract and urinary tract are rarely involved. Anemia is often found in individuals with HL accompanied by a low serum iron level and reduced iron-binding capacity. Other laboratory findings include elevated sedimentation rate, leukocytosis, and eosinophilia. Leukopenia occurs in advanced stages of HL.

Splenic involvement in HL depends on histologic type. In mixed cellularity and lymphocytic deletion types of HL, the spleen is involved in 60% of cases. With lymphocyte and nodular sclerosis types, 34% of cases involve the spleen.
Evaluation and treatment

Because of the variability in symptoms, early definitive detection may be challenging. Asymptomatic lymphadenopathy can progress undetected for several years. Diagnosis is made from physical examination and history, complete blood count, blood chemistry studies including sedimentation rate, lymph node biopsy, pathology review for Reed-Sternberg cells, and immunophenotyping for disease markers. Clinical staging for individuals with HL includes personal history; physical examination; laboratory studies, including sedimentation rate; and thoracic and abdominal/pelvic CT scans (Table 21-7). Positron emission tomography (PET) scans, usually combined with CT scans, have replaced gallium scans and lymphangiography for clinical staging. Staging laparotomy is no longer recommended; it should be considered only when the results will allow substantial reduction in treatment. It should not be done in individuals who require chemotherapy. If the laparotomy is required for treatment decisions, the risks of potential morbidity should be considered. Prognostic indicators include clinical stage, histologic type, tumor cell concentration and tumor burden, constitutional symptoms, and age of the individual.

The effectiveness of treatment is related to the age, gender, and general health of the individual; signs and symptoms; stage of the disease; blood test results; type of Hodgkin lymphoma; and classification of the disease as recurrent or progressive. Adult Hodgkin lymphoma can usually be cured with early diagnosis and treatment. Three types of treatment are used: chemotherapy, radiation therapy, and surgery. Treatment for pregnant women includes watchful waiting and steroid therapy.
Newer treatments undergoing testing include chemotherapy and radiation therapy with stem cell transplant and monoclonal antibody therapy. Treatment with chemotherapy or radiation therapy, or both, may increase the risk of second cancers, cardiovascular disease, and other health problems for many months or years after treatment.

Non-Hodgkin Lymphomas

The NHLs are a heterogeneous group of proliferative lymphoid tissue neoplasms with differing clinical patterns of behavior and responses to treatment. The previously used generic classification of non-Hodgkin lymphoma (NHL) has been reclassified in the WHO/REAL scheme into (1) B-cell neoplasms, a group that consists of a variety of lymphomas including myelomas that originate from B cells at various stages of differentiation; and (2) T-cell and NK-cell neoplasms, a group that includes lymphomas that originate from either T or NK cells. These cancers are differentiated from HL by lack of RS cells and other cellular changes not characteristic of HL.

More than 70,800 new cases of NHL and 18,990 deaths are predicted for 2014. The median age of diagnosis is 67 years and the highest incidences of NHL are in North America, Europe, Oceania, and several African countries. The occurrence of NHL is higher in men than in women. For unknown reasons, incidence increased in many high-income countries between the 1950s and 1990s and no further increase has been observed during the last decade. Part of the increased incidence has been attributed to diagnostic improvements as well as AIDS-related cancers following the HIV epidemic. Conversely, the mortality has risen at a slower rate. It is thought that newer treatment modalities are improving survival rates.

Pathophysiology

NHL is best described as a progressive clonal expansion of B cells, T cells, or NK cells. B cells account for 85% to 90% of NHLs, with most of the remainder being T cells and rarely NK cells. Oncogenes may be activated by chromosomal translocations or the tumor-suppressor loci may be inactivated by deletion or mutation of chromosomes. Certain subtypes may have altered genomes by oncogenic viruses. The various subtypes of NHL may be identified by specific diagnostic markers related to various cytogenetic lesions. The most common type of chromosomal alteration in NHL is translocation, which disrupts the genes encoded at the breakpoints. Unlike Hodgkin lymphoma, NHL spreads in a less predictable way and spreads widely early. Diffuse large B-cell lymphoma (DLBCL) is the most common form of NHL.
Risk factors for adult NHL include being older, male, or white and having one of the following: afflicted by certain inherited immune disorders, an autoimmune disease, or HIV/AIDS; exposure to a variety of mutagenic chemicals or certain pesticides; infection with certain cancer-related viruses (e.g., Epstein-Barr virus, HIV, HTLV-1); consumption of a diet high in meats and fat; and use of immunosuppression drugs after an organ transplant. Gastric infection with *Helicobacter pylori* increases the risk for gastric lymphomas. NHL is a disease of middle age, usually found in persons more than 50 years old.

**Clinical manifestations**

Clinical manifestations of NHL usually begin as localized or generalized lymphadenopathy, similar to HL. Differences in clinical features are noted in Table 21-8. The cervical, axillary, inguinal, and femoral lymph node chains are the most commonly affected sites. Generally, the swelling is painless and the nodes have enlarged and transformed over a period of months or years. Other sites of involvement are the nasopharynx, GI tract, bone, thyroid, testes, and soft tissue. Some individuals have retroperitoneal and abdominal masses with symptoms of abdominal fullness, back pain, ascites (fluid in the peritoneal cavity), skin rash or itchy skin, fatigue, fever of unknown origin, drenching night sweats, and leg swelling.

*Fever, weight loss, night sweats.

Lymphomas are classified as low, intermediate, or high grade. A low-grade lymphoma, which also may be termed *indolent*, has a slow progression. Individuals with low-grade lymphoma commonly present with a painless, peripheral adenopathy. Spontaneous regression of these nodes may occur, mimicking the presence of an infection. Night sweats with an elevated temperature (more than 38°C [100.4°F]) and weight loss, as well as extranodular involvement, are not
commonly present in the early stages but are common in advanced or end-stage disease. Cytopenia, or reduction in the number of blood cells, reflective of bone marrow involvement is often observed. Hepatomegaly is common; however, splenomegaly is present in approximately 40% of individuals. Fatigue and weakness are more prevalent with advanced stages.

Intermediate and high-grade lymphomas, which are more aggressive, have a more varied clinical presentation. A high-grade lymphoma also may be termed aggressive.

**Evaluation and treatment**

The primary means for diagnosis of NHL is physical examination and history, blood tests, urine tests, flow cytometry, and bone marrow aspirate and biopsy. A common finding in NHL is noncontiguous lymph node involvement, which is not common in HL.

Treatment for NHL is quite diverse and depends on type (B cell or T cell), tumor stage, histologic status (low, intermediate, or high grade), symptoms, age, and presence of comorbidities. Depending on the type (B cell or T cell) of the tumor, stage of disease, and aggressiveness of the tumor, treatment is usually initiated at the time of diagnosis. However, because treatment is not curative for some low-grade indolent lymphomas that are widely disseminated, observation without treatment may be the most appropriate choice. These indolent tumors are often not symptomatic for the individual and this approach improves quality of life. In some cases the disease may be so slow growing that treatment is not needed for an extended period of time.

Standard treatment for NHL includes radiation therapy, chemotherapy, target therapy (monoclonal antibody therapy, proteasome inhibitor therapy), plasmapheresis (if the blood becomes thick), biologic therapy (e.g., interferon), and watchful waiting. Several factors affect prognosis, including the stage of the cancer, the type of NHL, the blood levels of lactate dehydrogenase, the amount of β₂-microglobulin in the blood (for Waldenström macroglobulinemia), the age and general health of the patient, and the properties of the lymphoma (i.e., whether it was recently diagnosed or is a recurrence). Indolent NHL types can have a median survival as long as 20 years but are not curable in advanced stages. Those with the aggressive type of NHL have a more limited survival but a significant number of individuals can achieve a cure with an intensive combination of chemotherapy. With modern treatments for NHL, the overall survival at 5 years for nonaggressive NHL is >60%, and for aggressive types >50%. High-grade NHL is seen with increasing frequency in persons with AIDS and has an extremely poor prognosis. New research suggests that a novel therapeutic approach may hold promise for
individuals with chemotherapy-refractory advanced large B-cell lymphoma and indolent B-cell malignancies using engineered T cells that express an anti-CD19 chimeric antigen receptor.52

**Burkitt lymphoma.**

*Burkitt lymphoma* is a B-cell tumor with unique clinical and epidemiologic features. Although more common in Africa, Burkitt lymphoma is not confined to the African continent and is documented in the United States, Latin America, and other countries. Classification of Burkitt lymphoma includes (1) African (endemic) Burkitt lymphoma, (2) sporadic (nonendemic) Burkitt lymphoma, and (3) a subset of aggressive lymphomas in individuals infected with HIV. Burkitt lymphomas, in these classifications, are histologically identical but differ in some genetic, virologic, and clinical characteristics.34 Burkitt lymphoma is a fast-growing tumor that often appears as a large tumor mass in the jaw and sometimes the abdomen (Figure 21-14). It is now understood that Burkitt lymphoma is heterogeneous and pathologic confirmation is sometimes challenging.

![](FIGURE_21-14_Burkitt_Lymphoma.png)

**FIGURE 21-14 Burkitt Lymphoma.** Burkitt lymphoma involving the jaw in a young African boy. (Courtesy I. Magrath, MD, Bethesda, Md. From Zitelli BJ et al: Zitelli and Davis’ atlas of pediatric physical diagnosis, ed 6, Philadelphia, 2012, Saunders.)

Pathophysiology
Basically, all endemic Burkitt lymphomas are latently infected with EBV, which also is present in about 25% of HIV-associated tumors and 15% to 20% of sporadic cases.\textsuperscript{34} It is suspected that suppression of the immune system by other illnesses (e.g., HIV infection, chronic malaria) increases the individual's susceptibility to EBV. B cells are particularly sensitive because of specific surface receptors for EBV. As a result, the B cell undergoes chromosomal translocations that result in overexpression of the \textit{c-MYC} proto-oncogene and loss of control of cell growth (Figure 21-15). The most common translocation (75% of individuals) is between chromosomes 8 (containing the \textit{c-MYC} gene) and 14 (containing the immunoglobulin heavy chain genes). When the t(8;14) translocation occurs, the MYC gene becomes regulated by the B-cell immunoglobulin gene (\textit{IG}) on chromosome 14 and overproduction of MYC protein forces proliferation and blocks cellular differentiation. MYC is a transcriptional regulator that increases genes responsible for aerobic glycolysis (Warburg effect). When glucose and glutamine are available, the Warburg metabolism enables cells to synthesize nutrients that are needed for growth and cell division. Therefore, investigators believe that Burkitt lymphoma is the fastest growing tumor.\textsuperscript{34} Other translocations have been reported between chromosome 8 and chromosomes 2 or 22, which contain genes for immunoglobulin light chains.
Clinical manifestations
The endemic and sporadic Burkitt lymphomas (the most common type in the United States and without obvious infectious cofactors) are found mostly in children or young adults. Most tumors manifest at extranodal locations. Endemic Burkitt lymphoma usually presents as a mass of the mandible and an unusual tendency for involvement of the abdominal viscera, including the kidneys, ovaries, and adrenal glands. Sporadic Burkitt lymphoma usually appears as a mass involving the ileocecum and peritoneum. More advanced disease may involve other organs—eyes, ovaries, kidneys, glandular tissue (breast, thyroid, tonsil)—and presents with type B symptoms (night sweats, fever, weight loss).

Evaluation and treatment
The distribution of tumors and biopsies of enlarged lymph nodes or the bone marrow containing malignant B cells are usually indicative of Burkitt lymphoma. It is one of the most aggressive and quickly growing malignancies. Burkitt lymphoma, however, responds successfully to intensive chemotherapy in most children and adults. The outcome is more cautious in older adults.

Lymphoblastic lymphoma.
**Lymphoblastic lymphoma (LL)** is a relatively rare variant of NHL overall (2% to 4%) but accounts for almost one third of cases of NHL in children and adolescents, with a male predominance. The vast majority of LL (90%) is of T-cell origin; the remainder arises from B cells. LL is similar to acute lymphoblastic leukemia and may be considered a variant of that disease.

**Pathophysiology**
The disease arises from a clone of relatively immature T cells that becomes malignant in the thymus. As with most lymphoid tumors, LL is frequently associated with translocations, primarily of the chromosomes that encode for the T-cell receptor (chromosomes 7 and 14). These aberrations result in increased expression of a variety of transcription factors and loss of growth control.

**Clinical manifestations**
The first sign of LL is usually a painless lymphadenopathy in the neck. Peripheral lymph nodes in the chest become involved in about 70% of individuals. Involved nodes are located mostly above the diaphragm. LL is a very aggressive tumor that presents as stage IV in most people. T-cell LL is associated with a unique mediastinal mass (up to 75%) because of the apparent origin of the tumor in the thymus. The mass results in dyspnea and chest pain and may cause compression of bronchi or the superior vena cava. The tumor may infiltrate the bone marrow in about half of those affected, and suppression of bone marrow hematopoiesis leads to increased susceptibility to infections. Other organs, including the liver, kidney, spleen, and brain, also may be affected. Many individuals express type B symptoms: fever, night sweats, and significant weight loss.

**Evaluation and treatment**
The most common therapeutic approach is combined chemotherapy (intensive therapy). Bulky tumor masses are sometimes treated with radiation therapy. In early stages of the disease, the response rate is high with increased survival; the 5-year survival in children is 80% to 90% and 45% to 55% in adults. Although LL is easily treated, there is a high relapse rate: 40% to 60% of adults.

**Multiple myeloma.**
**Multiple myeloma (MM)** is a plasma cell (a white blood cell neoplasm called myeloma cells) cancer characterized by the slow proliferation of malignant cells, with tumor cell masses in the bone marrow usually resulting in destruction of the bone (Figure 21-16). Myeloma cells reside in the bone marrow and are usually not
found in the peripheral blood. As the number of myeloma cells increases, fewer red blood cells, white blood cells, and platelets are produced. Myeloma may spread to other tissues, especially in very advanced stages of the disease. The reported incidence of MM has doubled in the past 2 decades, possibly as a result of more sensitive testing used for diagnosis. The annual incidence rate in the United States is 6.1/100,000, with 24,050 new cases estimated for 2014. Multiple myeloma occurs in all races, but the incidence in blacks is about twice that of whites. It rarely occurs before the age of 40 years—the peak age of incidence is between 65 and 70 years. It is slightly more common in men (7.7 estimated new cases per 100,000 persons) than in women (4.9 new cases per 100,000 persons). Other risk factors include exposure to radiation or certain chemicals and a history of monoclonal gammopathy of undetermined significance (MGUS, see Clinical Manifestations) or plasmacytoma.

**Pathophysiology**

MM is a plasma cell neoplasia that causes lytic bone lesions (bony disease; radiologically appears as punched-out defects), hypercalcemia, renal failure, anemia, and immune abnormalities. Multiple mutations in different pathways alter the intrinsic biology of the plasma cell, generating the features of myeloma.
MM tumors are highly heterogeneous.\textsuperscript{56} Investigators observed frequent mutations in KRAS, NRAS, BRAF, FAM46C, TP53, and DIS3 and many mutations were found in the same pathway.\textsuperscript{56} Defining driver mutations and heterogeneity is essential for treatment decisions. Many myelomas are aneuploidy and, in most individuals with myeloma, chromosomal translocations are the most common. The primary translocation involves the immunoglobulin heavy chain on chromosome 14 (IgH locus) that relocates to loci containing genes of the cell cycle (cyclins) on chromosomes 11(q13), 12(p13), and 6(p21); oncogenes on chromosomes 16(q23), 8(q24), and 20; and fibroblast growth factor receptor on chromosome 4(p16).\textsuperscript{57} Other reported chromosomal abnormalities include deletion of chromosome 13 and deletion of chromosome 17 on which tumor-suppressor gene TP53 is localized.\textsuperscript{57} Development of further secondary genetic alterations causes progression to an aggressive MM. Investigators are studying various epigenetic alterations and interactions with extracellular matrix proteins. For example, myeloma cells interact and secrete peptides that adhere to stromal cells, inducing cytokines that possibly promote inflammation. Myeloma cells are prone to the accumulation of misfolded protein, such as unpaired Ig chains. Misfolded proteins activate apoptosis.

Malignant plasma cells arise from one clone of B cells that produce abnormally large amounts of one class of immunoglobulin (usually IgG, occasionally IgA, and rarely IgM, IgD, or IgE). The malignant transformation may begin early in B-cell development, possibly before encountering antigen in the secondary lymphoid organs. The myeloma cells return either to the bone marrow or to other soft tissue sites. Their return is aided by cell adhesion molecules that help them target favorable sites that promote continued expansion and maturation. Cytokines, particularly interleukin-6 (IL-6), have been identified as essential factors that promote the growth and survival of multiple myeloma cells. (Lymphocytes and cytokines are described in Chapter 5.)

Myeloma cells in the bone marrow produce several cytokines themselves (e.g., IL-6, IL-1, IL-11, TNF-α). IL-6 in particular acts as an osteoclast-activating factor and stimulates osteoclasts to reabsorb bone. This process results in bone lesions and hypercalcemia (high calcium levels in the blood) attributable to the release of calcium from the breakdown of bone.

The antibody produced by the transformed plasma cell is frequently defective, containing truncations, deletions, and other abnormalities, and is often referred to as a paraprotein (abnormal protein in the blood). Because of the large number of malignant plasma cells, the abnormal antibody, called the M protein, becomes the most prominent protein in the blood (see Figure 21-18, p. 539). Suppression of normal plasma cells by the myeloma results in diminished or absent normal antibodies. The excessive amount of M protein also may contribute to many of the
clinical manifestations of the disease. Frequently, the myeloma produces free immunoglobulin light chain (Bence Jones protein) that is present in the blood and urine and contributes to damage of renal tubular cells.

Clinical manifestations

The common presentation of MM is characterized by elevated levels of calcium in the blood (hypercalcemia), renal failure, anemia, and bone lesions. The hypercalcemia and bone lesions result from infiltration of the bone by malignant plasma cells and stimulation of osteoclasts to reabsorb bone. This process results in the release of calcium (hypercalcemia) and the development of “lytic lesions” (round, “punched out” regions of bone) (Figure 21-17). Destruction of bone tissue causes pain, the most common presenting symptom, and pathologic fractures. The bones most commonly involved, in decreasing order of frequency, are the vertebrae, ribs, skull, pelvis, femur, clavicle, and scapula. Spinal cord compression, because of the weakened vertebrae, occurs in about 10% of individuals. A condition called amyloidosis may occur, in which antibody proteins increase and stick together in peripheral nerves and organs, such as the kidney and heart. Signs and symptoms of amyloidosis include fatigue, purple spots on the skin, enlarged tongue, diarrhea, edema, and numbness or tingling in the legs and feet.
Proteinuria is observed in 90% of individuals. Renal failure may be either acute or chronic and is usually secondary to the hypercalcemia. Bence Jones protein may lead to damage of the proximal tubules. Anemia is usually normocytic and normochromic and results from inhibited erythropoiesis caused by tumor cell infiltration of the bone marrow.

The high concentration of paraprotein in the blood may lead to hyperviscosity syndrome. The increased viscosity interferes with blood circulation to various sites (brain, kidneys, extremities). Hyperviscosity syndrome is observed in up to 20% of persons. Additional neurologic symptoms (e.g., confusion, headaches, blurred vision) may occur secondary to hypercalcemia or hyperviscosity.

Suppression of the humoral (antibody-mediated) immune response results in repeated infections, primarily pneumonias and pyelonephritis. The most commonly involved microorganisms are encapsulated bacteria that are particularly sensitive to the effects of antibody; pneumonia caused by *Streptococcus pneumoniae*, *Staphylococcus aureus*, or *Klebsiella pneumonia*; or pyelonephritis caused by *Escherichia coli* or other gram-negative organisms. Cell-mediated (T-cell) function
is relatively normal. Overwhelming infection is the leading cause of death from MM.

MM is a progressive disorder and is often preceded by a condition known as **monoclonal gammopathy of undetermined significance (MGUS)**. MGUS is diagnosed by the presence of an M protein in the blood or urine without additional evidence of MM. \(^5^8\) MGUS is present in approximately 1% of the general population and in 3% of individuals older than 70 years. Although MGUS is considered nonpathologic and requires no treatment, about 2% of individuals with MGUS progress to malignant plasma cell disorders. Progression of MM following MGUS advances to asymptomatic MM and finally symptomatic MM. Asymptomatic MM also may be referred to as **smoldering myeloma** and indolent myeloma. \(^5^8\)

Smoldering myeloma is usually characterized by the presence of an M protein and clonal bone marrow plasma cells, but with no indication of end-organ damage.

**Evaluation and treatment**

Diagnosis of MM is made by symptoms and radiographic and laboratory studies; a definitive diagnosis requires a bone marrow biopsy. The International Myeloma Working Group's new criteria \(^5^8\) for the diagnosis of multiple myeloma include biomarkers (monoclonal components in serum and urine; quantification of IgG, IgA, and IgM immunoglobulins; and characterization of the heavy and light chains by immunofixation) and the presence of hypercalcemia, renal failure, anemia, and bone lesions (CRAB). Other criteria include evaluation of bone marrow plasma cell infiltration by bone marrow biopsy and radiologic evaluation of lytic bone lesions. Biomarkers based on quantitation of plasma cells (serum-free light chains) may help stratify risk for people with asymptomatic multiple myeloma and identification, staging, prognosis, and monitoring of those with smoldering multiple myeloma who are at an “ultra-high” risk of developing aggressive multiple myeloma.

New techniques use microRNAs extracted from serum to measure immunoglobulins (IgG, IgM, IgA). Typically, one class of immunoglobulin (the M protein produced by the myeloma cell) is greatly increased, whereas the others are suppressed. Serum electrophoretic analysis shows increased levels of M protein (**Figure 21-18**). Because the M protein is monoclonal, each molecule has the same electric charge and migrates at about the same site on electrophoresis, resulting in a highly concentrated protein (M spike) (see **Figure 21-18**). Bence Jones protein may be observed in the urine or serum by immunoelectrophoresis or in the serum using available enzyme-linked immunosorbent assays (ELISAs). Usually an intact antibody paraprotein coexists with Bence Jones protein. However, variants of MM include individuals in which free light chain only is produced and a rare variant that
produces only free heavy chain; about 1% of cases are nonsecretory so that neither M protein nor Bence Jones protein is produced. Measurement of another protein, free β2-microglobulin, is used as an indicator of prognosis or effectiveness of therapy.

![Figure 21-18](image)

**Figure 21-18**  M Protein. Serum protein electrophoresis (PEL) is used to screen for M proteins in multiple myeloma. A, In normal serum the proteins separate into several regions between albumin (Alb) and a broad band in the gamma (γ) region, where most antibodies (gamma globulins) are found. Immunofixation (IFE) can identify the location of IgG (G), IgA (A), IgM (M), and kappa (κ) and lambda (λ) light chains. B, Serum from an individual with multiple myeloma contains a sharp M protein (M spike). The M protein is monoclonal and contains only one heavy chain and one light chain. In this instance the IFE identifies the M protein as an IgG containing a lambda light chain. C, Serum and urine protein electrophoretic patterns in an individual with multiple myeloma. Serum demonstrates an M protein (Immunoglobulin) in the gamma region, and the urine has a large amount of the smaller-sized light chains with only a small amount of the intact immunoglobulin. (A and B from Abeloff M et al: Abeloff's clinical oncology, ed 4, Philadelphia, 2008, Churchill Livingstone. C from McPherson R, Pincus M: Henry's clinical diagnosis and management by laboratory methods, ed 22, Edinburgh, 2012, Saunders.)

Although combinations of chemotherapy, radiation therapy, plasmapheresis (exchange), and stem cell transplant have been used for treatment, the prognosis for persons with MM remains poor. However, with the new high-sensitivity biomarkers that are associated with inevitable development of clinical symptoms, early diagnosis and treatment may be possible before individuals develop more advanced disease and organ damage. Conventional combinations of chemotherapeutic agents have included melphalan and prednisone (MP); MP with vincristine, carmustine,
cyclophosphamide; vincristine, doxorubicin, and dexamethasone; and thalidomide and dexamethasone. The drug thalidomide disrupts the stromal marrow–MM cell interaction by modulating cell surface adhesion molecules and inhibiting angiogenesis. In addition, it increases apoptosis and G_1 growth arrest (i.e., the cell cycle gap 1; see Chapter 1) of MM cells. Hematopoietic stem cell transplantation has prolonged life but has not yet proven to be curative. Controversy exists concerning whether tandem stem cell transplant offers the best outcome. Biphosphonate therapy is the primary treatment for bone lesions. Individuals with multiple bone lesions, if untreated, rarely survive more than 6 to 12 months. Individuals with inactive (indolent) myeloma, however, can survive for many years. With chemotherapy and aggressive management of complications, the prognosis can improve significantly, with a median survival of 24 to 30 months and a 10-year survival rate of 3%. Promising new therapies include the use of proteasome inhibitors because proteasome degrades misfolded and unwanted proteins. The rates of new myeloma cases are increasing 0.7% each year and the death rates have decreased an average of 1.3% each year from 2002 to 2011. The 5-year survival for all stages of MM is 45.1%.

3. What are the main pathologic features of multiple myeloma?
Alterations of Splenic Function

The complexities of splenic function are not totally understood and its mysteries are still being studied. The normal functions of the spleen that may impact disease states include (1) phagocytosis of blood cells and particulate matter (e.g., bacteria), (2) antibody production, (3) hematopoiesis, and (4) sequestration of formed blood elements. The spleen is part of the mononuclear phagocyte system and is involved in all systemic inflammations, hematopoietic disorders, and many metabolic disorders.

In the past, splenomegaly (enlargement of the spleen) has been associated with various disease states. It is now recognized that splenomegaly is not necessarily pathologic; an enlarged spleen may be present in certain individuals without any evidence of disease. Splenomegaly may be, however, one of the first physical signs of underlying conditions, and its presence should not be ignored. In conditions where splenomegaly is present, the normal functions of the spleen may become overactive, producing a syndrome known as hypersplenism. Hypersplenism is characterized by anemia, leukopenia, and thrombocytopenia alone or in combination. Some individuals may seek treatment for problems even though they have not met all the aforementioned clinical criteria; therefore, the relevance and significance of hypersplenism are still uncertain.

Pathophysiology

Specific conditions causing splenomegaly and resulting hypersplenism are many and are related to other categories of disease (Box 21-3). Different pathologic processes that produce splenomegaly are described briefly next.

Box 21-3

Diseases Related to Classification of Splenomegaly

Inflammation or Infection

Acute: viral (hepatitis, infectious mononucleosis, cytomegalovirus), bacterial (salmonella, gram negative), parasitic (typhoid)

Subacute or chronic: bacterial (subacute bacterial endocarditis, tuberculosis), parasitic (malaria), fungal (histoplasmosis), Felty syndrome, systemic lupus erythematosus, rheumatoid arthritis, thrombocytopenia
### Congestive

Cirrhosis, heart failure, portal vein obstruction (portal hypertension), splenic vein obstruction

### Infiltrative

Gaucher disease, amyloidosis, diabetic lipemia

### Tumors or Cysts

**Malignant:** polycythemia rubra vera, chronic or acute leukemias, Hodgkin lymphoma, metastatic solid tumors

**Nonmalignant: Hamartoma**

Cysts: true cysts (lymphangiomas, hemangiomas, epithelial, endothelial); false cysts (hemorrhagic, serous, inflammatory)

---

Acute inflammatory or infectious processes cause splenomegaly because of an increased demand for defensive activities. Acutely enlarged spleens secondary to infection may become so filled with erythrocytes that their natural rubbery resilience is lost and they become fragile and vulnerable to blunt trauma. Splenic rupture is a complication associated with infectious mononucleosis; rupture occurs mostly in males between days 4 and 21 of acute illness.

**Congestive splenomegaly** is accompanied by ascites, portal hypertension, and esophageal varices and is most commonly seen in those with hepatic cirrhosis. Splenic hyperplasia develops in disorders that increase splenic workload and is associated most commonly with various types of anemia (hemolytic) and chronic myeloproliferative disorders (i.e., polycythemia vera).

**Infiltrative splenomegaly** is caused by engorgement by the macrophages with indigestible materials associated with various “storage diseases.” Tumors and cysts cause actual growth of the spleen. Metastatic tumors in the spleen are rare and may result from primary tumors of the skin, lung, breast, and cervix.

### Clinical manifestations

Overactivity of the spleen results in hematologic alterations that affect all blood components. Sequestering of red blood cells, granulocytes, and platelets results in a reduction of all circulating blood cells. The spleen may sequester up to 50% of the
red blood cell population, thereby upsetting the normal physiologic concentration of red blood cells in the circulation. The rate of splenic pooling is directly related to spleen size and the degree of increased blood flow through it. Sequestering exposes the red blood cells to splenic conditions that accelerate destruction, further contributing to the decreased red blood cell concentration. Anemia is the result of these combined activities. Anemia may be further potentiated by an increase in blood volume, which produces a dilutional effect on the already reduced concentration of red blood cells. The dilutional effect, as well as the removal and destruction of red blood cells, depends primarily on the degree of splenomegaly.

White blood cells and platelets also are affected by sequestering, although not to the same degree as the red blood cell. Again, the size of the spleen is the determining factor in the number of cells sequestered.

**Evaluation and treatment**

Treatment for hypersplenism is splenectomy; however, it may not always be indicated. A splenectomy is considered necessary to alleviate the destructive effects on red blood cells. Clinical indicators should determine the need for splenectomy, not necessarily specific conditions. Splenectomy for splenic rupture is no longer considered mandatory because of the possibility of overwhelming sepsis after removal. Repair and preservation are now considered before the decision to remove the spleen. Splenectomy also may be performed as treatment for hairy cell leukemia, Felty syndrome, agnogenic myeloid metaplasia, thalassemia major, Gaucher disease, hemodialysis, splenomegaly, splenic venous thrombosis, and thrombotic thrombocytopenia purpura (TTP).

Individuals are able to lead normal lives after splenectomy but blood cell abnormalities often exist after removal of the spleen (i.e., red blood cells become thinner, broader, and wrinkled; white blood cell counts initially increase and then plateau; platelet counts rise after surgery and then stabilize). A major postoperative complication following splenectomy is overwhelming postsplenectomy infection (OPSI). Unless treated in time, OPSI may rapidly progress to septic shock and possibly disseminated intravascular coagulation (DIC, see p. 545).

2. What is Burkitt lymphoma?
3. Identify the major causes of splenomegaly. How does it differ from hypersplenism?
Hemorrhagic Disorders and Alterations of Platelets and Coagulation

The arrest of bleeding, or hemostasis, is dependent on adequate numbers of platelets, normal levels of coagulation factors, and absence of defects in vessels walls. The spectrum of abnormal bleeding varies widely from massive bleeds, such as rupture of large vessels like the aorta, to small bleeds in skin or mucosal membranes. Diminished or excessive levels of coagulation factors can lead to defective hemostasis or spontaneous and unnecessary clotting. (Hemostasis is discussed in Chapter 20.) Diminished hemostasis results in either internal or external hemorrhage. A classification of hemorrhagic disorders is included in Table 21-9.

### TABLE 21-9
Classification of Hemorrhagic Disorders

<table>
<thead>
<tr>
<th>Type of Defect</th>
<th>Example</th>
<th>Manifestation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Defects of primary hemostasis</td>
<td>Platelet defects or von Willebrand disease</td>
<td>Usually present with small bleeds in skin or mucosal membrane; bleeds are usually petechiae (&lt;3-mm minute hemorrhages) or purpuras (&gt;3-mm red-purple discolorations); common in capillaries; also includes epistaxis (nose bleeds), GI bleeds, or excessive menstruation</td>
</tr>
<tr>
<td>Defects of secondary hemostasis</td>
<td>Coagulation factor defects</td>
<td>Bleeds into soft tissue, muscle, or joints; intracranial bleeds may occur</td>
</tr>
<tr>
<td>Generalized defects of small vessels</td>
<td>Palpable purpura and ecchymoses</td>
<td>Extravasated blood creates a palpable mass (or palpable purpura), ecchymoses (simply called a bruise), or a larger palpable lesion (or hematoma); systemic disorders disrupt small blood vessels, called vasculitis</td>
</tr>
</tbody>
</table>

Purpuric disorders occur when there is a deficiency of normal platelets necessary to plug damaged vessels or prevent leakage from the tiny tears that occur daily in capillaries. More serious internal bleeding occurs from events that simply overwhelm hemostatic mechanisms, such as rupture of large blood vessels, trauma, and diseases associated with massive hemorrhage including abdominal aneurysm. Between these smaller bleeds and massive bleeds are deficiencies of coagulation factors found with the hemophilias (see Chapter 22). Disorders that result in spontaneous clotting can develop from genetic disorders of the clotting system components or from acquired diseases that activate clotting. These disorders are known collectively as thromboembolic disease. Additionally, any disorder of the blood that predisposes to clotting of blood or thrombosis is called hypercoagulability (thrombophilia).

### Disorders of Platelets
Quantitative or qualitative abnormalities of platelets can interrupt normal blood coagulation and prevent hemostasis. The quantitative abnormalities are thrombocytopenia, a decrease in the number of circulating platelets, and thrombocythemia, an increase in the number of platelets. Qualitative disorders affect the structure or function of individual platelets and can coexist with the quantitative disorders. Qualitative disorders usually prevent platelet adherence and aggregation, preventing formation of a platelet plug.

**Thrombocytopenia**

Thrombocytopenia is defined as a platelet count less than 150,000 platelets/µL of blood, although most individuals do not consider the decrease significant unless it falls below 100,000 platelets/µL of blood. The risk for hemorrhage associated with minor trauma does not appreciably increase until the count falls below 50,000 platelets/µL. Spontaneous bleeding without trauma can occur with counts ranging from 10,000 platelets/µL to 15,000 platelets/µL, resulting in skin manifestations (i.e., petechiae, ecchymoses, and larger purpuric spots) or frank bleeding from mucous membranes. Severe spontaneous bleeding may result if the count is less than 10,000 platelets/µL and can be fatal if it occurs in the gastrointestinal tract, respiratory tract, or central nervous system.

Before the diagnosis of thrombocytopenia is made, pseudothrombocytopenia must be ruled out. This phenomenon occurs in approximately 1 in 1000 to 1 in 10,000 laboratory samples and results from an error in platelet counting when a blood sample is analyzed by an automated cell counter. Platelets in the blood sample may become nonspecifically agglutinated by immunoglobulins in the presence of ethylenediaminetetraacetic acid (EDTA), a preservative in banked blood. The agglutinated platelets are not counted, thus giving an apparent, but false, thrombocytopenia. Thrombocytopenia also may be falsely diagnosed because of a dilutional effect observed after massive transfusion of platelet-poor packed cells to treat a hemorrhage. This occurs when more than 10 units of blood have been transfused within a 24-hour period. The hemorrhage that necessitated the transfusion also accelerates the loss of platelets, contributing to the pseudothrombocytopenic state. Splenic sequestering of platelets in hypersplenism (congestive) also induces an apparent thrombocytopenia as does hypothermia (less than 25° C [77° F]), which is reversed when temperatures return to normal, suggesting an increased platelet sequestration in response to chilling.

**Pathophysiology**

Thrombocytopenia results from decreased platelet production, increased
consumption, or both. The condition may also be either congenital or acquired and may be either primary or secondary to other acquired or congenital conditions.\textsuperscript{61,62} Thrombocytopenia secondary to congenital conditions occurs in a large number of different diseases, although each is relatively rare.\textsuperscript{63} These include thrombocytopenia–absent radius (TAR) syndrome, Wiskott-Aldrich syndrome (see Chapter 8), various forms of \textit{MYH9} gene mutation (e.g., May-Hegglin anomaly), X-linked thrombocytopenia, and many other examples.

Acquired thrombocytopenia is more common and may occur as a result of decreased platelet production secondary to viral infections (e.g., EBV, rubella, CMV, HIV), drugs (e.g., thiazides, estrogens, quinine-containing drugs, chemotherapeutic agents, ethanol), nutritional deficiencies (vitamin B\textsubscript{12} or folic acid in particular), chronic renal failure, bone marrow hypoplasia (e.g., aplastic anemia), radiation therapy, or bone marrow infiltration by cancer. Most common forms of thrombocytopenia are the result of increased platelet consumption. Examples include heparin-induced thrombocytopenia, idiopathic (immune) thrombocytopenia purpura, thrombotic thrombocytopenia purpura, and disseminated intravascular coagulation (discussed later in this chapter).

**Heparin-induced thrombocytopenia.**

Heparin is the most common cause of drug-induced thrombocytopenia.\textsuperscript{64} Approximately 4\% of individuals treated with unfractionated heparin develop \textbf{heparin-induced thrombocytopenia (HIT)}. The incidence is lower (about 0.1\%) with the use of low-molecular-weight heparin. HIT is an immune-mediated, adverse drug reaction caused by IgG antibodies against the heparin–platelet factor 4 complex leading to platelet activation through platelet Fc \gamma IIa receptors.\textsuperscript{65} The release of additional platelet factor 4 from activated platelets and activation of thrombin lead to increased platelet consumption and a decrease in platelet counts beginning 5 to 10 days after administration of heparin.

**Clinical manifestations**

The hallmark of HIT is thrombocytopenia. A decrease of approximately 50\% in the platelet count is observed in more than 95\% of individuals. However, 30\% or more of those with thrombocytopenia are also at risk for venous or arterial thrombosis because a \textit{prothrombotic state} is caused by antibody binding to platelets, inducing activation, aggregation, and consumption (thus the term \textit{thrombocytopenia} in the syndrome name) of platelets. Venous thrombosis is more common and results in deep venous thrombosis and pulmonary emboli. Arterial thrombosis affects the lower extremities, causing limb ischemia. Arterial thrombosis may lead to
cerebrovascular accidents and myocardial infarctions. Other major arteries also may be affected (e.g., renal, mesenteric, upper limb). Although platelet counts are low, bleeding is uncommon.

**Evaluation and treatment**

Diagnosis is primarily based on clinical observations. The individual presents with dropping platelet counts after 5 days or longer of heparin treatment. On average, platelet counts may reach 60,000/µL. Because most individuals are postsurgery and the onset of symptoms, including thrombosis, may be delayed until after release from the hospital, other possible causes of thrombocytopenia (e.g., infection, other drug reactions) must be considered. Tests are available to measure anti-heparin–platelet factor 4 antibodies. The sensitivity of this test is extremely high (>90%), but the specificity is less because of false-positive reactions (e.g., those receiving dialysis). Treatment is the withdrawal of heparin and use of alternative anticoagulants.

**Immune thrombocytopenia purpura.**

The most common cause of thrombocytopenia secondary to increased platelet destruction is **immune thrombocytopenic purpura (ITP)**. ITP, formerly known as *idiopathic thrombocytopenic purpura*, however, is widely recognized now as an immune process, hence the change from idiopathic to immune. Although results and estimates are conflicting, the incidence of ITP is estimated to range from 9.5 to 20 per 100,000 in the general population and tends to increase with age. In individuals younger than 60 years, females have a higher incidence than males. ITP may be acute or chronic. The acute form is frequently observed in children and typically lasts 1 to 2 months with a complete remission. In some instances it may last for up to 6 months, and some children (7% to 28%) may progress to the chronic condition (see Chapter 22). Acute ITP is usually secondary to infections (particularly viral) or other conditions that lead to large amounts of antigen in the blood, such as drug allergies or systemic lupus erythematosus (SLE). Under these conditions, the antigen usually forms immune complexes with circulating antibody, and it is thought that the immune complexes bind to Fc receptors on platelets, leading to their destruction in the spleen. The acute form of ITP usually resolves as the source of antigen is resolved (infection) or removed (drugs). Recently, *Helicobacter pylori* has been implicated in various autoimmune disorders, including pernicious anemia and immune thrombocytopenic purpura. Similar to other autoimmune diseases, the epidemiology and gene-environment interactions and potential triggers for ITP need much study.
Chronic ITP is caused by autoantibody-mediated destruction against platelet-specific antigens. This form is more commonly observed in adults, being most prevalent in women between 20 and 40 years old, although it can be found in all ages. The chronic form tends to get progressively worse. It can occur from a variety of predisposing conditions or exposures (secondary) or have no known risk factors (primary). The autoantibodies are generally of the IgG class and are against one or more of several platelet glycoproteins (e.g., GPIIb/IIIa, GPIIb/IX, GPIa/IIa). The antibodies bind directly to the platelet antigens, after which the antibody-coated platelets are recognized and removed from the circulation by macrophages in the spleen. Autoreactive T cells also play a large role in the crosstalk between antigen-presenting cells and autoantibody-producing B cells and may play a role in ITP.\(^1\)

**Clinical manifestations**

Initial manifestations range from minor bleeding problems (development of petechiae and purpura) over the course of several days to major hemorrhage from mucosal sites (epistaxis, hematuria, menorrhagia, bleeding gums). Rarely will an individual present with intracranial bleeding or other sites of internal bleeding.

During pregnancy, a woman with ITP may have a newborn that is also thrombocytopenic. If the fetal platelets express the same antigen as the mother, the maternal antibody will coat the platelets, potentially resulting in thrombocytopenia in utero. A variant of neonatal thrombocytopenia (*neonatal alloimmune thrombocytopenia*) occurs when the mother does not have ITP but makes IgG antibodies against an antigen inherited from the father found on fetal platelets but not on maternal platelets.\(^2\)

**Evaluation and treatment**

Diagnosis of ITP is based on a history of bleeding and associated symptoms (weight loss, fever, headache). Physical examination includes notations on the type, location, and severity of bleeding. In addition, evidence of infections (bacterial, HIV and other viral), medication history, family history, and evidence of thrombosis are assessed. Other diagnostic tests include complete blood count (CBC) and peripheral blood smear. Unlike some other forms of thrombocytopenia, there is usually no evidence of splenectomy. Testing for antiplatelet antibodies is usually not helpful. Although most cases of ITP are associated with elevated levels of IgG on platelets, other forms of thrombocytopenia also have a high incidence of platelet-associated antibodies; thus, the specificity is low (50% to 65%).\(^3\) In addition, some cases of ITP will not present with elevated platelet-associated antibodies; the sensitivity is 75% to 94%; therefore, a negative test does not rule out ITP.

The acute form of ITP usually resolves without major clinical consequences but
the chronic form, like many autoimmune diseases, is variable with multiple remissions and exacerbations. Treatment is palliative, not curative, and focuses on prevention of platelet destruction. Initial therapy for ITP is glucocorticoids (e.g., prednisone), which suppress the immune response and prevent sequestration and further destruction of platelets. If steroid therapy is ineffective, other reagents have been used. Treatment with intravenous immunoglobulin (IVIg) is used to prevent major bleeding. The response rate is 80%, but the effects are transient, lasting only days to a few weeks. Anti-Rh₀(D) (RhoGAM) has been used with limited success to treat individuals who are Rh-positive. Newer drug therapies are now available.

If platelet counts do not increase appropriately, splenectomy is considered to remove the site of platelet destruction. However, splenectomy is not without risks, and approximately 10% to 20% of individuals who undergo a splenectomy suffer a relapse and require further treatment. In that situation, it is believed that the liver has become the site for platelet destruction. If splenectomy is unsuccessful and life-threatening thrombocytopenia persists, more aggressive immunosuppressive medications (e.g., azathioprine, cyclophosphamide) are usually recommended. Because of potential complications, these medications are reserved for individuals who are severely thrombocytopenic and refractive to other therapies.

**Thrombotic thrombocytopenia purpura.**

**Thrombotic thrombocytopenia purpura (TTP)** is a multisystem disorder characterized by thrombotic microangiopathy (TMA) (small or microvessel disease) in which platelets aggregate and cause occlusion of arterioles and capillaries within the microcirculation.⁷⁴,⁷⁵ Aggregation may lead to increased platelet consumption and organ ischemia. TTP is relatively uncommon, occurring in about 5 per million individuals per year. The incidence is increasing and does appear to be an actual increase and not just the result of improved recognition. One suspected etiologic factor for TMA, thrombotic thrombocytopenic purpura, and hemolytic-uremic syndrome is drug-induced, and a recent report found definite evidence from three drugs: quinine, cyclosporine, and tacrolimus.⁷⁶

There are two types of TTP: familial and acquired idiopathic. The familial type is the more rare type and is usually chronic, relapsing, and typically seen in children. When recognized and treated early, the child experiences predictable recurring episodes approximately every 3 weeks that are responsive to treatment. Acquired TTP is more common and more acute and severe. It occurs mostly in females in their thirties and is rarely observed in infants and the elderly.

The microthrombi formation is found throughout the entire vascular system, causing damage to multiple organs. The most susceptible organs for damage
include the kidney, brain, and heart. Also affected are the pancreas, spleen, and adrenal glands. The thrombi are composed of platelets with minimal fibrin and red cells, differentiating them from thrombi secondary to intravascular coagulation (see p. 545). Most cases of TTP are related to a dysfunction of the plasma metalloprotease ADAMTS13. This enzyme is responsible for digesting large precursor molecules of von Willebrand factor (vWF) produced by endothelial cells into smaller molecules. Defects in ADAMTS13 result in expression of large-molecular-weight vWF on the endothelial cell surface and the formation of large aggregates of platelets, which can break off and form occlusions in smaller vessels. People with TTP (about 80%) have less than 5% of normal plasma ADAMTS13 levels. Most individuals with familial TTP are homozygous for mutations in ADAMTS13. Acquired TTP of unexplained origin is associated in most people with an IgG autoantibody against ADAMTS13 that is able to neutralize the enzyme's activity and accelerate its clearance from the plasma.

Clinical manifestations

Chronic relapsing TTP is a rare familial form of TTP observed in children and usually recognized and successfully treated. The acquired acute idiopathic TTP is much more common and more severe.\(^7\) TTP is clinically related to and must be distinguished from other thrombotic microangiopathic conditions, including hemolytic uremic syndrome (HUS), malignant hypertension, preeclampsia, and pregnancy-induced HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome. Early diagnosis and treatment is essential because TTP may prove fatal within 90 days.

Acute idiopathic TTP is characterized by a “pentad” of symptoms, including extreme thrombocytopenia (less than 20,000 platelets/\(\mu L\)), intravascular hemolytic anemia, ischemic signs and symptoms most often involving the CNS (about 65% present with memory disturbances, behavioral irregularities, headaches, or coma), kidney failure (present in about 65%), and fever (present in about 33%).

Evaluation and treatment

A routine blood smear usually shows fragmented red cells (schizocytes) produced by shear forces when red cells are in contact with the fibrin mesh in clots that form in the vessels. As a result of tissue injury, serum levels of lactate dehydrogenase (LDH) may be very high, and low-density lipoprotein (LDL) levels may be elevated. Tests for antibody on red cells are negative, excluding immune hemolytic anemia.

Plasma exchange with fresh frozen plasma, which replenishes functional ADAMTS13, is the treatment of choice, achieving a 70% to 85% response rate. Additionally, steroids (glucocorticoids) are administered. In the absence of major
organ damage, this approach may lead to complete recovery with no long-term complications. The anti-CD20 monoclonal antibody rituximab has shown some success in people who are refractory to plasma exchange. Relapses do occur at a rate of 13% to 36%, and recurrences have been reported, sometimes delayed until 9 years after treatment. Individuals who do not respond to conventional treatment may be candidates for splenectomy; however, postoperative hemorrhage remains a dangerous complication. Immunosuppression therapy has been successful in some individuals.

**Thrombocythemia**

**Thrombocythemia** (also called *thrombocytosis*) is defined as a platelet count greater than 400,000/µL of blood. Thrombocythemia may be primary or secondary (reactive) and is usually asymptomatic until the count exceeds 1 million/µL. Then intravascular clot formation (thrombosis), hemorrhage, or other abnormalities can occur.

**Pathophysiology**

**Essential (primary) thrombocythemia (ET)** is a myeloproliferative neoplasm characterized by an increase in platelet production (or thrombocytosis) and often an increase in red blood cell production (or erythrocytosis). Other disease features include leukocytosis, splenomegaly, thrombosis, bleeding, microcirculatory symptoms, itching (or pruritus), and risk of leukemic or bone marrow fibrotic transformation. Myeloproliferative neoplasms (MPNs) are one of five categories of myeloid malignancies according to the WHO classification for hematologic tumors (see p. 532). ET is characterized by stem cell–derived clonal bone marrow proliferation (myeloproliferation) with a unique “gain-of-function” mutation that induces overactivity in cell signaling from Janus kinase 2 (JAK2). JAK2, a tyrosine kinase, is an essential player downstream of cytokine receptors, such as the thrombopoietin (TPO, affects platelet proliferation) and erythropoietin (EPO, affects erythrocyte proliferation) receptors, and a gain-of-function mutation contributes to the development of MPN. More simply, both erythropoietin and thrombopoietin convey their signals and consequent proliferation through JAK2. The alteration is a valine-to-phenylalanine (V617F) mutation that causes constant activation of JAK2, leading to an increased responsiveness or production of platelets and other cells in the bone marrow. Along with increased platelets, there may be a concomitant increase in the number of red cells, indicating a myeloproliferative disorder; however, the increase in red cells is not to the extent seen in polycythemia vera (see p. 521). Red blood cells (RBCs) in ET tend to
aggregate and adhere to the endothelium and contribute to the blockage of flow in the microvasculature and altered interactions between platelets and the vascular endothelium. The JAK2 (V617F) mutation is present in 50% to 60% of persons with ET. Other mutually exclusive mutations found include calreticulin (CALR) or leukemia virus oncogene (MPL) mutation. The overall incidence of ET is 0.8 per 100,000 in the United Kingdom, 2.53 per 100,000 in the United States, and 0.59 per 100,000 in Denmark. It is more common in middle-age individuals, with the majority of cases occurring between ages 50 and 60 years. There is no known gender preference. There also is a rare hereditary type of ET called familial essential thrombocythemia (FET) that is inherited in an autosomal dominant pattern.

Secondary thrombocythemia may occur after splenectomy because platelets that normally would be stored in the spleen remain in circulating blood. The increase in platelets may be gradual, with thrombocythemia not occurring for up to 3 weeks after splenectomy. Reactive thrombocythemia may occur during some inflammatory conditions, such as rheumatoid arthritis and cancers. In these conditions, excessive production of some cytokines (e.g., IL-6, IL-11) may induce increased production of thrombopoietin in the liver, resulting in increased megakaryocyte proliferation. Reactive thrombocythemia also may occur during a variety of physiologic conditions, such as after exercise.

Clinical manifestations

Clinical manifestations vary among individuals. Those with ET are at risk for large-vessel arterial or venous thrombosis, although the most common complication is microvasculature thrombosis leading to ischemia in the fingers, toes, or cerebrovascular regions. The primary presenting symptoms of microvasculature thrombosis are erythromyalgia, headache, and paresthesias. Erythromyalgia is characterized by unilateral or bilateral warm, congested, red hands and feet with painful burning sensations, particularly in the forefoot sole and one or more toes. The lower extremities are affected more often and only one side may be involved. The pain is initiated by standing, exercise, or warmth and relieved by elevation and cooling. In extreme situations, acrocyanosis and gangrene may result.

Arterial thrombosis is more common than venous thrombosis and may involve the coronary and renal arteries. Deep venous thrombosis of the lower extremities and pulmonary embolism are the major sites for venous involvement. Other common venous sites include intra-abdominal venous thrombosis (portal and hepatic). People older than 60 years of age or those with prior history of thrombotic events have as much as a 25% chance of developing a cerebral, cardiac, or peripheral arterial thrombus and, less often, developing a pulmonary embolism or deep vein thrombosis. Conversion to acute leukemia is found in less than 10%. 
Symptoms related to microvascular thrombosis in the CNS include headache, dizziness with paresthesias, transient ischemic attacks (TIAs), strokes, visual disturbances, and seizures. Major thrombotic events, not directly related to the platelet count, occur in about 20% to 30% of individuals with ET. Prior history of thrombotic events, advanced age, and duration of thrombocytosis are predictors of future thrombotic complications. Individuals older than age 60 are at greatest risk.

Although thrombosis is the more common symptom, hemorrhage can also occur. Sites for bleeding include the GI tract, skin, mucous membranes, urinary tract, gums, teeth sockets after extraction, joints, eyes, and brain. GI bleeding may be mistaken for a duodenal ulcer. Hemorrhage is not severe and generally occurs in the presence of very high platelet counts; transfusions are required only occasionally. Bleeding and clotting may occur simultaneously, and individuals will not necessarily be “bleeders” or “clotters.”

**Evaluation and treatment**

Initial diagnosis is not difficult; as many as two thirds of cases are diagnosed from a routine complete blood cell count (CBC). Secondary thrombocytosis also may occur as a moderate rise in the platelet count that resolves with treatment or resolution of the underlying condition. The World Health Organization (WHO) criteria for the diagnosis of ET require the following four criteria be met: (1) sustained platelet count of at least $450 \times 10^9$/L; (2) bone marrow biopsy showing proliferation of enlarged mature megakaryocytes and no increase of granulocyte or erythrocyte precursors; (3) failure to meet the criteria of polycythemia vera, myelofibrosis, CML, or other myelodysplastic syndrome; and (4) presence of JAK2 617F or another clonal marker or evidence of reactive thrombocytosis. Because ET can be mistaken for CML, careful differentiation is necessary because treatment varies significantly.

Treatment of ET is directed toward preventing thrombosis or hemorrhage. Reducing the platelet count remains a significant treatment issue. Hydroxyurea (HU), a nonalkylating myelosuppressive agent, has been the drug of choice to suppress platelet production; however, long-term use may cause progression to other myeloplastic disorders, particularly acute myeloid leukemia or myelofibrosis. Another drug used to treat ET is interferon (IFN). IFN has a response rate of 80% but may not be effective for everyone because of side effects. Anagrelide is now the drug of choice. Anagrelide interferes with platelet maturation rather than production, thus not interfering with red and white cell growth and development. Low-dose aspirin may be effective to alleviate erythromyalgia and transient neurologic manifestations. ET is not necessarily considered life-threatening but, in those older than age 60 and who have had previous incidences of
thrombosis, complications are more common and have a higher risk of mortality.

**Alterations of Platelet Function**

Qualitative alterations in platelet function are characterized by an increased bleeding time in the presence of a normal platelet count. Associated clinical manifestations include spontaneous petechiae and purpura, and bleeding from the GI tract, genitourinary tract, pulmonary mucosa, and gums. Congenital alterations in platelet function (*thrombocytopathies*) are quite rare and may be categorized into several types of disorders: (1) platelet–vessel wall adhesion (e.g., defect in GPIb-IX-V expression [Bernard-Soulier syndrome]), (2) platelet-platelet interactions (e.g., deficiency in αIIbβ3 expression [Glanzmann thrombasthenia]), (3) platelet granules and secretion (e.g., receptor defects [ADP, collagen]), (4) arachidonic acid pathways (defects of prostaglandins and release granules), and (5) membrane phospholipid regulation or coagulation protein-platelet interactions (e.g., Scott syndrome).  

Acquired disorders of platelet function are more common than the congenital disorders and may be categorized into three principal causes: (1) drugs, (2) systemic inflammatory conditions, and (3) hematologic alterations. Multiple drugs are known to interfere with platelet function in several ways: inhibition of platelet membrane receptors, inhibition of prostaglandin pathways, and inhibition of phosphodiesterase activity. Aspirin is the most commonly used drug that affects platelets. It irreversibly inhibits cyclooxygenase function for several days after administration. Nonsteroidal anti-inflammatory drugs also affect cyclooxygenase, although in a reversible fashion.  

Systemic disorders that affect platelet function are chronic renal disease, liver disease, cardiopulmonary bypass surgery, and severe deficiencies of iron or folate and antiplatelet antibodies associated with autoimmune disorders. Hematologic disorders associated with platelet dysfunction include chronic myeloproliferative disorders, multiple myeloma, leukemias, and myelodysplastic syndromes and dysproteinemias.

**Disorders of Coagulation**

Disorders of coagulation are usually caused by defects or deficiencies of one or more of the clotting factors. (Normal function of the clotting factors is described in Chapter 20.) Qualitative or quantitative abnormalities interfere with or prevent the enzymatic reactions that transform clotting factors, circulating as plasma proteins, into a stable fibrin clot (see Figure 20-17). Some clotting factor defects are inherited and involve one a single factor, such as the hemophilias and von Willebrand
disease, caused by deficiencies of specific clotting factors. Other coagulation defects are acquired and tend to result from deficient synthesis of clotting factors by the liver. Causes include liver disease and dietary deficiency of vitamin K.

Other coagulation disorders are attributed to pathologic conditions that trigger coagulation inappropriately, engaging the clotting factors and causing detrimental clotting within blood vessels. For example, any cardiovascular abnormality that alters normal blood flow by acceleration, deceleration, or obstruction can create conditions in which coagulation proceeds within the vessels. An example of this is thromboembolic disease, in which blood clots obstruct blood vessels. Coagulation is also stimulated by the presence of tissue factor that is released by damaged or dead tissues. Vasculitis, or inflammation of the blood vessels, along with vessel damage activates platelets, which in turn activates the coagulation cascade. In extensive or prolonged vasculitis, blood clot formation can suppress mechanisms that normally control clot formation and dissolution, leading to clogging of the vessels. In each of these acquired conditions, normal hemostatic function proves detrimental to the body by consuming coagulation factors excessively or by overwhelming normal control of clot formation and breakdown (fibrinolysis) (see Figure 20-19).

**Impaired Hemostasis**

**Impaired hemostasis**, or the inability to promote coagulation and the development of a stable fibrin clot, is commonly associated with liver dysfunction, which may be caused by either specific liver disorders or lack of vitamin K.

**Vitamin K deficiency.**

Vitamin K, a fat-soluble vitamin, is required for the synthesis and regulation of prothrombin; the procoagulant factors (VII, IX, X); and the anticoagulant factors within the liver (proteins C and S). Unknown is the contribution of vitamin K to the overall supply by the intestinal flora. The primary source of vitamin K is found in green leafy vegetables. The most common cause of vitamin deficiency is parenteral nutrition in combination with antibiotics that destroy normal gut flora. Rarely is the deficiency caused by a lack of dietary intake; however, bulimia can suppress vitamin K–dependent activity. Parenteral administration of vitamin K is the treatment of choice and usually results in correction of the deficiency within 8 to 12 hours. Fresh frozen plasma also may be administered but is usually reserved for individuals with life-threatening hemorrhages or those who require emergency surgery.

**Liver disease.**
Individuals who have liver disease (for example, acute or chronic hepatocellular diseases, cirrhosis, vitamin K deficiency, or liver surgery) present with a broad range of hemostatic derangements that may be characterized by defects in the clotting or fibrinolytic systems and by platelet function. The hepatic parenchyma cells produce most of the factors involved in hemostasis; therefore, damage to the liver frequently results in diminished production of factors involved in clotting. Factor VII level is the first to decline after liver damage because of its rapid turnover. Factor IX levels are less affected and do not decline until the liver destruction is well advanced. The liver also is a major site for production of plasminogen and α₂-antiplasmin of the fibrinolytic system, as well as thrombopoietin and the metalloprotease ADAMTS13. Diminished thrombopoietin may lead to thrombocytopenia from decreased platelet production. Decreased production of ADAMTS13 results in increased levels of large precursor molecules of vWF, which leads to the formation of large aggregates of platelets.

With severe liver disease, such as cirrhosis, most clotting factors are significantly depressed. Levels of clotting system regulators, such as antithrombin, protein C, protein S, and fibrinogen, also are diminished. The fibrinolytic system is commonly active because of plasmin inhibitor and unaffected other activators. Thrombocytopenia occurs in affected individuals because of diminished thrombopoietin and ADAMTS13, as well as increased sequestration (pooling) of platelets in the spleen, which is frequently enlarged in cirrhosis and is associated with portal hypertension. Thus, these individuals may appear to have a condition similar to DIC (see Consumptive Thrombohemorrhagic Disorders).

Treatment of hemostasis alterations in liver disease must be comprehensive to cover all aspects of dysfunctions. Fresh frozen plasma (FFP) administration is the treatment of choice; however, not all individuals tolerate the volume needed to adequately replace all deficient factors. Alternative modalities include the addition of exchange transfusions and platelet concentration to plasma administration.

**Consumptive Thrombohemorrhagic Disorders**

**Consumptive thrombohemorrhagic disorders** are a heterogeneous group of conditions that demonstrate the entire spectrum of hemorrhagic and thrombotic pathologic findings. Symptoms range from the subtle to the devastating and generally are considered to be intermediary disease processes that complicate a vast number of primary disease states. These disorders are also characterized by confusion and controversy related to their diagnosis, treatment, and management. No one definition can cover all possible varieties of these disorders; however, DIC is most commonly used in the clinical setting to describe a pathologic condition that
Disseminated intravascular coagulation.

**Disseminated intravascular coagulation (DIC)** is an acquired clinical syndrome characterized by widespread activation of coagulation resulting in formation of fibrin clots in medium and small vessels or microvasculature throughout the body. Widespread clotting may lead to blockage of blood flow to organs, resulting in multiple organ failure. The magnitude of clotting may result in consumption of platelets and clotting factors, leading to tendency to bleed despite widespread clots.

The clinical course of DIC is largely determined by the stimulus intensity, host response, and comorbidities and ranges from an acute, severe, life-threatening process that is characterized by massive hemorrhage and thrombosis to a chronic, low-grade condition. The chronic condition is characterized by subacute hemorrhage and diffuse microcirculatory thrombosis. DIC may be localized to one specific organ or generalized, involving multiple organs.

The diagnosis of DIC has been confusing and difficult because of the complexity and wide variations in clinical manifestations. Minimally acceptable diagnostic criteria have been established and include a systemic thrombohemorrhagic disorder with laboratory evidence of (1) clotting activation, (2) fibrinolytic activation, (3) coagulation inhibitor consumption, and (4) biochemical evidence of end-organ damage or failure.

DIC is secondary to a wide variety of well-defined clinical conditions, specifically those capable of activating the clotting cascade. Sepsis is the most common condition associated with DIC. Gram-negative microorganisms, as well as some gram-positive microorganisms, fungi, protozoa (malaria), and viruses (influenza, herpes), are capable of precipitating DIC by causing damage to the vascular endothelium. Gram-negative endotoxins are the primary cause of endothelial damage; DIC may occur in up to 50% of individuals with gram-negative sepsis. DIC occurs in approximately 10% to 20% of individuals with metastatic cancer or acute leukemia. The adenocarcinomas most frequently associated with DIC include the lung, pancreas, colon, and stomach. Direct tissue damage (e.g., massive trauma, extensive surgery, severe burns) also results in release of tissue factor (TF), an initiator of DIC, by the endothelium. Severe trauma, especially to the brain, can induce DIC. DIC occurs in about two thirds of individuals with a systemic inflammatory response to trauma. Some complications of pregnancy also are associated with DIC; incidences range from 50% for women with placental abruptions to less than 10% for severe preeclampsia. Other causes of DIC have been identified, most notably blood transfusion. Transfused blood dilutes the clotting
factors, as well as circulating naturally occurring antithrombins. In hemolytic transfusion reactions, the endothelium is damaged by complement-mediated reactions.

**Pathophysiology**

The coagulation system is designed to function at local areas of vascular damage, resulting in cessation of bleeding and activation of repair to the vessels. The function of clotting is to prevent excessive blood loss and the function of fibrinolysis is to ensure easy circulation within the vasculature (see Chapter 20). DIC results from abnormally widespread and ongoing activation of clotting — *coagulopathy*—in small and midsize vessels that alters the microcirculation, leading to ischemic necrosis in various organs, particularly the kidney and lung. Concomitantly, DIC can be caused by the imbalance between the coagulant system and the fibrinolytic system (which generates plasmin) to maintain normal circulation. DIC can cause widespread deposition of fibrin in the microcirculation that leads to ischemia, microvascular thrombotic obstruction, and organ failure (Figure 21-19).
Seemingly paradoxical, DIC involves both widespread clotting and bleeding because of simultaneous procoagulant activation, fibrinolytic activation, and consumption of platelets and coagulation factors, which results directly in serious bleeding (see Figure 21-19).

DIC is not a disease but is secondary to a variety of conditions (Box 21-4) because of activation of the clotting cascade. The common pathway for DIC appears to be excessive and widespread exposure to TF. This may occur by several mechanisms: (1) damage to the vascular endothelium results in exposure to TF; (2) when stimulated by inflammatory cytokines, endothelial cells and monocytes...
express surface TF; (3) endotoxin triggers the release of many cytokines that can both promote and cause progression of DIC; (4) sepsis is associated with many cytokines, interleukins, and platelet activating factor (PAF) that promote DIC as well as activate endothelial cells that stimulate thrombi development; and (5) TF may be released directly into the bloodstream from circulating white blood cells.

TF binds clotting factor VII, which leads to conversion of prothrombin to thrombin and formation of fibrin clots (see Figure 20-19). This pathway appears to be the primary route by which DIC is initiated; in animal models of DIC, inhibition of TF or factor VIIa completely prevents the generation of thrombi by gram-
negative bacterial endotoxin.

Not only is the clotting system extensively activated in DIC, but also the activities of the predominant natural anticoagulants (tissue factor pathway inhibitor, antithrombin III, protein C) are greatly diminished. During DIC, the activation of clotting is prolonged and is a result of certain conditions (for example, bacteremia or endotoxemia); thrombin generation is increased and is insufficiently balanced by impaired anticoagulant systems, such as antithrombin and protein C. The overall result is fibrin generation and deposition in the vascular system. In early DIC, plasmin (naturally occurring clot busting or fibrinolytic agent) produced from endothelial cells causes fibrinolysis to maintain circulation. Bleeding can occur with excess fibrinolytic activity. However, fibrinolysis becomes blunted by high levels of plasminogen activator inhibitor-1 (PAI-1), a fibrinolytic inhibitor. Over time the activity of plasmin is diminished by PAI-1. Although some fibrinolytic activity remains, the level is inadequate to control the systemic deposition of fibrin. The slow breakdown of fibrin by plasmin produces fibrin split products (FSPs) (also known as fibrin degradation products [FDPs]). These products are powerful anticoagulants that are normally removed from blood by fibronectin and macrophages. FSPs, along with thrombin, induce further cytokine release from monocytes, contributing to endothelial damage and TF release. During DIC, the presence of FSPs is prolonged possibly because of diminished production of fibronectin. Fibronectin is a glycoprotein with adhesive properties that mediates removal of particulate matter, such as fibrin clumps. Low levels of fibronectin suggest a poor prognosis.

Although thrombosis is generalized and widespread, individuals with DIC are paradoxically at risk for hemorrhage. Hemorrhage is secondary to the abnormally high consumption of clotting factors and platelets, as well as the anticoagulant properties of FSPs, which interfere with fibrin mesh formation or polymerization. Both thrombin and FSPs have a high affinity for platelets and cause platelet activation and aggregation—an event that occurs early in the development of DIC—which facilitates microcirculatory coagulation and obstruction in the initial phase. However, platelet consumption exceeds production, resulting in a thrombocytopenia that increases bleeding.

Activation of clotting also leads to activation of other inflammatory pathways, including the kallikrein-kinin and complement systems (see Chapter 6). Factor XIIa, generated in DIC, converts prekallikrein to kallikrein, ultimately resulting in conversion to circulating kinins. Activation of these systems contributes to increased vascular permeability, hypotension, and shock. Activated complement components also induce platelet destruction, which initially contributes to the thrombosis and later to the thrombocytopenia.
The deposition of fibrin clots in the circulation interferes with blood flow, causing widespread organ hypoperfusion. This condition may lead to ischemia, infarction, and necrosis, further potentiating and complicating the existing DIC process by causing further release of TF and eventually organ failure. Manifestations of multisystem organ dysfunction and failure ultimately result.

In addition to initiation of clotting by tissue factor, DIC may be precipitated by direct proteolytic activation of factor X. This has been described as “thrombin mimicry” and is the result of proteases directly converting fibrinogen to fibrin. These proteases may come from snake venom, some tumor cells, or the pancreas and liver, where they are respectively released during episodes of pancreatitis and various stages of liver disease. Direct proteolytic activity appears to be independent of any type of damage to the endothelium or tissue.

Whatever initiates the process of DIC, the cycle of thrombosis and hemorrhage persists until the underlying cause of the DIC is removed or appropriate therapeutic interventions are used.

**Clinical manifestations**

Clinical signs and symptoms of DIC present a wide spectrum of possibilities, depending on the underlying disease process that initiates DIC and whether the DIC is acute or chronic in nature (Box 21-5). Most symptoms are the result of either bleeding or thrombosis. Acute DIC presents with rapid development of hemorrhaging (oozing) from venipuncture sites, arterial lines, or surgical wounds or development of ecchymotic lesions (purpura, petechiae) and hematomas. Other sites of bleeding include the eyes (sclera, conjunctiva), the nose, and the gums. Most individuals with DIC demonstrate bleeding at three or more unrelated sites, and any combination may be observed. Shock of variable intensity, out of proportion to the amount of blood loss, also may be observed. Hemorrhaging into closed compartments of the body also can occur and may precede the development of shock.

**Box 21-5**

**Clinical Manifestations Associated with DIC**

**Integumentary System**

Widespread hemorrhage and vascular lesions

Oozing from puncture sites, incisions, mucous membranes
Acrocyanosis (irregular-shaped cyanotic patches)

Gangrene

**Central Nervous System**

Subarachnoid hemorrhage

Altered state of consciousness (slight confusion to convulsions and coma)

**Gastrointestinal System**

Occult bleeding to massive gastrointestinal bleeding

Abdominal distention

Malaise

Weakness

**Pulmonary System**

Pulmonary infarctions

ARDS

Cyanosis

Tachypnea

Hypoxemia

**Renal System**

Hematuria

Oliguria

Renal failure

Manifestations of thrombosis are not always as evident, even though it is often the
first pathologic alteration to occur. The initial observations may be bleeding and sometimes very extensive hemorrhage. Several organ systems are susceptible to microvascular thrombosis associated with dysfunction: cardiovascular, pulmonary, central nervous, renal, and hepatic systems. Acute and accurate clinical interpretations are critical to preventing progression of DIC that may lead to multisystem organ dysfunction and failure. (Multiple organ dysfunction and failure are discussed further in Chapter 24.) Indicators of multisystem dysfunction include changes in level of consciousness or behavior, confusion, seizure activity, oliguria, hematuria, hypoxia, hypotension, hemoptysis, chest pain, and tachycardia. Symmetric cyanosis of fingers and toes (blue finger/toe syndrome), nose, and breast may be observed and indicates macrovascular thrombosis. This may lead to infarction and gangrene that may require amputation. Jaundice also is observed and most likely results from red cell destruction rather than liver dysfunction.

Individuals with chronic or low-grade DIC do not present with the overt manifestations of hemorrhaging and thrombosis but instead have subacute bleeding and diffuse thrombosis; these individuals are described as having compensated DIC, or non-overt DIC. The major characteristic of this state is an increased turnover and decreased survival time of the components of hemostasis: platelets and clotting factors. Occasionally, diffuse or localized thrombosis develops, but this is infrequent.

**Evaluation and treatment**

No single laboratory test can be used to effectively diagnose DIC. Diagnosis is based primarily on clinical symptoms and confirmed by a combination of laboratory tests. The person must present with a clinical condition that is known to be associated with DIC. The most commonly used combination of laboratory tests usually confirms thrombocytopenia or a rapidly decreasing platelet count on repeated testing, prolongation of clotting times, the presence of fibrin split products, and decreased levels of coagulation inhibitors. Platelet counts below 100,000/µL or a progressive decrease in platelet counts is very sensitive for DIC, although not greatly specific. These changes usually indicate consumption of platelets.

The standard coagulation tests (e.g., prothrombin time [PT], activated partial thromboplastin time [aPTT]) also have a high degree of sensitivity, but they are not highly specific for DIC. As a result of consumption of circulating clotting factors, these tests are usually abnormal, ranging from shortened to prolonged times. However, conditions other than DIC may prolong clotting times.

Detection of fibrin split products is more specific for DIC. Detection of D-dimers is a widely used test for DIC. A D-dimer is a molecule produced by plasmin
degradation of cross-linked fibrin in clots. D-Dimers in the blood can be quantified using ELISA tests that include commercially available and highly specific monoclonal antibody against the D-dimer. Agglutination tests for other fibrin split products are available. Levels of fibrin split products are elevated in the plasma in 95% to 100% of cases; however, they are less specific and only document the presence of plasmin and its action on fibrin. ELISAs for markers of thrombin activity are sometimes used.

Levels of coagulation inhibitors (e.g., antithrombin III [AT-III], protein C) can be measured by assays that rely on function or by ELISAs that quantify the amount of the specific inhibitor. AT-III levels can provide key information for diagnosing and monitoring therapy of DIC. Initial levels of functional AT-III are low in DIC because thrombin is irreversibly complexed with activated clotting factors and AT-III.

Treatment of DIC is directed toward (1) eliminating the underlying pathologic condition, (2) controlling ongoing thrombosis, and (3) maintaining organ function. Elimination of the underlying pathologic condition is the initial intervention in the treatment phase in order to remove the trigger for activation of clotting. Once the stimulus is gone, production of coagulation factors in the liver leads to restoration of normal plasma levels within 24 to 48 hours.

Control of thrombosis is more difficult to attain. Heparin has been used for this; however, its use is controversial because its mechanism of action is binding to and activating AT-III, which is deficient in many types of DIC. Currently, heparin is only indicated in certain types of situations related to DIC. For instance, heparin seems to be effective in DIC caused by a retained dead fetus or associated with acute promyelocytic leukemia. Organ function is compromised by microthrombi, and there is a risk of losing an extremity because of vascular occlusion; thus heparin is also indicated in these conditions. Heparin's usefulness, however, for DIC that is precipitated by septic shock has not been established and so is contraindicated in that instance; heparin is also contraindicated when there is evidence of postoperative bleeding, peptic ulcer, or central nervous system bleeding.

Replacement of deficient coagulation factors, platelets, and other coagulation elements is gaining recognition as an effective treatment modality. Their use is not without controversy, however, because a major concern with replacement therapy is the possible risk of adding components that will increase the rate of thrombosis. Clinical judgment is the key factor in determining whether replacement is to be used as a treatment modality.

Several clinical trials are evaluating replacement of anticoagulants (i.e., AT-III, protein C). Replacement of AT-III appears to be effective in DIC caused by sepsis. Low levels of AT-III correlate with sepsis-initiated DIC, which makes a case for its use. AT-III inactivates thrombin, factor Xa, factor IXa, and other activated
components of the clotting system. Heparin augments AT-III, but the effectiveness of the combination of heparin with AT-III replacement has not been established. Antifibrinolytic drugs also are used in treatment but are limited to instances of life-threatening bleeding that have not been controlled by blood component replacement therapy.

Maintenance of organ function is achieved by fluid replacement to sustain adequate circulating blood volume and maintain optimal tissue and organ perfusion. Fluids may be required to restore blood pressure, cardiac output, and urine output to normal parameters.

**Thromboembolic Disorders**

Certain conditions within the blood vessels predispose an individual to develop clots spontaneously. A stationary clot attached to the vessel wall is called a **thrombus** (Figure 21-20). A thrombus is composed of fibrin and blood cells and can develop in either the arterial or the venous system. **Arterial thrombi** form under conditions of high blood flow and are composed mostly of platelet aggregates held together by fibrin strands. **Venous thrombi** form under conditions of low flow and are composed mostly of red cells with larger amounts of fibrin and few platelets.
A thrombus eventually reduces or obstructs blood flow to tissues or organs, such as the heart, brain, or lungs, depriving them of essential nutrients critical to survival. A thrombus also has the potential of detaching from the vessel wall and circulating within the bloodstream (referred to as an embolus). The embolus may become lodged in smaller blood vessels, blocking blood flow into the local tissue or organ and leading to ischemia. Whether episodes of thromboembolism are life-threatening depends on the site of vessel occlusion.

Therapy consists of removal or dissolution of the clot and supportive measures. Anticoagulant therapy is effective in treating or preventing venous thrombosis; it is not as useful in treating or preventing arterial thrombosis. Parenteral heparin is the major anticoagulant used to treat thromboembolism. Oral coumarin drugs also are widely used, including a newer direct factor Xa inhibitor (rivaroxaban). More aggressive therapy may be indicated for such conditions as pulmonary embolism, coronary thrombosis, or thrombophlebitis. Streptokinase, tissue plasminogen activator (t-PA), and urokinase activate the fibrinolytic system and are administered to accelerate the lysis of known thrombi. These drugs are known as fibrinolytic or thrombolytic therapy and are prescribed with a high degree of caution because they can cause hemorrhagic complications.

The risk for developing spontaneous thrombi is related to several factors, referred to as the Virchow triad: (1) injury to the blood vessel endothelium, (2)
abnormalities of blood flow, and (3) hypercoagulability of the blood. The role of estrogens as a cause of thrombi has received much attention.

Endothelial injury to blood vessels can result from atherosclerosis (plaque deposits on arterial walls) (see Chapter 24). Atherosclerosis initiates platelet adhesion and aggregation, promoting the development of atherosclerotic plaques that enlarge, causing further damage and occlusion. Other causes of vessel endothelial injury may be related to hemodynamic alterations associated with hypertension and turbulent blood flow. Injury also is caused by radiation injury, exogenous chemical agents (e.g., toxins from cigarette smoke), endogenous agents (e.g., cholesterol), bacterial toxins or endotoxins, or immunologic mechanisms.

Sites of turbulent blood flow in the arteries and stasis of blood flow in the veins are at risk for thrombus formation. In areas of turbulence, platelets and endothelial cells may be activated, leading to thrombosis. In sites of stasis, platelets may remain in contact with the endothelium for prolonged lengths of time, and clotting factors that would normally be diluted with fresh flowing blood are not diluted and may become activated. The most common clinical conditions that predispose to venous stasis and subsequent thromboembolic phenomena are major surgery (e.g., orthopedic surgery), acute myocardial infarction, congestive heart failure, limb paralysis, spinal injury, malignancy, advanced age, the postpartum period, and bed rest longer than 1 week. Turbulence and stasis occur with ulcerated atherosclerotic plaques (myocardial infarction), hyperviscosity (polycythemia), and conditions with deformed red cells (sickle cell anemia).

**Hypercoagulability**, or **thrombophilia**, is the condition in which an individual is at risk for thrombosis, but by itself it is a rare cause of thrombosis. Hypercoagulability is differentiated according to whether it results from primary (hereditary) or secondary (acquired) causes.

**Hereditary thrombophilies.**

Thrombophilies can result from both inherited conditions and, more commonly, acquired conditions. Several inherited conditions increase the risk of developing thrombosis and most are autosomal dominant. Thus individuals who are homozygous for the mutation are at greatest risk for thrombosis. These include mutations in platelet receptors, coagulation proteins, fibrinolytic proteins, and other factors. The particular mutations that have been most strongly linked as risk factors for venous thrombosis or for arterial thrombosis leading to coronary artery disease or stroke include those that affect fibrinogen, prothrombin (G20210A variant), factor V (factor V Leiden) of the coagulation system, PAI-1 of the fibrinolytic system, the platelet receptor GPIIIa, and methylenetetrahydrofolate reductase
(MTHFR), as well as mutations that result in excessive levels of homocysteine (hyperhomocysteinemia). Other inherited thrombophilias are risk factors mostly for venous thrombosis and include deficiencies in protein C, protein S, and AT-III.\textsuperscript{90,91} Factor V Leiden results from a single nucleotide mutation that confers partial resistance to inactivation by activated protein C, resulting in prolonged high levels of activated factor V (factor Va) and overproduction of thrombin. Although this mutation increases the risk for thrombosis, most individuals with factor V Leiden do not have clinically relevant thrombotic events. It is the most common hereditary thrombophilia and is primarily observed in individuals of European ancestry. It is observed in about 5\% of whites in the United States and in about 30\% of individuals presenting with deep venous thrombosis (DVT) or pulmonary embolism.

Other hereditary thrombophilias are less common. Prothrombin mutation, which leads to high levels of circulating prothrombin, is observed in about 2\% to 5\% of individuals of European ancestry. It is, however, found in 5\% to 10\% of individuals presenting with thrombosis.

THFR mutation leads to alterations in the metabolism of the amino acid homocysteine into methionine and abnormally elevated levels of that amino acid in the blood (hyperhomocysteinemia). Acquired hyperhomocysteinemia may result from deficiencies in vitamins B\textsubscript{6} or B\textsubscript{12}, endocrine diseases (e.g., diabetes mellitus, hypothyroidism), pernicious anemia, inflammatory bowel disease, renal failure, and therapy with some drugs. Individuals with homocysteine levels greater than the 95th percentile are 2.5 times more likely to experience an episode of DVT.

More than 100 different known mutations lead to defects of proteins C, protein S, and AT-III and increase the risk of venous thrombosis. Mutations may lead to either quantitative (low levels of protein) or qualitative (production of defective protein) changes.

Tests to diagnose inherited thrombophilias include prothrombin time; partial thromboplastin time; and levels of protein C, protein S, and AT-III. More elaborate tests to detect precise mutations in factor V, prothrombin, or MTHFR may be indicated.

**Acquired hypercoagulability.**

Deficiencies in proteins S and C and AT-III may be acquired and contribute to a hypercoagulable state.\textsuperscript{92} Conditions associated with an acquired protein deficiency include DIC, liver disease, infection, DVT, acute respiratory distress syndrome, L-asparaginase therapy, HUS, and TTP. The postoperative state also predisposes an individual to protein C or S deficiency; however, its role in contributing to DVT remains unclear.
Acquired hypercoagulable states include *antiphospholipid syndrome (APS)*. APS is an autoimmune syndrome characterized by autoantibodies against plasma membrane phospholipids and phospholipid-binding proteins. As with most autoimmune diseases, the predominantly affected individual is female and of reproductive age. Those with APS are at risk for both arterial and venous thrombosis and a variety of obstetric complications, including pregnancy loss and preeclampsia/eclampsia. In severe cases the individual may die from recurrent major thrombus formation. The pathophysiology is related to autoantibodies directly reacting with platelets or endothelial cells (increasing the risk for thrombosis) or the placental surface (resulting in damage to the placenta). The predominant diagnostic tests measure prolongation of laboratory blood coagulation tests related to an antibody inhibitor (lupus anticoagulant) and specific ELISAs for antibodies against phospholipids (e.g., anticardiolipin antibody) or proteins that bind to phospholipids (e.g., β₂-glycoprotein I). Highly effective therapy (i.e., unfractionated or low-molecular-weight heparin with low-dose aspirin) is available to prevent the obstetric complications.

**Quick Check 21-6**

1. Identify three pathologic causes of DIC, and describe the manifestations associated with DIC.

2. Compare and contrast thrombocytopenia with thrombocytosis.

3. Why does vitamin K deficiency predispose an individual to a coagulation disorder?

4. Compare and contrast a thrombus with an embolus.
Did You Understand?
Alterations of Erythrocyte Function

1. Anemia is defined as a reduction in the number or volume of circulating red cells or a decrease in the quality or quantity of hemoglobin.

2. The most common classification of anemias is based on changes in the cell size—represented by the cell suffix -cytic—and changes in the cell’s hemoglobin content—represented by the suffix -chromic.

3. Clinical manifestations of anemia can be found in all organs and tissues throughout the body. Decreased oxygen delivery to tissues causes fatigue, dyspnea, syncope, angina, compensatory tachycardia, and organ dysfunction.

4. Macrocytic (megaloblastic) anemias are characterized by unusually large stem cells in the marrow that mature into very large erythrocytes. Macrocytic anemias are caused most commonly by deficiency of vitamin $B_{12}$. Pernicious anemia, the most common type of macrocytic anemia, can be fatal unless vitamin $B_{12}$ replacement is given (lifelong replacement is required).

5. Microcytic-hypochromic anemias are characterized by abnormally small red cells with insufficient hemoglobin content. The most common cause is iron deficiency.

6. Iron deficiency anemia is the most common type of anemia worldwide and usually develops slowly, with a gradual, insidious onset of symptoms, including fatigue, weakness, dyspnea, alteration of various epithelial tissues, and vague neuromuscular complaints.

7. Iron deficiency anemia is usually a result of a chronic blood loss or decreased iron intake. Once the source of blood loss is identified and corrected, iron replacement therapy can be initiated.

8. Sideroblastic anemias are a heterogeneous group of inherited and acquired disorders. Sideroblastic anemias have various causes but share altered heme synthesis.

9. Normocytic-normochromic anemias are characterized by insufficient numbers of normal erythrocytes. Included in this category are aplastic, posthemorrhagic,
acquired hemolytic, hereditary hemolytic, and anemia of chronic inflammation.

**Myeloproliferative Red Cell Disorders**

1. Polycythemia vera is a stem cell disorder with hyperplastic and neoplastic bone marrow alterations. It is characterized by excessive proliferation of erythrocyte precursors (frequently with increased white blood cells and platelets) in the bone marrow. Polycythemia is responsible for most of the clinical symptoms, including increased blood volume and viscosity. Frequent phlebotomies reduce iron levels and hydroxyurea is the drug of choice for myelosuppression. Use of radioactive phosphorus has been helpful in decreasing the excessive red cell pool.

2. Polycythemia vera may spontaneously convert to acute myelogenous leukemia.

**Alterations of Leukocyte Function**

1. Quantitative alterations of leukocytes (too many or too few) can be caused by bone marrow dysfunction or premature destruction of cells in the circulation. Many quantitative changes in leukocytes occur in response to invasion by microorganisms.

2. Leukocytosis is a condition in which the leukocyte count is higher than normal and is usually a response to physiologic stressors and invasion of microorganisms.

3. Leukopenia is present when the leukocyte count is lower than normal and is caused by pathologic conditions, such as malignancies and hematologic disorders.

4. Granulocytosis (particularly as a result of an increase in neutrophils, eosinophils, or basophils) occurs in response to infection and inflammation.

5. Eosinophilia results most commonly from allergic disorders, parasitic invasion, and ingestion or inhalation of toxic foreign particles.

6. Basophilia is rare and generally is a response to inflammation and immediate hypersensitivity reactions. Basopenia is a decrease in circulating numbers of basophils.

7. Monocytosis is an increase in numbers of circulating monocytes and is often transient. It occurs during the late or recuperative phase of infection.
Monocytopenia is a decrease in circulating monocytes.

8. Granulocytopenia, a significant decrease in the number of neutrophils, can be a life-threatening condition if sepsis occurs; it is often caused by chemotherapeutic agents, severe infection, and radiation.

9. Lymphocytopenia is a decrease in the number of circulating lymphocytes in the blood. It is associated with neoplasias, immune deficiencies, and destruction by drugs, viruses, or radiation.

10. Infectious mononucleosis (IM) is an acute infection of B lymphocytes most commonly (85% of IM cases) associated with the Epstein-Barr virus (EBV). The classic symptoms are pharyngitis, lymphadenopathy, and fever. The proliferation of infected B cells may be uncontrolled and lead to B-cell lymphomas.

11. Transmission of EBV is usually through saliva from close personal contact. IM is self-limiting and treatment consists of rest and symptomatic treatment.

12. The common pathologic feature of all forms of leukemia is an uncontrolled proliferation of leukocytes, overcrowding the bone marrow and resulting in decreased production and function of the other blood cell lines.

13. The classification of leukemias is based on the cell type involved—myeloid or lymphoid—and the rate of progression—acute or chronic. There are four major types of leukemia: acute lymphocytic leukemia (ALL), acute myelogenous leukemia (AML), chronic lymphocytic leukemia (CLL), and chronic myelogenous leukemia (CML).

14. Although the exact cause of leukemia is unknown, several risk factors and related genetic aberrations are associated with the onset of malignancy. The leukemias are clonal disorders driven by genetically abnormal stem-like cancer cells.

15. Abnormal immature white blood cells, called blasts, fill the bone marrow and spill into the blood. The blasts overcrowd the marrow and cause cellular proliferation of the other cell lines to cease.

16. The major clinical manifestations of leukemia include fatigue caused by anemia, bleeding caused by thrombocytopenia, fever secondary to infection, anorexia, and weight loss.
17. Treatment varies depending on the type of leukemia and includes observation, steroids, chemotherapy, monoclonal antibodies, and transplant options.

18. Chronic leukemias progress differently than acute leukemias (which can be abrupt and stormy onset), advancing slowly and insidiously.

**Alterations of Lymphoid Function**

1. Lymphadenopathy is enlarged lymph nodes.

2. Lymphomas consist of a diverse group of neoplasms that develop from the proliferation of malignant lymphocytes in the lymphoid system. The WHO classification, based on structure and cell lineage, recognizes three major categories of lymphomas: B-cell neoplasms, T-cell/natural killer–cell (NK-cell) neoplasms, and Hodgkin lymphoma. Two basic categories of lymphomas are Hodgkin lymphoma and non-Hodgkin lymphoma.

3. In general, lymphomas are the result of genetic mutations or viral infection. Malignant transformation produces a cell with uncontrolled and excessive growth that accumulates in the lymph nodes and other sites, producing tumor masses.

4. Hodgkin lymphoma is characterized by the abnormal cell called the Reed-Sternberg cell.

5. The pathogenesis of Hodgkin lymphoma may be linked to infection with Epstein-Barr virus (EBV).

6. An enlarged, painless mass or swelling, most commonly in the neck, is an initial sign of Hodgkin lymphoma; however, asymptomatic lymphadenopathy can progress undetected for years.

7. Treatment of Hodgkin lymphoma includes chemotherapy, radiation therapy, and surgery. Treatment with chemotherapy or radiation therapy, or both, may increase the risk of second cancers, cardiovascular disease, and other health problems months or years after treatment.

8. The non-Hodgkin lymphomas (NHLs) are a heterogeneous group of proliferative lymphoid tissue neoplasms. Clonal expansion of B cells accounts for the majority of NHLs. Oncogenes may be activated by chromosomal translocation (most common alteration) or by deletion of tumor-suppressor genes. Certain subtypes
may have altered genomes by oncogenic viruses.

9. Generally, with non-Hodgkin lymphoma, the swelling of lymph nodes is painless and the nodes enlarge and transform over a period of months or years.

10. Standard treatment for NHL includes radiation therapy, chemotherapy, target therapy (monoclonal antibody therapy, proteasome inhibitor therapy), plasmapheresis, biologic therapy, and watchful waiting.

11. Burkitt lymphoma is a B-cell tumor and involves the jaw and facial bones and sometimes the abdomen. Although more common in Africa, it is documented in the United States, Latin America, and other countries. Burkitt lymphoma is heterogeneous and may involve infection with EBV and suppression of the immune system by other illnesses.

12. Treatment for Burkitt lymphoma is intensive chemotherapy.

13. Multiple myeloma (MM) is a neoplasm of plasma cells in the bone marrow and usually not found in the blood. It is characterized by multiple malignant tumor masses of plasma cells scattered throughout the skeletal system (lytic bone lesions) and sometimes found in soft tissue.

14. MM tumors are highly heterogeneous and involve mutations in different signaling pathways. Chromosomal translocations are common. The exact cause of multiple myeloma is unknown, but risk factors include radiation, certain chemicals, and a history of monoclonal gammopathy of undetermined significance (MGUS).

15. The common presentation of MM is characterized by elevated levels of calcium in the blood, renal failure, anemia, and bone (lytic) lesions.

16. Treatment includes chemotherapy, radiation therapy, plasmapheresis, and stem cell transplant.

Alterations of Splenic Function

1. Splenomegaly (enlargement of the spleen) may be considered normal in certain individuals but its presence is associated with various diseases.

2. Splenomegaly results from (1) acute inflammatory or infectious processes, (2) congestive disorders, (3) infiltrative processes, and (4) tumors or cysts.
3. Hypersplenism (overactivity of the spleen) results from splenomegaly. Hypersplenism results in sequestering of the blood cells, causing increased destruction of red blood cells, leukopenia, and thrombocytopenia.

**Hemorrhagic Disorders and Alterations of Platelets and Coagulation**

1. The arrest of bleeding is called hemostasis.

2. Thrombocytopenia is characterized by a platelet count below 150,000/µL of blood; the most significant count is less than 100,000 platelets/µL, and a count less than 50,000/µL increases the potential for hemorrhage associated with minor trauma.

3. Thrombocytopenia exists in primary or secondary forms and is associated with autoimmune diseases, viral infections, drugs, nutritional deficiencies, chronic renal failure, cancer, radiation therapy, bone marrow hypoplasia, and DIC.

4. Immune thrombocytopenic purpura (ITP) is the most common cause of thrombocytopenia secondary to increased platelet destruction.

5. Thrombocythemia is characterized by a platelet count more than 400,000 platelets/µL of blood and is symptomatic when the count exceeds 1 million/µL, at which time the risk for intravascular clotting (thrombosis) is high.

6. Thrombocythemia is a myeloproliferative neoplasm characterized by an increase in platelet production in the bone marrow. It also can include an increase in red blood cell production.

7. Qualitative alterations in normal platelet function prevent platelet plug formation and may result in prolonged bleeding times. Acquired disorders of platelet function are more common than congenital disorders.

8. Disorders of coagulation are usually caused by defects or deficiencies of one or more clotting factors. Coagulation is stimulated by the presence of tissue factor that is released by damaged or dead tissues.

9. Coagulation is impaired when there is a deficiency of vitamin K because of insufficient production of prothrombin and synthesis of clotting factors VII, IX, and
X, often associated with liver diseases.

10. Disseminated intravascular coagulation (DIC) is an acquired clinical syndrome characterized by widespread activation of coagulation, resulting in formation of fibrin clots in medium and small vessels or microvasculature throughout the body. Widespread clotting may lead to blockage of blood flow to organs, resulting in multiple organ failure. The magnitude of clotting may result in consumption of platelets and clotting factors, leading to a tendency to bleed despite widespread clots.

11. DIC is secondary to a wide variety of clinical conditions with sepsis as the most common condition associated with DIC.

12. For a diagnosis of DIC, the person must present with a clinical condition that is known to be associated with DIC. The most commonly used combination of laboratory tests usually confirms thrombocytopenia, or a rapidly decreasing platelet count on repeated testing, prolongation of clotting times, the presence of fibrin split products, and decreased levels of coagulation inhibitors may indicate the presence of DIC.

13. Treatment of DIC is directed toward (1) eliminating the underlying pathologic condition, (2) controlling ongoing thrombosis, and (3) maintaining organ function.

14. Thromboembolic disease results from a fixed (thrombus) or moving (embolus) clot that blocks flow within a vessel, denying nutrients to tissues distal to the occlusion; death can result when clots obstruct blood flow to the heart, brain, or lungs.

15. Hypercoagulability, or thrombophilia, is a condition in which an individual is at risk for thrombosis.

16. The term Virchow triad refers to three factors that can cause thrombus formation: (1) loss of integrity of the vessel wall, (2) abnormalities of blood flow, and (3) alterations in the blood constituents.

CHAPTER OUTLINE

Disorders of Erythrocytes, 554
   Acquired Disorders, 554
   Inherited Disorders, 557

Disorders of Coagulation and Platelets, 563
   Inherited Hemorrhagic Disease, 563
   Antibody-Mediated Hemorrhagic Disease, 563

Neoplastic Disorders, 564
   Leukemia, 564
   Lymphomas, 565
   Hodgkin Lymphoma, 566
Among the diseases that affect erythrocytes in children are acquired disorders, such as iron deficiency anemia and hemolytic disease of the newborn, and inherited disorders, such as glucose-6-phosphate dehydrogenase deficiency, sickle cell disease, and the thalassemias.

Childhood disorders that involve the coagulation process and platelets include inherited hemorrhagic diseases, such as the hemophilias, and antibody-mediated hemorrhagic diseases, including immune thrombocytopenic purpura. Finally, leukocyte disorders, such as leukemia and the lymphomas (both Hodgkin lymphoma and non-Hodgkin lymphoma), are discussed in this chapter.
Disorders of Erythrocytes

Anemia is the most common blood disorder in children. Like the anemias of adulthood, the anemias of childhood are caused by ineffective erythropoiesis or premature destruction of erythrocytes. The most common cause of insufficient erythropoiesis is iron deficiency, which may result from insufficient dietary intake or chronic loss of iron caused by bleeding. The hemolytic anemias of childhood may be divided into (1) disorders that result from premature destruction caused by intrinsic abnormalities of the erythrocytes and (2) disorders that result from damaging extraerythrocytic factors. The hemolytic anemias are either inherited or acquired.

The most dramatic form of acquired congenital hemolytic anemia is hemolytic disease of the fetus and newborn (HDFN), also termed erythroblastosis fetalis. HDFN is an alloimmunity (isoimmunity) disease in which maternal blood and fetal blood are incompatible, causing the mother's immune system to produce antibodies against fetal erythrocytes. Fetal erythrocytes attacked by (i.e., bound to) maternal antibodies are recognized as foreign or defective by the fetal mononuclear phagocyte system and are removed from the circulation by phagocytosis, usually in the fetal spleen. (For a complete examination of HDFN, see the discussion that follows.) Other acquired hemolytic anemias—some of which begin in utero—include those caused by infections or the presence of toxic chemicals.

The inherited forms of hemolytic anemia result from intrinsic defects of the child's erythrocytes, any of which can lead to erythrocyte removal by the mononuclear phagocyte system. Structural defects include abnormal cellular size or shape and abnormalities of plasma membrane structure (spherocytosis). Intracellular defects include enzyme deficiencies, the most common of which is glucose-6-phosphate dehydrogenase (G6PD) deficiency, and defects of hemoglobin synthesis, which manifest as sickle cell disease or thalassemia, depending on which component of hemoglobin is defective. These and other causes of childhood anemia are listed in Table 22-1.

**Acquired Disorders**

**Iron Deficiency Anemia**

Iron is *critical* to the developing child, especially for normal brain development, and without it the damage from the periods of iron deficiency anemia (IDA) in children is irreversible. IDA is the most common nutritional disorder worldwide with the highest incidence occurring between 6 months and 2 years of age. IDA is common in the United States with prevalence higher in toddlers, adolescent girls, and women of childbearing age; IDA causes clinical manifestations mostly related to inadequate hemoglobin synthesis.¹

IDA can result from (1) dietary lack of iron, (2) problems with iron absorption, (3) blood loss, and (4) increased requirement for iron. Inadequate intake of iron is the most common cause of IDA during the first few years of life. Blood loss is the most common cause during childhood and adolescence, and for adults in the Western world. Chronic IDA from occult (hidden) blood loss may be caused by a gastrointestinal lesion, parasitic infestation, or hemorrhagic disease. A reasonable hypothesis for infants and young children who develop IDA is that it occurs because of chronic intestinal blood loss induced by exposure to a heat-labile protein in cow's milk. Such exposure causes an inflammatory gastrointestinal reaction that damages
the mucosa and results in diffuse microhemorrhage. Growing evidence indicates that cellular components of both innate and adaptive immunity play significant roles during the pathogenesis of cow's milk allergy.  

Dietary lack of iron is not common in developed countries, where iron is in the readily absorbed form from heme found in meat. IDA was recently found in Israel, mainly in children 1.5 to 3 years old, and was associated with low red meat intake. In developing countries, food may be less available and the iron found in plants is in the poorly absorbable inorganic form. Infants are at increased risk for IDA because of very small amounts of iron in milk. Bioavailability of iron from breast milk is higher than that from cow's milk. Impaired absorption is found in chronic diarrhea, fat malabsorption, and sprue (Health Alert: A Significant Number of Children Develop and Suffer from Severe Iron Deficiency Anemia).

### Health Alert

**A Significant Number of Children Develop and Suffer from Severe Iron Deficiency Anemia**

A recent study in the United States found children aged 36 months to 15 years are particularly vulnerable to iron deficiency anemia (IDA), especially those consuming excessive quantities of whole cow's milk. The prevalence of IDA in infancy has not changed in the past four decades and remains about 7%. Several children who were not anemic at 12 months of age went on to develop IDA as their iron stores became depleted. These children had typical signs of anemia although their parents were not aware of the abnormalities. Chronic severe IDA in the first years of life increases the risk of irreversible cognition problems as well as affective and motor development. The American Academy of Pediatrics (AAP) recommends screening for IDA with hemoglobin concentration and clinical assessment at about 1 year of age, and the Centers for Disease Control and Prevention (CDC) recommends that all children aged 2 through 5 years be assessed annually for risk factors for IDA and screened appropriately. IDA is a preventable disease.

Children in developing countries are often affected by chronic parasite infestations that result in blood and iron loss greater than dietary intake. Treatment of helminth (parasitic worm) infections results in improvement in both appetite and growth as well as reduction of anemia. The association between iron deficiency
anemia and lead poisoning is controversial. Newer areas of investigation include iron deficiency in overweight children and the association of *Helicobacter pylori* infection with IDA.  

**Pathophysiology**

No matter the cause, a deficiency of iron produces a hypochromic-microcytic anemia. Progressive depletion of blood and low serum levels of ferritin and transferrin saturation eventually lead to a lowering of hemoglobin and hematocrit levels. In the early stages, an adaptive increase in red blood cell activity in the bone marrow may prevent the development of anemia. When the iron stores are depleted, with accompanying important laboratory indicators, anemia develops.

**Clinical manifestations**

The symptoms of mild anemia—listlessness and fatigue—usually are not present or are undetectable in infants and young children, who are unable to describe these symptoms. Therefore parents generally do not note any change in the child's behavior or appearance until moderate anemia has developed. General irritability, decreased activity tolerance, weakness, and lack of interest in play are nonspecific indications of anemia. When hemoglobin levels fall below 5 g/dl, pallor, anorexia, tachycardia, and systolic murmurs may occur.

Other symptoms and signs of chronic IDA include splenomegaly, widened skull sutures, decreased physical growth, developmental delays, *pica* (a behavior in which nonfood substances are eaten, such as clay), and altered neurologic and intellectual functions, especially those involving attention span, alertness, and learning ability.

**Evaluation and treatment**

The diagnosis of IDA is confirmed by laboratory tests. These tests include measurement of hemoglobin, hematocrit, serum iron, and ferritin levels and determination of the total iron binding capacity. Most essential is obtaining a thorough history of present illness and dietary history in addition to performing a complete physical examination. Evaluation and treatment of iron deficiency anemia in children is similar to that used for adults with IDA (see Chapter 21). Oral administration of a simple ferrous salt is usually satisfactory and additional vitamin C helps promote absorption. Iron in a liquid form should be administered through a straw because it can stain teeth. Dietary modification is required to prevent recurrences of iron deficiency anemia. Intake of iron-rich foods is increased and the intake of cow's milk may be restricted.

**Hemolytic Disease of the Fetus and Newborn**
The most common cause of hemolytic anemia in newborns is alloimmune disease. **Hemolytic disease of the fetus and newborn (HDFN) (erythroblastosis fetalis)** can occur only if antigens on fetal erythrocytes differ from antigens on maternal erythrocytes. Maternal-fetal incompatibility exists if mother and fetus differ in ABO blood type or if the fetus is Rh-positive and the mother is Rh-negative. Some minor blood antigens also may be involved (see Chapter 7).

ABO incompatibility occurs in about 20% to 25% of all pregnancies, but only 1 in 10 cases of ABO incompatibility results in HDFN. Rh incompatibility occurs in less than 10% of pregnancies and rarely causes HDFN in the first incompatible fetus. Even after five or more pregnancies, only 5% of women have babies with hemolytic disease. Usually erythrocytes from the first incompatible fetus cause the mother's immune system to produce antibodies that affect the fetuses of subsequent incompatible pregnancies. Only one in three cases of HDFN is caused by Rh incompatibility; most cases are caused by ABO incompatibility.

**Pathophysiology**

HDFN will result (1) if the mother's blood contains preformed antibodies against fetal erythrocytes or produces them on exposure to fetal erythrocytes, (2) if sufficient amounts of antibody (usually immunoglobulin G [IgG]) cross the placenta and enter fetal blood, and (3) if immunoglobulin G (IgG) binds with sufficient numbers of fetal erythrocytes to cause widespread antibody-mediated hemolysis or splenic removal. (Antibody-mediated cellular destruction is described in Chapter 8.)

Maternal antibodies may be formed against type B erythrocytes if the mother is type A or against type A erythrocytes if the mother is type B. Usually, however, the mother is type O and the fetus is A or B. ABO incompatibility can cause HDFN even if fetal erythrocytes do not escape into the maternal circulation during pregnancy. This occurs because the blood of most adults already contains anti-A or anti-B antibodies, which are produced on exposure to certain foods or infection by gram-negative bacteria. (Anti-O antibodies do not exist because type O erythrocytes are not antigenic.) Therefore IgG against type A or B erythrocytes is usually preformed in maternal blood and can enter the fetal circulation throughout the first incompatible pregnancy.

Anti-Rh antibodies, on the other hand, are formed only in response to the presence of incompatible (Rh-positive) erythrocytes from the fetus in the blood of an Rh-negative mother. Sources of exposure include fetal blood that is mixed with the mother's blood at the time of delivery, transfused blood, and, rarely, previous sensitization of the mother by her own mother's incompatible blood (**Figure 22-1**).
The first Rh-incompatible pregnancy generally presents no difficulties because few fetal erythrocytes cross the placental barrier during gestation. When the placenta detaches at birth, however, a large number of fetal erythrocytes usually enter the mother's bloodstream. If the mother is Rh-negative and the fetus is Rh-positive, the mother produces anti-Rh antibodies. Anti-Rh antibodies persist in the bloodstream for a long time, and if the next offspring is Rh-positive, the mother's anti-Rh antibodies can enter the bloodstream of the fetus and destroy the erythrocytes. Antibodies against Rh antigen D are of the IgG class and easily cross the placenta.

IgG-coated fetal erythrocytes usually are destroyed in the spleen. As hemolysis proceeds, the fetus becomes anemic. Erythropoiesis accelerates, particularly in the
liver and spleen, and immature nucleated cells (erythroblasts) are released into the bloodstream (hence the name *erythroblastosis fetalis*). The degree of anemia depends on the length of time the antibody has been in the fetal circulation, the concentration of the antibody, and the ability of the fetus to compensate for increased hemolysis. Unconjugated (indirect) bilirubin, which is formed during breakdown of hemoglobin, is transported across the placental barrier into the maternal circulation and is excreted by the mother. Hyperbilirubinemia occurs in the neonate after birth because excretion of lipid-soluble unconjugated bilirubin through the placenta is no longer possible.

The pathophysiologic effects of HDFN are more severe in Rh incompatibility than in ABO incompatibility. ABO incompatibility may resolve after birth without life-threatening complications. Maternal-fetal incompatibility in which a mother with type O blood has a child with type A or B blood usually is so mild that it does not require treatment.

Rh incompatibility is more likely than ABO incompatibility to cause severe or even life-threatening anemia, death in utero, or damage to the central nervous system. Severe anemia alone can cause death as a result of cardiovascular complications. Extensive hemolysis also results in increased levels of unconjugated bilirubin in the neonate's circulation. If bilirubin levels exceed the liver's ability to conjugate and excrete bilirubin, some of it is deposited in the brain, causing cellular damage and, eventually, death if the neonate does not receive exchange transfusions.

Fetuses that do not survive anemia in utero usually are stillborn, with gross edema in the entire body, a condition called *hydrops fetalis*. Death can occur as early as 17 weeks' gestation and results in spontaneous abortion.

**Clinical manifestations**

Neonates with mild HDFN may appear healthy or slightly pale, with slight enlargement of the liver or spleen. Pronounced pallor, splenomegaly, and hepatomegaly indicate severe anemia, which predisposes the neonate to cardiovascular failure and shock. Life-threatening Rh incompatibility is rare today, largely because of the routine use of Rh immunoglobulin.

Because the maternal antibodies remain in the neonate's circulatory system after birth, erythrocyte destruction can continue. This causes hyperbilirubinemia and *icterus neonatorum* (*neonatal jaundice*) shortly after birth. Without replacement transfusions, in which the child receives Rh-negative erythrocytes, the bilirubin is deposited in the brain, a condition termed *kernicterus*. Kernicterus produces cerebral damage and usually causes death (*icterus gravis neonatorum*). Infants who do not die may have intellectual disabilities, cerebral palsy, or high-frequency deafness.
Evaluation and treatment

Routine evaluation of fetuses at risk for HDFN (i.e., fetuses resulting from Rh- or ABO-incompatible matings) includes the Coombs test. The indirect Coombs test measures antibody in the mother's circulation and indicates whether the fetus is at risk for HDFN. The direct Coombs test measures antibody already bound to the surfaces of fetal erythrocytes and is used primarily to confirm the diagnosis of antibody-mediated HDFN. With a prior history of fetal hemolytic disease, diagnostic tests are done to determine risk with the current pregnancy. These tests include maternal antibody titers, fetal blood sampling, amniotic fluid spectrophotometry, and ultrasound fetal assessment.

The key to treatment of HDFN resulting from Rh incompatibility lies in prevention (immunoprophylaxis). One of the success stories of immunology has been the result obtained with Rh immune globulin (RhoGAM), a preparation of antibody against Rh antigen D (anti-D Ig). If an Rh-negative woman is given Rh immune globulin within 72 hours of exposure to Rh-positive erythrocytes, she will not produce antibody against the D antigen, and the next Rh-positive baby she conceives will be protected. Updated recommendations also state that if anti-D Ig is not given within 72 hours, every effort should still be made to administer the anti-D Ig within 10 days. The newer updates on the use of anti-D Ig as prophylaxis to prevent sensitization to the D antigen during pregnancy or at delivery for the prevention of HDFN can be found at the National Guideline Clearinghouse at www.guideline.gov/content.aspx?id=34964#Section 420. The British Committee for Standards in Haematology (BCSH) also established guidelines for the use of anti-D immunoglobulin for rhesus D prophylaxis.

Inherited Disorders

Sickle Cell Disease

Sickle cell disease is a group of disorders characterized by the production of abnormal hemoglobin S (Hb S) within the erythrocytes. Hb S is formed by a genetic mutation in which one amino acid (valine) replaces another (glutamic acid) (Figure 22-2). Hb S, the so-called sickle hemoglobin, reacts to deoxygenation and dehydration by solidifying and stretching the erythrocyte into an elongated sickle shape, producing hemolytic anemia (Figure 22-3).
Sickle cell anemia hemoglobin β-chain

A, Sickle cell hemoglobin is produced by a recessive allele of the gene encoding the β-chain of the protein hemoglobin. It represents a single amino acid change—from glutamic acid to valine at the sixth position of the chain. In this model of a hemoglobin molecule, the position of the mutation can be seen near the end of the upper arm. B, Color-enhanced electron micrograph shows normal erythrocytes and sickled blood cell. C, Brief summary of sickle cell. (A from Raven PH, Johnson GB: Biology, ed 3, St Louis, 1992, Mosby; B copyright Dennis Kunkel Microscopy Inc; C from Kierszenbaum A, Tres L: Histology and cell biology: an introduction to pathology, ed 3, St Louis, 2012, Mosby)
Sickle cell disease is an inherited, autosomal recessive disorder expressed as sickle cell anemia, sickle cell–thalassemia disease, or sickle cell–hemoglobin C disease, depending on mode of inheritance (Table 22-2). (See Chapter 2 for a discussion of genetic inheritance of disease.) Sickle cell anemia, a homozygous form, is the most severe. Sickle cell–thalassemia and sickle cell–Hb C disease are heterozygous forms in which the child simultaneously inherits another type of abnormal hemoglobin from one parent. Sickle cell trait, in which the child inherits Hb S from one parent and normal hemoglobin (Hb A) from the other, is a heterozygous carrier state that rarely has clinical manifestations. All forms of sickle cell disease are lifelong conditions.

Sickle cell disease tends to occur in persons with origins in equatorial countries, particularly central Africa, the Near East, the Mediterranean area, and parts of India. In the United States, sickle cell disease is most common in blacks, with a reported incidence ranging from 1 : 400 to 1 : 500 live births. In the general population, the risk of two black parents having a child with sickle cell anemia is 0.7%. Sickle cell–
hemoglobin C disease is less common (1 in 800 births), and sickle cell–thalassemia occurs in 1 in 1700 births.

Sickle cell trait occurs in 7% to 13% of African Americans, whereas its incidence among East Africans may be as high as 45%. The sickle cell trait may provide protection against lethal forms of malaria, a genetic advantage to carriers who reside in endemic regions for malaria (Mediterranean and African zones) but no advantage to carriers living in the United States.

**Pathophysiology**

Hemoglobin S is soluble and usually causes no problem when properly oxygenated. When oxygen tension decreases, the single amino acid substitution in the β-globin chain of Hb S polymerizes, forming abnormal fluid polymers. As these polymers realign, they cause the red cell to deform into the sickle shape. Sickling depends on the degree of oxygenation, pH, and dehydration of the individual. A decrease in oxygenation (hypoxemia) and pH, as well as dehydration, increases sickling. Deoxygenation is probably the most important variable in determining the occurrence of sickling. Sickle-trait cells sickle at oxygen tensions of about 15 mm Hg, whereas those from an individual with sickle cell disease begin to sickle at about 40 mm Hg. Sickled erythrocytes tend to plug the blood vessels, increasing the viscosity of the blood, which slows circulation and causes vascular occlusion, pain, and organ infarction. Viscosity increases the time of exposure to less oxygenation, promoting further sickling. Sickled cells undergo hemolysis in the spleen or become sequestered there, causing blood pooling and infarction of splenic vessels. The anemia that follows triggers erythropoiesis in the marrow and, in extreme cases, in the liver (Figure 22-4).
Sickling usually is not permanent; most sickled erythrocytes regain a normal shape after reoxygenation and rehydration. Irreversible sickling is caused by irreversible plasma membrane damage caused by sickling. In persons with sickle cell anemia, in which the erythrocytes contain a high percentage of Hb S (75% to 95%), up to 30% of the erythrocytes can become irreversibly sickled. Occasionally, irreversible sickling occurs in sickle cell disease but not in the carrier state (sickle cell trait). Sickling also can be triggered by increased plasma osmolality, decreased plasma volume, and low environmental temperature.

**Clinical manifestations**

There is much variation in the clinical manifestations of sickle cell disease. Some individuals have mild symptoms and others suffer from repeated vasoocclusive crises.

When sickling occurs, the general manifestations of hemolytic anemia—pallor, fatigue, jaundice, and irritability—sometimes are accompanied by acute manifestations called crises. Extensive sickling can precipitate the following four...
types of crises:

1. **Vasoocclusive crisis (thrombotic crisis).** This begins with sickling in the microcirculation. As blood flow is obstructed by sickled cells, vasospasm occurs and a “logjam” effect blocks all blood flow through the vessel. Unless the process is reversed, thrombosis and infarction of local tissue follow. Vasoocclusive crisis is extremely painful and may last for days or even weeks, with an average duration of 4 to 6 days. The frequency of this type of crisis is variable and unpredictable. Vasoocclusion in vessels to the brain can result in stroke. Chronic vasoocclusion in vessels to the kidneys results in end-stage renal disease.

2. **Sequestration crisis.** Large amounts of blood become acutely pooled in the liver and spleen. This type of crisis is seen only in the young child. Because the spleen can hold as much as one fifth of the body's blood supply at one time, up to 50% mortality has been reported, with death being caused by cardiovascular collapse.

3. **Aplastic crisis.** Profound anemia is caused by diminished erythropoiesis despite an increased need for new erythrocytes. In sickle cell anemia, erythrocyte survival is only 10 to 20 days. Normally a compensatory increase in erythropoiesis (five to eight times normal) replaces the cells lost through premature hemolysis. If this compensatory response is compromised, aplastic crisis develops in a very short time.

4. **Hyperhemolytic crisis.** Although unusual, this may occur in association with certain drugs or infections.

   The clinical manifestations of sickle cell disease usually do not appear until the infant is at least 6 months old, at which time the postnatal decrease in concentrations of Hb F causes concentrations of Hb S to rise (Figure 22-5). Infection is the most common cause of death related to sickle cell disease. Sepsis and meningitis develop in as many as 10% of children with sickle cell anemia during the first 5 years of life. Survival time is unpredictable and has improved over the past decades.
Sickle cell–Hb C disease is usually milder than sickle cell anemia. The main clinical problems are related to vasoocclusive crises and are thought to result from higher hematocrit values and viscosity. In older children, sickle cell retinopathy, renal necrosis, and aseptic necrosis of the femoral heads occur along with obstructive crises.

Sickle cell–thalassemia has the mildest clinical manifestations of all the sickle cell diseases. The normal hemoglobins, particularly Hb F, inhibit sickling. In addition, the erythrocytes tend to be small (microcytic) and to contain relatively little hemoglobin (hypochromic), making them less likely to occlude the microcirculation, even when in a sickled state.

Evaluation and treatment
The sickle cell trait does not affect life expectancy or interfere with daily activities. However, on rare occasions, severe hypoxia caused by shock, vigorous exercising at high altitudes, flying at high altitudes in unpressurized aircraft, or undergoing
anesthesia is associated with vasoocclusive episodes in persons with sickle cell trait. These cells form an ivy shape instead of a sickle shape.

The parents' hematologic history and clinical manifestations may suggest that a child has sickle cell disease, but hematologic tests are necessary for diagnosis. If the sickle solubility test confirms the presence of Hb S in peripheral blood, hemoglobin electrophoresis provides information about the amount of Hb S in erythrocytes. Prenatal diagnosis can be made after chorionic villus sampling as early as 8 to 10 weeks' gestation or by amniotic fluid analysis at 15 weeks' gestation (Figure 22-6). Newborn screening for sickle cell disease should be performed according to state law.

![FIGURE 22-6 Prepregnancy Sickle Cell Test. This technique has potential for detection of other inherited diseases. 1, Fertilization produces several embryos. 2, The embryos are tested for the presence of the gene. 3, The embryos without the gene are implanted. 4, Amniocentesis confirms whether the fetus (or fetuses) has the sickle cell gene. 5, Woman has a normal child.](image)

The main treatment for sickle cell disease is hydroxyurea; it inhibits DNA synthesis, causes an increase in hemoglobin F concentration, and results in an anti-inflammatory effect (decreases leukocyte production). These outcomes are thought to decrease crises. Treatment of sickle cell disease consists of supportive care aimed at preventing consequences of anemia and avoiding crises, including adequate hydration and pain management. Debate about transfusion therapy exists because of iron overload that can cause liver damage and fibrosis, delayed physical and sexual development, and heart disease; in addition, transfusion therapy requires chelation therapy to remove excess iron. Genetic counseling and psychologic support are important for the child and family.

**Thalassemias**

The alpha- and beta-thalassemias are inherited autosomal recessive disorders that
cause an impaired rate of synthesis of one of the two chains—α or β—of adult hemoglobin (Hb A). The disorder was named thalassemia, which is derived from the Greek word for sea, because it was discovered initially in persons with origins near the Mediterranean Sea. Beta-thalassemia, in which synthesis of the β-globin chain is slowed or defective, is prevalent among Greeks, Italians, and some Arabs and Sephardic Jews. Alpha-thalassemia, in which the α-chain is affected, is most common among Chinese, Vietnamese, Cambodians, and Laotians. Both alpha- and beta-thalassemias are common among blacks.

Both alpha- and beta-thalassemias are referred to as major or minor, depending on how many of the genes that control α- or β-chain synthesis are defective and whether the defects are inherited homozygously (thalassemia major) or heterozygously (thalassemia minor). Pathophysiologic effects range from mild microcytosis to death in utero, depending on the number of defective genes and mode of inheritance. The anemic manifestation of thalassemia is microcytic-hypochromic hemolytic anemia.

Pathophysiology

The beta-thalassemias are caused by mutations that decrease the synthesis of β-globin chains, leading to anemia, tissue hypoxia, and red cell hemolysis. β-Chain production is depressed—moderately in the heterozygous form, beta-thalassemia minor, and severely in the homozygous form, beta-thalassemia major (also called Cooley anemia). This results in erythrocytes having a reduced amount of hemoglobin and accumulation of free α-chains (Figure 22-7). The free α-chains are unstable and easily precipitate in the cell. Most erythroblasts that contain precipitates are destroyed by mononuclear phagocytes in the marrow, resulting in ineffective erythropoiesis and anemia. Some of the precipitate-carrying cells do mature and enter the bloodstream, but they are destroyed prematurely in the spleen, resulting in mild hemolytic anemia.
There are four forms of alpha-thalassemia: (1) alpha trait (the carrier state), in which a single α-chain–forming gene is defective; (2) alpha-thalassemia minor, in which two genes are defective; (3) hemoglobin H disease, in which three genes are defective; and (4) alpha-thalassemia major, a fatal condition in which all four α-forming genes are defective. Death is inevitable because α-chains are absent and oxygen cannot be released to the tissues.

**Clinical manifestations**

Beta-thalassemia occurs more commonly than does alpha-thalassemia. Occasionally, synthesis of γ- or δ-polypeptide chains is defective, resulting in gamma- or delta-thalassemia. (Hemoglobin chains are described in Chapter 20.)

Beta-thalassemia minor causes mild to moderate microcytic-hypochromic
anemia, mild splenomegaly, bronze coloring of the skin, and hyperplasia of the bone marrow. The degree of reticulocytosis depends on the severity of the anemia and results in skeletal changes. Hemolysis of immature (and therefore fragile) erythrocytes may cause a slight elevation in serum iron and indirect bilirubin levels. Persons with beta-thalassemia minor are usually asymptomatic.

Persons with beta-thalassemia major may become quite ill. Anemia is severe and results in a significant cardiovascular burden with high-output congestive heart failure. In the past, death resulted from cardiac failure. Today, blood transfusions can increase life span by one to two decades, and death usually is caused by hemochromatosis (from transfusions). Liver enlargement occurs as a result of progressive hemosiderosis, whereas enlargement of the spleen is caused by extramedullary hemopoiesis and increased destruction of red blood cells. Growth and maturation are retarded, and a characteristic chipmunk deformity develops on the face, caused by expansion of bones to accommodate hyperplastic marrow.

Persons who inherit the mildest form of alpha-thalassemia (the alpha trait) usually are symptom free or have mild microcytosis. Alpha-thalassemia minor has clinical manifestations that are virtually identical to those of beta-thalassemia minor: mild microcytic-hypochromic reticulocytosis, bone marrow hyperplasia, increased serum iron concentrations, and moderate splenomegaly.

Signs and symptoms of alpha-thalassemia major are similar to those of beta-thalassemia major, but milder. Moderate microcytic-hypochromic anemia, enlargement of the liver and spleen, and bone marrow hyperplasia are evident.

Alpha-thalassemia major causes hydrops fetalis, the most severe form of alpha-thalassemia, caused by deletion of all four α-globin genes. The infant suffers from severe tissue anoxia and may develop fulminant intrauterine congestive heart failure. Signs of fetal distress became evident by the third trimester of pregnancy. In the past, severe tissue anoxia led to death in utero; now many such infants are saved by intrauterine transfusions.

Both alpha- and beta-thalassemia major are life-threatening. Children with thalassemia major generally are weak, fail to thrive, show poor development, and experience cardiovascular compromise with high-output failure secondary to anemia. Untreated, they will die by 5 to 6 years of age.

**Evaluation and treatment**

Evaluation of thalassemia is based on familial disease history, clinical manifestations, and blood tests. Peripheral blood smears that show microcytosis and hemoglobin electrophoresis that demonstrates diminished amounts of α- or β-chains are used to make the diagnosis. Analysis of fetal DNA from withdrawn amniotic fluid is used as a screening test to detect hydrops fetalis (alpha-thalassemia
major). Newborn screening for thalassemia should be done according to state law.

Persons who are silent carriers or have thalassemia minor generally have few if any symptoms and require no specific treatment. However, therapies to support and prolong life are necessary for thalassemia major and include chronic blood transfusion therapy and management of resultant iron overload (see Figure 22-7). Allogeneic hematopoietic stem cell transplantation (HSCT) is the only cure. For both symptom-free carriers and those with the disease, prenatal diagnosis and genetic counseling may be the most important therapeutic measures that can be offered.

Quick Check 22-1

1. Why do clinical manifestations of sickle cell disease not appear until the infant is at least 6 months old?

2. Why is Rh incompatibility rare today?

3. Why do children with thalassemia major develop cardiovascular complications?
Disorders of Coagulation and Platelets

Inherited Hemorrhagic Disease

Hemophilias

Hemophilia A is defined as factor VIII deficiency and is the most common hereditary disease associated with life-threatening bleeding. It is caused by a mutation in factor VIII, an essential cofactor for factor IX in the coagulation cascade. Factor IX deficiency is most often called hemophilia B (Christmas disease, after the first person identified and not the holiday) but is clinically indistinguishable from factor VIII deficiency because factors VIII and IX function together to activate factor X. Both hemophilia A and hemophilia B are inherited as X-linked recessive traits, thus affecting mainly males and homozygous females. Excessive bleeding rarely occurs in heterozygous females. New mutations, not family history, are the cause of about 30% of cases. The incidence of hemophilia A is approximately 1 in 5000 male births, whereas hemophilia B is five times less common, with an incidence of approximately 1 in 30,000 male births. The incidence worldwide of hemophilia is not well known, but it is estimated to be at more than 400,000 people. Races are affected equally for both disorders.

Only hemophilias A and B will be discussed in this chapter. Of note is a third, less common hemophilia, termed hemophilia C, which results from a deficiency of factor XI. Table 22-3 lists the coagulation factors and deficiencies associated with clinical bleeding.

Pathophysiology

Hemophilia may be inherited or caused by a spontaneous mutation of the factor gene. The genetic instructions for both factor VIII and factor IX lie on the long arm
of the X chromosome. Deficiencies of factor VIII and factor IX are clinically manifested almost exclusively in males. Because a male's DNA contains only one X chromosome, hemophilia affects mostly males. Women have two X chromosomes, and if one X chromosome has a defective gene, the other X chromosome has the information needed to create clotting factors. A female can have hemophilia because of X-inactivation or lyonization (see Chapter 2). It is possible for one X chromosome to not express itself. If the X chromosome with the hemophilia gene is the active chromosome, the woman will have lower levels of clotting factors. Fifty percent of carriers have low clotting factor levels. There is a known family history of hemophilia A and B in about two thirds of cases; the remaining third are new genetic mutations, either in the individual with hemophilia or in his unaffected carrier mother.

Numerous gene mutations and deletions have been identified at the molecular level in factor VIII and IX deficiency. The molecular defect that leads to hemophilia is identical among members of a given family; however, the deletion mutation has been unique in each family studied.¹¹

Clinical manifestations
The clinical manifestations and severity of hemophilia depend largely on the level of factor VIII and IX activity. The severity designation of an individual's hemophilia will determine the characteristics of the resulting disorder and will direct treatment strategies.¹² Joint bleeding is the most characteristic type of bleeding in hemophilia. Bleeding into muscles, usually from trauma, also occurs with both hemophilia A and hemophilia B. Oral bleeding is common in the setting of dental surgery. Spontaneous painless hematuria, which is relatively common in hemophilia, generally does not result in significant blood loss but requires evaluation. Hematuria accompanied by pain requires prompt evaluation and treatment. Intracranial bleeds, bleeding of internal organs, and bleeding into the tissues of the neck, chest, or abdomen are all life-threatening. Delayed or suboptimal treatment of these bleeds may lead to permanent brain injury, loss of organ function, or death.

Evaluation and treatment
Because hemophilia is most often an inherited disease, a positive family history may expedite a diagnosis of hemophilia. When a suspected carrier mother is pregnant, genetic testing in utero through amniocentesis or chorionic villus sampling (CVS) may reveal a hemophilia diagnosis before childbirth. In the absence of a positive family history, when a bleeding disorder is suspected, personal bleed history, laboratory testing, family history, and physical assessment contribute to a
thorough evaluation and accurate diagnosis. In general, those with hemophilia A or B will have a prolonged partial thromboplastin time (PTT) and the prothrombin time (PT) will be normal. Measurement of factor VIII (hemophilia A) and factor IX (hemophilia B) levels is necessary for diagnosis.

The majority of children with hemophilia A (factor VIII deficiency) can be treated with recombinant factor VIII, and the majority of children with hemophilia B (factor IX deficiency) can be treated with recombinant factor IX. Recombinant factor is reconstituted in a small volume of diluent, administered by slow intravenous push, and raises the factor level almost immediately.

Antibody-Mediated Hemorrhagic Disease

The antibody-mediated hemorrhagic diseases are a group of disorders caused by the immune response. Antibody-mediated destruction of platelets or antibody-mediated inflammatory reactions to allergens damage blood vessels and cause seepage into tissues. The thrombocytopenic purpuras may be intrinsic or idiopathic, or they may be transient phenomena transmitted from mother to fetus. The inflammatory, or “allergic,” purpuras, although rare, occur in response to allergens in the blood. All of these disorders first appear during infancy or childhood.

Immune Thrombocytopenic Purpura

Acute immune thrombocytopenic purpura (ITP; autoimmune [primary] thrombocytopenic purpura) is the most common disorder of platelet consumption. Autoantibodies bind to the plasma membranes of platelets, causing platelet sequestration and destruction by mononuclear phagocytes in the spleen and other lymphoid tissues at a rate that exceeds the ability of the bone marrow to produce them. The destruction of platelets is triggered by drugs, infections, lymphomas, or an unknown cause.

Pathophysiology

The autoantibodies that produce the destruction are often of the IgG class and are usually against the platelet membrane glycoproteins (IIb-IIIa or Ib-IX). In approximately 70% of cases of ITP, there is an antecedent viral disease (e.g., cytomegalovirus [CMV], Epstein-Barr virus [EBV], parvovirus, or respiratory tract infection) that precedes the eruption of petechiae or purpura by 1 to 3 weeks.

Clinical manifestations

Bruising and a generalized petechial rash often occur with acute onset. Petechiae can develop into ecchymoses. Asymmetric bruising is typical and is found most often
on the legs and trunk. Hemorrhagic bullae of the gums, lips, and other mucous membranes may be prominent, and epistaxis (nose bleeding) may be severe and difficult to control. Otherwise, the child appears well. The principal changes are found in the spleen, bone marrow, and blood. The acute phase lasts 1 to 2 weeks, but thrombocytopenia often persists. Although the incidence is less than 1%, intracranial hemorrhage is the most serious complication of ITP. In some cases, the onset is more gradual, and clinical manifestations consist of moderate bruising and a few petechiae.

**Evaluation and treatment**

Laboratory examination reveals an isolated low platelet count, and the few platelets observed on a smear are large, reflecting increased bone marrow production. The Ivy bleeding time is prolonged. Bone marrow aspiration is not recommended for children with typical features of ITP. The primary treatment for children with ITP is observation regardless of platelet count. When bleeding is present, primary treatment is with an infusion of intravenous immune globulin (IVIG) or a short course of corticosteroids.

Even without treatment, the prognosis for children with ITP is excellent: 75% recover completely within 3 months. After the initial acute phase, spontaneous clinical manifestations subside. By 6 months after onset, 80% of affected children have regained normal platelet counts. ITP that persists longer than 12 months in children is considered chronic and immunosuppressive therapies are utilized.

### Quick Check 22-2

1. List the major disorders of coagulation and platelets found in children.

2. How do gene deletions differ from point mutations?

3. Why are persons with hemophilia at risk for developing degenerative joint changes?

4. What is the major abnormality in immune thrombocytopenic purpura (ITP)?
Neoplastic Disorders

Leukemia

Leukemia is cancer of the blood-forming tissues, such as the bone marrow, that most often produces abnormal white blood cells called leukemic cells. Once in the blood, leukemic cells can spread to other organs, such as the lymph nodes, spleen, and brain. Leukemia is the most common malignancy in children and teens.

Among children and teens, about 75% of leukemias are ALL; the remaining cases are AML. ALL is most common in early childhood, peaking between 2 and 4 years of age. AML is slightly more common during the first 2 years of life and during the teenage years, and occurs about equally among boys and girls of all races. ALL is more common in boys than girls and among Hispanic and white children than among black and Asian-American children.

The cause of most childhood cancer is unknown. About 5% of all childhood cancers are caused by inherited mutations. Genetic mutations can occur during fetal development. Other genetic conditions associated with leukemia include Down syndrome, neurofibromatosis, Shwachman syndrome, Bloom syndrome, and ataxia-telangiectasia. Many studies have shown that exposure to ionizing radiation (prenatal exposure to x-rays and postnatal exposure to high doses) can lead to the development of childhood leukemia and possibly other cancers. There is recent concern for performing computed tomography (CT) scans in children because increased use combined with wide variability in radiation doses has resulted in many children receiving a high dose of radiation. Studies of other possible environmental risk factors, including parental exposure to cancer-causing chemicals, prenatal exposure to pesticides, childhood exposure to common infectious agents, and living near a nuclear power plant, have so far produced inconsistent results. Higher risks of cancer have not been seen in children of individuals treated for sporadic cancer (cancer not caused by an inherited mutation).

Pathogenesis

Acute lymphoblastic leukemia (ALL) is composed of immature B (pre-B) or T (pre-T) cells called lymphoblasts. The bone marrow is dense with lymphoblasts, considered hypercellular, that replace the normal marrow and disrupt normal function. Many of the chromosomal abnormalities documented in ALL cause dysregulation of the expression and function of transcription factors required for normal B-cell and T-cell development. The mutations can include both gain of function and loss of function that are required for normal development.
Acute myeloid leukemia (AML) is caused by acquired oncogenic mutations that impair differentiation, resulting in the accumulation of immature myeloid blasts in the marrow and other organs. Epigenetic alterations are frequent in AML and have a central role. The bone marrow crowding by blasts produces marrow failure and complications, including anemia, thrombocytopenia, and neutropenia. AML is very heterogeneous because myeloid cell differentiation is very complex. To be called \textit{acute}, the bone marrow usually must include greater than 20\% leukemic blasts.

\textbf{Clinical manifestations}

The onset of leukemia may be abrupt or insidious, but the most common symptoms reflect the consequences of bone marrow failure: decreased levels of both red blood cells and platelets and changes in white blood cells. Pallor, fatigue, petechiae, purpura, bleeding, and fever generally are present. Approximately 45\% of children have a hemoglobin level below 7 g/dl. If acute blood loss occurs, characteristic symptoms of tachycardia, air hunger, restlessness, and thirst may be present. Epistaxis often occurs in children with severe thrombocytopenia.

Fever is usually present as a result of (1) infection associated with the decrease in functional neutrophils and (2) hypermetabolism associated with the ongoing rapid growth and destruction of leukemic cells. White blood cell counts greater than 200,000/mm$^3$ can cause leukostasis, an intravascular clumping of cells that results in infarction and hemorrhage, usually in the brain and lung.

Renal failure as a result of hyperuremia (high uric acid levels) can be associated with ALL, particularly at diagnosis or during active treatment. Extramedullary invasion with leukemic cells can occur in nearly all body tissue. The central nervous system (CNS) is a common site of infiltration of extramedullary leukemias, although less than 10\% of children with ALL have CNS involvement at diagnosis. The most common symptoms of CNS involvement relate to increased intracranial pressure, causing early morning headaches, nausea, vomiting, irritability, and lethargy.

Gonadal involvement can occur and leukemic infiltration into bones and joints is common. Reports of bone or joint pain actually lead to the diagnosis of leukemia in some children. In most children, bone pain is characterized as migratory, vague, and without areas of swelling or inflammation. However, if joint pain is the primary symptom and some swelling is associated with the pain, misdiagnoses of rheumatoid arthritis and rheumatic fever have occurred.

Other organs reported to be sites of leukemic invasion include the kidneys, heart, lungs, thymus, eyes, skin, and gastrointestinal tract. Children with leukemia can show symptoms only 1 week before diagnosis.
Evaluation and treatment

The diagnosis of leukemia is made from blood tests and examination of peripheral blood smears. A bone marrow aspiration is usually performed in order to further characterize the leukemia. The blast cell is the hallmark of acute leukemia (Figure 22-8). Healthy children have less than 5% blast cells in the bone marrow and none in the peripheral blood. In ALL, the bone marrow often is replaced by 80% to 100% blast cells, with a reduction in normal developing red blood cells and granulocytes. Occasionally, the marrow appears hypocellular, making the diagnosis difficult to differentiate from aplastic anemia. When this occurs, bone marrow biopsy or biopsy of extramedullary sites is necessary to confirm the diagnosis.

Remarkable success has occurred with treatment of ALL in children. Chemotherapy is the treatment of choice for acute leukemia. Radiation has special considerations for use. In ALL, identification of various risk groups has led to the development of different intensities of drug protocols. Thus treatment is tailored specifically for a particular risk group.

Chronic myelogenous leukemia accounts for less than 5% of childhood leukemias. In the past, it was treated with high-dose chemotherapy followed by allogeneic stem cell transplant, resulting in significant treatment-related mortality.
However, targeted medications, known as tyrosine kinase inhibitors (TKIs), have revolutionized the treatment of CML. Several TKIs are now approved for use in children; treatment requires continued adherence to an oral regimen and the health impact of long-term TKI therapy is not yet known.\textsuperscript{22}

**Lymphomas**

**Lymphoma** (Hodgkin lymphoma and non-Hodgkin lymphoma [NHL]) develops from the proliferation of malignant lymphocytes (immune cells) in the lymphoid system (see Chapters 12 and 21). The four most common types of leukemia are (1) acute lymphoblastic leukemia (ALL), (2) acute myeloid leukemia (AML), (3) chronic lymphocytic leukemia (CLL), and (4) chronic myeloid leukemia (CML) (see Chapter 21). Most childhood leukemias are ALL. Chronic leukemias are rare in children.\textsuperscript{16}

Lymphomas are malignant proliferations that arise from discrete tissue masses.\textsuperscript{1} Lymphoid neoplasms involve some recognizable stage of lymphocyte B- or T-cell differentiation. With time and better understanding, it is clear that some lymphomas occasionally have leukemic presentations and evolution to “leukemia” is not unusual during the progression of incurable “lymphomas.” The terms, therefore, merely reflect the usual tissue distribution.\textsuperscript{1} Much controversy has surrounded the classifications of lymphoma and a consensus has been reached with the current World Health Organization (WHO) classification scheme found at www.cancer.gov/cancertopics/pdq/treatment/adult-non-hodgkins/HealthProfessional/page3. Non-Hodgkin lymphoma (NHL) and Hodgkin lymphoma constitute approximately 11% of all cases of childhood cancer. Approximately 1800 children younger than 20 years of age are diagnosed with lymphoma in the United States each year.\textsuperscript{23} NHL (including Burkitt lymphoma) occurs more often than Hodgkin lymphoma (for newborns to children age 14 years, 5% to 6% versus 4%; and for ages 15 to 19 years, 8% versus 15% of all pediatric malignancies). Either group of diseases is rare before the age of 5 years, and the relative incidence increases throughout childhood. Boys are more likely to be diagnosed with a malignant lymphoma than are girls. At particular risk are children with inherited or acquired immunodeficiency syndromes, who have increased rates of lymphoreticular cancers that range between 100 and 10,000 times the rate of normal children.

**Non-Hodgkin lymphoma.**

**Non-Hodgkin lymphomas (NHLs)** are neoplasms of immune cells. NHLs are a large and diverse group of tumors; some tumors have a slow-growing (indolent)
course, whereas others have a fast-growing (aggressive) course. Almost without exception, childhood NHL becomes evident as a diffuse disease and can be further subdivided into four major types: (1) B-cell non-Hodgkin lymphoma (Burkitt and Burkitt-like lymphoma and Burkitt leukemia); (2) diffuse large B-cell lymphoma; (3) lymphoblastic lymphoma; and (4) anaplastic large cell lymphoma. The common types of NHL in children are different than those in adults. The most common types of NHL in children are Burkitt lymphoma (40%), lymphoblastic lymphoma (25% to 30%), and large cell lymphoma (10%).

Pathogenesis

Burkitt lymphoma will be discussed as an example of pathogenesis of NHL in children. All forms of Burkitt lymphoma are associated with translocations of the MYC gene on chromosome 8 that lead to increased MYC protein levels. MYC is a transcriptional regulator that increases the expression of genes required for aerobic glycolysis, called the Warburg effect (see Chapter 10). Most Burkitt lymphomas are latently infected with the Epstein-Barr virus (EBV). EBV is also present in about 25% of HIV-associated tumors and 15% to 20% of sporadic cases. There is increased evidence of NHL in children with congenital immunodeficiency syndromes, such as Wiskott-Aldrich syndrome, ataxia-telangiectasia, and Bloom syndrome.

Clinical manifestations

NHL has been found to arise from any lymphoid tissue. Signs and symptoms therefore are specific for the site involved. Associated signs of NHL include swelling of the lymph nodes in the neck, underarm, stomach, or groin; trouble swallowing; painless lump or swelling in a testicle; weight loss for unknown reason; night sweats; and possibly trouble breathing. Involvement of facial bones, particularly the jaw, is common in African Burkitt lymphoma.

Evaluation and treatment

Diagnosis is made by physical exam and health history, followed by biopsy of disease sites, usually the involved lymph nodes, tonsils, bone marrow, spleen, liver, bowel, or skin. Burkitt lymphoma is very aggressive and responds well to treatment. With intensive chemotherapy most children and young adults can be cured.

Hodgkin Lymphoma

Hodgkin lymphoma (HL) is a group of lymphoid neoplasms that, unlike NHL, arises in a single chain of lymph nodes and spreads first in a contiguous way to
lymphoid tissue. NHL frequently arises at extranodal sites and spreads in a noncontiguous or unpredictable way. HL is characterized by the presence of *Reed-Sternberg* cells, which are large cells derived from the germinal center of B cells (Figure 22-9). The World Health Organization (WHO) has identified five types of HL: (1) nodular sclerosis, (2) mixed cellularity, (3) lymphocyte rich, (4) lymphocyte depletion, and (5) lymphocyte predominance. The first four types are considered the *classic* types of HL with similar expression of Reed-Sternberg cells. In the lymphocyte predominance type, the Reed-Sternberg cell is distinctive but different than the others. HL is a common type of cancer in young adults and adolescents but rare in childhood. The average age at diagnosis is 32 years of age.

**FIGURE 22-9** Diagnostic Reed-Sternberg Cell. A large multinucleated or multilobated cell with inclusion body–like nucleoli (arrow) surrounded by a halo of clear nucleoplasm. (From Damjanov I, Linder J: Pathology: a color atlas, St Louis, 2000, Mosby.)

**Pathogenesis**

The Reed-Sternberg cells fail to express most of the B-cell normal genes, including the immunoglobulin (Ig) genes. The causes of the genetic rearrangements or reprogramming are not fully known but are thought to be the result of widespread epigenetic changes. Activation of the transcription factor NF-κB, which controls transcription of DNA, is a very common event in classic HL. NF-κB may be activated by EBV infection. EBV-infected B cells, resembling Reed-Sternberg cells, are found in lymph nodes in individuals with infectious mononucleosis, suggesting
that the EBV proteins may have a role in changes of the B cells into Reed-Sternberg cells.\textsuperscript{1} NF-κB is involved in many biologic processes, including inflammation, immunity, cell growth, differentiation, and apoptosis. The cytoplasm is abundant with Reed-Sternberg cells and tissue is reactive with many inflammatory type cells and immune cells. These reactive cells crosstalk with Reed-Sternberg cells and support the growth and survival of the tumor cells.

**Clinical manifestations**

Painless lymphadenopathy in the lower cervical chain, with or without fever, is the most common symptom in children. Other lymph nodes and organs also may be involved (Figure 22-10). Mediastinal involvement can cause pressure on the trachea or bronchi, leading to airway obstruction. Extranodal primary sites in Hodgkin lymphoma are rare. Initial symptoms consist of anorexia, malaise, and lassitude. Intermittent fever is present in 30\% of children, and weight loss also may accompany these symptoms. Hodgkin lymphoma has a well-defined staging system that considers the extent and location of disease and the presence of fever, weight loss, or night sweats at diagnosis.
Evaluation and treatment

Treatment for Hodgkin lymphoma includes chemotherapy and radiation therapy. Long-term survivors treated with radiotherapy had a much higher incidence of secondary cancers, including lung cancer, melanoma, and breast cancer. Individuals previously treated with chemotherapy alkylating agents also had a high incidence of secondary tumors. These results have changed the treatment protocols to minimize the use of radiotherapy and use less toxic chemotherapy. A promising target therapy is anti-CD30.

Quick Check 22-3

1. List the childhood leukemias in order of rate of incidence.
2. Why do children with leukemia experience bone or joint pain?

3. What are the common types of non-Hodgkin lymphoma (NHL) in children?
Did You Understand?

Disorders of Erythrocytes

1. Anemia is the most common blood disorder in children. Like the anemias of adulthood, the anemias of childhood are caused by ineffective erythropoiesis or premature destruction of erythrocytes.

2. Iron deficiency anemia (IDA) is the most common nutritional disorder worldwide. IDA has the highest incidence occurring between 6 months and 2 years of age. Iron is critical for the developing child and without it damage from the periods of IDA is irreversible.

3. No matter the cause of IDA it produces a hypochromic-microcytic anemia eventually lowering hemoglobin and hematocrit.

4. Hemolytic disease of the fetus and newborn (HDFN) results from incompatibility between the maternal and the fetal blood, which may involve differences in Rh factors or blood type (ABO). Maternal antibodies (anti-Rh antibodies) formed in response to the presence of fetal incompatible (Rh-positive) erythrocytes in the blood of an Rh-negative mother. The maternal antibodies then enter the fetal circulation and cause hemolysis of fetal erythrocytes. However, ABO incompatibility can cause HDFN even if fetal erythrocytes do not escape into the maternal circulation during pregnancy.

5. The key to treatment of HDFN resulting from Rh incompatibilities lies in prevention or immunoprophylaxis.

6. Sickle cell disease is a group of disorders characterized by the production of abnormal hemoglobin S (Hb S) within the erythrocytes.

7. Sickle cell disease is an inherited, autosomal recessive disorder expressed as sickle cell anemia, sickle cell–thalassemia disease, or sickle cell–hemoglobin C disease, depending on mode of inheritance. Sickle cell anemia, a homozygous form, is the most severe.

8. Sickle cell–thalassemia and sickle cell–Hb C disease are heterozygous forms in which the child simultaneously inherits another type of abnormal hemoglobin from one parent. Sickle cell trait, in which the child inherits Hb S from one parent and normal hemoglobin (Hb A) from the other, is a heterozygous carrier state that
rarely has clinical manifestations. All forms of sickle cell disease are lifelong conditions.

9. Sickle cell disease causes a change in the shape of red blood cells, resulting in deoxygenation or dehydration. It is most common among blacks and those of Mediterranean descent.

10. The alpha- and beta-thalassemias are inherited autosomal recessive disorders that cause an impaired rate of synthesis of one of the two chains—α or β—of adult hemoglobin (Hb A).

**Disorders of Coagulation and Platelets**

1. Hemophilia A is defined as factor VIII deficiency and is the most common hereditary disease associated with life-threatening bleeding. It is caused by a mutation in factor VIII, an essential cofactor for factor IX in the coagulation cascade. Factor IX deficiency is most often called hemophilia B.

2. Hemophilia may be inherited or caused by a spontaneous mutation of the factor gene.

3. The antibody-mediated hemorrhagic diseases are a group of disorders caused by the immune response. Antibody-mediated destruction of platelets or antibody-mediated inflammatory reactions to allergens damage blood vessels and cause seepage into tissues.

4. ITP, the most common of the childhood thrombocytopenic purpuras, is a disorder of platelet consumption in which antiplatelet antibodies bind to the plasma membranes of platelets. This results in platelet sequestration and destruction by mononuclear phagocytes at a rate that exceeds the ability of the bone marrow to produce them.

**Neoplastic Disorders**

1. Leukemia is cancer of the blood-forming tissues, such as the bone marrow, that most often produces abnormal white blood cells called leukemic cells.

2. Among children and teens, about 75% of leukemias are ALL, the remaining cases are AML. Chronic leukemias are rare in children.
3. The cause of childhood leukemia is unknown. About 5% of all childhood cancers are caused by inherited mutations. Genetic mutations can occur during fetal development.

4. Studies have shown exposure to ionizing radiation can lead to the development of childhood leukemia and possible other cancers.

5. ALL causes dysregulation of the expression and function of transcription factors required for normal B-cell and T-cell development.

6. Epigenetic alterations are frequent in AML and have a central role.

7. The onset of leukemia may be abrupt or insidious and the most common symptoms reflect the consequences of bone marrow failure. These changes can include decreased levels of red blood cells and platelets and changes in white blood cells.

8. Lymphomas are malignant proliferations that arise from discrete tissue masses. Lymphoid neoplasms involve some recognizable stage of lymphocyte B- or T-cell differentiation.

9. With time and better understanding it is now clear that some lymphomas occasionally have leukemic presentations.

10. The lymphomas of childhood are Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL).

11. NHL are neoplasms of immune cells. The most common types of NHL in children are Burkitt lymphoma (40%), lymphoblastic lymphoma (25% to 30%), and large cell lymphoma (10%).

12. Most Burkitt lymphomas are latently infected with the Epstein-Barr virus (EBV). There is increased evidence of NHL in children with congenital immunodeficiency syndromes.

13. Unlike NHL, HL arises in a single chain of lymph nodes and spreads first in a contiguous way to lymphoid tissue.

14. HL is characterized by the presence of Reed-Sternberg cells, which are large cells derived from the germinal center of B cells.

</table>
The functions of the circulatory system include delivery of oxygen, nutrients, hormones, immune system components, and other substances to body tissues and removal of the waste products of metabolism. Delivery and removal are achieved by an extensive array of tubes—the blood and lymphatic vessels—connected to a pump, the heart. The heart continuously pumps blood through the blood vessels in collaboration with other systems, particularly the nervous and endocrine systems, which regulate the heart and blood vessels. Immune system components, nutrients, and oxygen are supplied by the immune, digestive, and respiratory systems; gaseous wastes of metabolism are expired through the lungs; and other wastes are removed by the kidneys and digestive tract.

The vascular endothelium also is a key component of the circulatory system and is sometimes considered a separate endocrine organ. This endothelium is a multifunctional tissue whose health is essential to normal vascular, immune, and hemostatic system function. Endothelial dysfunction is a critical factor in the development of vascular and other diseases.¹
The Circulatory System

The heart is composed of two conjoined pumps moving blood through two separate circulatory systems in sequence: one pump supplies blood to the lungs, whereas the second pump delivers blood to the rest of the body. Structures on the right side, or right heart, pump blood through the lungs. This system is termed the pulmonary circulation and is described in Chapter 26. The left side, or left heart, sends blood throughout the systemic circulation, which supplies all of the body except the lungs (Figure 23-1). These two systems are serially connected; thus the output of one becomes the input of the other.
Arteries carry blood from the heart to all parts of the body, where they branch into arterioles and even smaller vessels, ultimately becoming a fine meshwork of capillaries. Capillaries allow the closest contact and exchange between the blood and the interstitial space, or interstitium—the environment in which cells live. Venules and then veins next carry blood from the capillaries back to the heart. Some of the plasma or liquid part of the blood passes through the walls of the capillaries into the interstitial space. This fluid, lymph, is returned to the cardiovascular system by vessels of the lymphatic system. The lymphatic system is a critical component of the immune system as described in Chapters 6 and 7.
The Heart

Adult hearts weigh between 200 and 350 grams and are about fist-sized. The heart lies obliquely (diagonally) in the mediastinum, the area above the diaphragm and between the lungs. Heart structures can be categorized by function:

1. **Structural support of heart tissues and circulation of pulmonary and systemic blood through the heart.** This category includes the heart wall and fibrous skeleton enclosing and supporting the heart and dividing it into four chambers: the valves directing flow through the chambers and the great vessels conducting blood to and from the heart.

2. **Maintenance of heart cells.** This category includes all the vessels of the coronary circulation—the arteries and veins that serve the metabolic needs of all the heart cells—and the heart's lymphatic vessels.

3. **Stimulation and control of heart action.** Among these structures are the nerves and specialized muscle cells that direct the rhythmic contraction and relaxation of the heart muscles, propelling blood throughout the pulmonary and systemic circulatory systems.

Structures That Direct Circulation Through the Heart

**The Heart Wall**

The three layers of the heart wall—the epicardium, myocardium, and endocardium—are enclosed in a double-walled membranous sac, the pericardium (Figure 23-2). The pericardial sac has three main functions: it prevents displacement of the heart during gravitational acceleration or deceleration, serves as a physical barrier to protect the heart against infection and inflammation coming from the lungs and pleural space, and contains pain receptors and mechanoreceptors that can cause reflex changes in blood pressure and heart rate. The two layers of the pericardium, the parietal and the visceral pericardia (see Figure 23-2), are separated by a fluid-containing space called the pericardial cavity. The pericardial fluid (about 20 ml) is secreted by cells of the mesothelial layer of the pericardium and lubricates the membranes that line the pericardial cavity, enabling them to slide smoothly over one another with minimal friction as the heart beats. The amount and character of the pericardial fluid are altered if the pericardium is inflamed (see Chapter 24).
FIGURE 23-2 Wall of the Heart. This section of the heart wall shows the fibrous pericardium, the parietal and visceral layers of the serous pericardium (with the pericardial space between them), the myocardium, and the endocardium. Note the fatty connective tissue between the visceral layer of the serous pericardium (epicardium) and the myocardium. Note also that the endocardium covers tubular projections of myocardial muscle tissue called *trabeculae*. (Revised from Applegate E: The anatomy and physiology learning system, ed 4, St Louis, 2011, Saunders.)

The smoothness of the outer layer of the heart, the epicardium, also minimizes the friction between the heart wall and the pericardial sac. The thickest layer of the
heart wall, the **myocardium**, is composed of cardiac muscle and is anchored to the heart's fibrous skeleton. The heart muscle cells, **cardiomyocytes**, provide the contractile force needed for blood to flow through the heart and into the pulmonary and systemic circulations. About 0.5% to 1% of the cardiomyocytes are replaced annually; thus over a lifetime about half of these muscle cells are replaced.\(^2\) There is great interest in finding therapies that will increase the rate of cardiomyocyte replacement for persons who have suffered a myocardial infarction or have heart failure from another cause (see *Health Alert: Myocardial Regeneration*).

---

**Health Alert**

**Myocardial Regeneration**

Myocardial infarction causes the loss of some of the muscle cells needed to maintain cardiac output, thus increasing the risk of heart failure in survivors. Given that heart failure is a growing problem with a poor prognosis in both the United States and internationally, finding an effective therapy is a critical need.

To replace the approximately 1 billion cardiomyocytes that are estimated to be lost with a myocardial infarction, researchers have identified four possible approaches: (1) accelerating the rate of heart cell division, (2) inserting new cells into the heart, (3) stimulating the heart muscle precursor cells already in the heart, and (4) reprogramming other cells so that they will become cardiomyocyte precursor cells. To stimulate adult heart cells to enter the cell cycle and thus accelerate cell division, various signaling molecules, such as neuregulin and fibroblast growth factor 1, have been used with some success. Currently, the most promising cell types that have been injected into the heart include cells from the bone marrow, cardiac-derived cells taken from myocardial biopsies, and human pluripotent stem cells. Although there are cardiac progenitor or precursor cells in the heart, their rate of division is not adequate to replace lost tissue after an infarction. Some of the methods being investigated to stimulate these cardiomyocytes or other progenitor cells in the heart include treatment with peptides that act as paracrines and some types of modified RNAs (ribonucleic acids) for vascular endothelial growth factor (VEGF). Reprogramming from one cell type into a pluripotent stem cell has been attempted with fibroblasts with some success. Each of these four approaches to replacing cardiomyocytes after injury comes with its own set of risks and challenges. Associated risks include increasing the chances for tumor development, damage to other organs, and myocardial scarring.
The internal lining of the myocardium, the **endocardium**, is composed of connective tissue and squamous cells (see Figure 23-2). This lining is continuous with the endothelium that lines all the arteries, veins, and capillaries of the body, creating a continuous, closed circulatory system.

**Chambers of the Heart**

The heart has four chambers: the **left atrium**, the **right atrium**, the **right ventricle**, and the **left ventricle**. These chambers form two pumps in series: the right heart is a low-pressure system pumping blood through the lungs and the left heart is a high-pressure system pumping blood to the rest of the body (Figure 23-3). The atria are smaller than the ventricles and have thinner walls. The ventricles have a thicker myocardial layer and constitute much of the bulk of the heart. The ventricles are formed by a continuum of muscle fibers originating from the fibrous skeleton at the base of the heart.
The wall thickness of each cardiac chamber depends on the amount of pressure or resistance it must overcome to eject blood. The two atria have the thinnest walls because they are low-pressure chambers that serve as storage units and channels for blood that is emptied into the ventricles. Normally, there is little resistance to flow from the atria to the ventricles. The ventricles, on the other hand, must propel the blood all the way through the pulmonary or systemic vessels. The mean pulmonary artery pressure, the force the right ventricle must overcome, is only 15 mm Hg, whereas the mean arterial pressure the left ventricle must pump against is about 92 mm Hg. Because the pressure is markedly higher in the systemic circulation, the wall of the left ventricle is about three times thicker than that of the right ventricle.

The right ventricle is shaped like a crescent or triangle, enabling a bellows-like action that efficiently ejects large volumes of blood through the pulmonary semilunar valve into the low-pressure pulmonary system. The larger left ventricle is bullet shaped, which allows it to generate enough pressure to eject blood through a relatively larger aortic semilunar valve into the high-pressure systemic circulation.

The septal membrane separates the right and left sides of the heart and prevents
blood from crossing between the two circulatory systems. The atria are separated by the interatrial septum, and the ventricles by the interventricular septum. Because the fetus does not depend on the lungs for oxygenation, there is an opening before birth between the right and left atria called the foramen ovale that facilitates circulation. This opening closes functionally at the time of birth as the higher pressure in the left atrium pushes a flap, the septum primum, over the hole. In 75% to 80% of infants these septa are permanently fused within the first year of life\textsuperscript{3,4} (see Chapter 25).

**Fibrous Skeleton of the Heart**

Four rings of dense fibrous connective tissue provide a firm anchorage for the attachments of the atrial and ventricular musculature, as well as the valvular tissue (Figure 23-4). The fibrous rings are adjacent and form a central, fibrous supporting structure collectively termed the *annuli fibrosi cordis*.

![Figure 23-4](image)

**Valves of the Heart**

Four heart valves and the pressure gradients they maintain ensure that blood only flows one way through the heart. When the ventricles are relaxed, the two *atrioventricular valves* open and blood flows from the relatively higher pressure
in the atria to the lower pressure in the ventricles. As the ventricles contract ventricular pressure increases and causes these valves to close and prevent backflow into the atria. The semilunar valves of the heart open when intraventricular pressure exceeds aortic and pulmonary pressures, and blood flows out of the ventricles and into the pulmonary and systemic circulations. After ventricular contraction and ejection, intraventricular pressure falls and the pulmonic and aortic semilunar valves close when the pressure in the vessels is greater than the pressure in the ventricles, thus preventing backflow into the right and left ventricles, respectively. The actions of the heart valves are shown in Figures 23-3 and 23-4.

The atrioventricular (tricuspid and mitral) valve openings are composed of tissue flaps called leaflets or cusps, which are attached at the upper margin to a ring in the heart's fibrous skeleton and by the chordae tendineae at the lower end to the papillary muscles (see Figure 23-3). The papillary muscles, extensions of the myocardium, help hold the cusps together and downward at the onset of ventricular contraction, thus preventing their backward expulsion or prolapse into the atria.

The atrioventricular valve in the right heart is called the tricuspid valve because it has three cusps. The left atrioventricular valve is a bicuspid (two-cusp) valve called the mitral valve. The tricuspid and mitral valves function as a unit because the atria, fibrous rings, valvular tissue, chordae tendineae, papillary muscles, and ventricular walls are connected. Collectively, these six structures are known as the mitral and tricuspid complex. Damage to any one of the six components of this complex can alter function significantly and contribute to heart failure.

Blood leaves the right ventricle through the pulmonic semilunar valve, and it leaves the left ventricle through the aortic semilunar valve (see Figures 23-3 and 23-4). Both the pulmonic and aortic semilunar valves have three cup-shaped cusps that arise from the fibrous skeleton.

**The Great Vessels**

Blood moves in and out of the heart through several large veins and arteries (see Figure 23-3). The right heart receives venous blood from the systemic circulation through the superior and inferior vena cavae, which join and then enter the right atrium. Blood leaving the right ventricle enters the pulmonary circulation through the pulmonary artery, which divides into right and left branches to transport unoxygenated blood from the right heart to the lungs. The pulmonary arteries branch further into the pulmonary capillary beds, where oxygen and carbon dioxide exchange occurs.

Four pulmonary veins, two from the right lung and two from the left lung, carry oxygenated blood from the lungs to the left side of the heart. The oxygenated blood
moves through the left atrium and ventricle, out into the aorta that subsequently branches into the systemic arteries that supply the body.

**Blood Flow during the Cardiac Cycle**

The pumping action of the heart consists of contraction and relaxation of the heart muscle, or myocardium. Each ventricular contraction and the relaxation that follows it constitute one **cardiac cycle**. (Blood flow through the heart during a single cardiac cycle is illustrated in **Figure 23-5**.) During the period of relaxation, termed **diastole**, blood fills the ventricles. The ventricular contraction that follows, termed **systole**, propels the blood out of the ventricles and into the pulmonary and systemic circulations. Contraction of the left ventricle occurs slightly earlier than contraction of the right ventricle.

![Figure 23-5](image)

**FIGURE 23-5** Blood Flow Through the Heart during a Single Cardiac Cycle. **A**, During diastole, blood flows into atria, atrioventricular valves are pushed open, and blood begins to fill ventricles. Atrial systole squeezes blood remaining in the atria into the ventricles. **B**, During ventricular systole, the ventricles contract, pushing blood out through semilunar valves into the pulmonary artery (right ventricle) and the aorta (left ventricle). (From Patton KT, Thibodeau GA: Structure & function of the body, ed 15, St Louis, 2016, Elsevier.)

The five phases of the cardiac cycle are said to begin with the opening of the mitral and tricuspid valves and atrial contraction (**Figures 23-6 and 23-7**). Closing of the mitral and tricuspid valves as passive ventricular filling begins marks the end of one cardiac cycle.
FIGURE 23-6 Composite Chart of Heart Function. This chart is a composite of several diagrams of heart function (cardiac pumping cycle, blood pressure, blood flow, volume, heart sounds, venous pulse, and electrocardiogram [ECG]), all on the same timescale.
The Five Phases of the Cardiac Cycle.

1. Atrial systole: Atria contract, pushing blood through the open tricuspid and mitral valves into the ventricles. Semilunar valves are closed.

2. Beginning of ventricular systole: Ventricles contract, increasing pressure within the ventricles. The tricuspid and mitral valves close, causing the first heart sound.

3. Period of rising pressure: Semilunar valves open when pressure in the ventricle exceeds that in the arteries. Blood spurts into the aorta and pulmonary arteries.

4. Beginning of ventricular diastole: Pressure in the relaxing ventricles drops below that in the arteries. Semilunar valves snap shut, causing the second heart sound.

5. Period of falling pressure: Blood flows from veins into the relaxed atria. Tricuspid and mitral valves open when pressure in the ventricles falls below that in the atria. (Adapted from Solomon E: Introduction to human anatomy and physiology, ed 4, St Louis, 2016, Saunders.)

Normal Intracardiac Pressures

Normal intracardiac pressures are shown in Table 23-1.
Quick Check 23-1

1. Why are the two separate circulatory systems said to be “serially connected”?

2. What are the functions of the pericardial sac?

3. Why is the thickness of the myocardium different in the right and left ventricles?

4. Trace the flow of blood through the heart during one cardiac cycle.

Structures That Support Cardiac Metabolism: The Coronary Vessels

The myocardium and other heart structures are supplied with oxygen and nutrients by the coronary circulation, which is part of the systemic circulation. The coronary arteries originate at the upper edge of the aortic semilunar valve cusps (Figure 23-8B) and receive blood through openings in the aorta called the coronary ostia. The cardiac veins empty into the right atrium through another ostium, the opening of a large vein called the coronary sinus (Figure 23-8C). (Regulation of the coronary circulation, which is similar to regulation of flow through systemic and pulmonary vessels, is described in a later section.)
Coronary Arteries

The major coronary arteries, the **right coronary artery (RCA)** and the **left coronary artery (LCA)** (see Figure 23-8A), traverse the epicardium, myocardium, and endocardium and branch to become arterioles and then capillaries. Their main
branches are outlined in **Box 23-1**. The coronary arteries are smaller in women than in men because women's hearts weigh proportionately less than men's hearts.

### Box 23-1

**Main Branches of the Coronary Arteries**

*Left coronary artery.* Arises from single ostium behind left cusp of aortic semilunar valve; ranges from a few millimeters to a few centimeters long; passes between left arterial appendage and pulmonary artery and generally divides into two branches: the left anterior descending artery and the circumflex artery; other branches are distributed diagonally across the free wall of the left ventricle.

*Left anterior descending artery (or anterior interventricular artery).* Delivers blood to portions of left and right ventricles and much of interventricular septum; travels down the anterior surface of the interventricular septum toward apex of the heart.

*Circumflex artery.* Travels in a groove (*coronary sulcus*) that separates left atrium from left ventricle and extends to left border of heart; supplies blood to left atrium and lateral wall of left ventricle; often branches to posterior surfaces of left atrium and left ventricle.

*Right coronary artery.* Originates from an ostium behind the right aortic cusp, travels from behind the pulmonary artery, and extends around the right heart to the heart's posterior surface, where it branches to atrium and ventricle; three major branches are conus (supplies blood to upper right ventricle), right marginal branch (supplies right ventricle to the apex), and posterior descending branch (lies in posterior interventricular sulcus and supplies smaller branches to both ventricles).

### Collateral Arteries

**Collateral arteries** are anastomoses or connections between branches of the same coronary artery or connections of branches of the right coronary artery with branches of the left. The epicardium contains more collateral vessels than the endocardium. New collateral vessels are formed through two processes: **arteriogenesis** (new artery growth branching from preexisting arteries) and **angiogenesis** (growth of new capillaries within a tissue). This collateral growth is stimulated by **shear stress**, that results from increased blood flow speed within and
just beyond areas of stenosis, as well as the production of growth factors and cytokines, including monocyte chemoattractant protein-1 (MCP-1) and vascular endothelial growth factor (VEGF). The collateral circulation assists in supplying blood and oxygen to myocardium that has become ischemic following gradual narrowing, or stenosis, of one or more major coronary arteries (coronary artery disease). Unfortunately, diabetes, which predisposes to coronary artery disease, also impedes collateral formation because of increased production of antiangiogenic factors, such as endostatin and angiostatin. Current research is focused on identifying whether some factors that stimulate collateral growth might be useful treatments for myocardial ischemia; so far none have been demonstrated to be effective.

**Coronary Capillaries**

The heart requires an extensive capillary network to function. Blood travels from the arteries to the arterioles and then into the capillaries, where oxygen and other nutrients enter the myocardium while waste products enter the blood. At rest, the heart extracts 50% to 80% of the oxygen delivered to it, and coronary blood flow is directly correlated with myocardial oxygen consumption. Any alteration of the cardiac muscles dramatically affects blood flow in the capillaries.

**Coronary Veins and Lymphatic Vessels**

After passing through the capillary network, blood from the coronary arteries drains into the cardiac veins located alongside the arteries. Most of the venous drainage of the heart occurs through veins in the visceral pericardium. The veins then feed into the great cardiac vein (see Figure 23-8C) and coronary sinus on the posterior surface of the heart, between the atria and ventricles, in the coronary sulcus.

The myocardium has an extensive system of lymphatic capillaries and collecting vessels within the layers of the myocardium and the valves. With cardiac contraction, the lymphatic vessels drain fluid to lymph nodes in the anterior mediastinum that empty into the superior vena cava. The lymphatics are important for protecting the myocardium against infection and injury.

**Structures That Control Heart Action**

Life depends on continuous repetition of the cardiac cycle (systole and diastole), which requires the transmission of electrical impulses, termed cardiac action potentials, through the myocardium. (Action potentials are described in Chapters 1
The muscle fibers of the myocardium are electrically coupled so that action potentials pass from cell to cell rapidly and efficiently.

The myocardium contains its own pacemakers and conduction system—specialized cells that enable it to generate and transmit action potentials without input from the nervous system (Figure 23-9). The pacemaker cells are concentrated at two sites, or nodes, in the myocardium. The cardiac cycle is stimulated by these nodes of specialized cells. Although the heart is innervated by the autonomic nervous system (both sympathetic and parasympathetic fibers), neural impulses are not needed to maintain the cardiac cycle. Thus the heart will beat in the absence of any innervation, one of the many factors that allow heart transplantation to be successful.

Heart action is also influenced by substances delivered to the myocardium in coronary blood. Nutrients and oxygen are needed for cellular survival and normal function. Hormones and biochemical substances, including medications, can affect
the strength and duration of myocardial contraction and the degree and duration of myocardial relaxation. Normal or appropriate function depends on the supply of these substances, which is why coronary artery disease can seriously disrupt heart function.

**The Conduction System**

Normally, electrical impulses arise in the sinoatrial (SA) node (sinus node), the usual pacemaker of the heart. The SA node is located at the junction of the right atrium and superior vena cava, just superior to the tricuspid valve. The SA node is heavily innervated by both sympathetic and parasympathetic nerve fibers. In the resting adult the SA node generates about 60 to 100 action potentials per minute depending on age and physical condition. Each action potential travels rapidly from cell to cell and through the atrial myocardium, carrying the action potential onward to the atrioventricular node (AV node), as well as causing both atria to contract, beginning systole.

The AV node, located in the right atrial wall superior to the tricuspid valve and anterior to the ostium of the coronary sinus, conducts the action potentials onward to the ventricles. It is innervated by nerves from the autonomic parasympathetic ganglia that serve as receptors for the vagus nerve and cause slowing of impulse conduction through the AV node.

Conducting fibers from the AV node converge to form the bundle of His (atrioventricular bundle), within the posterior border of the interventricular septum. The bundle of His then gives rise to the right and left bundle branches. The **right bundle branch (RBB)** is thin and travels without much branching to the right ventricular apex. Because of its thinness and relative lack of branches, the RBB is susceptible to interruption of impulse conduction by damage to the endocardium. The **left bundle branch (LBB)** in some hearts divides into two branches, or fascicles. The left anterior bundle branch (LABB) passes the left anterior papillary muscle and the base of the left ventricle and crosses the aortic outflow tract. Damage to the aortic valve or the left ventricle can interrupt this branch. The left posterior bundle branch (LPBB) travels posteriorly, crossing the left ventricular inflow tract to the base of the left posterior papillary muscle. This branch spreads diffusely through the posterior inferior left ventricular wall. Blood flow through this portion of the left ventricle is relatively nonturbulent, so the LBB is somewhat protected from injury caused by wear and tear.

The **Purkinje fibers** are the terminal branches of the RBB and LBB. They extend from the ventricular apexes to the fibrous rings and penetrate the heart wall to the outer myocardium. The first areas of the ventricles to be excited are portions of the
interventricular septum. The septum is activated from both the RBB and the LBB. The extensive network of Purkinje fibers promotes the rapid spread of the impulse to the ventricular apexes. The basal and posterior portions of the ventricles are the last to be activated.

Quick Check 23-2

1. Draw a diagram of the conduction system of the heart.

2. Why are the left and right coronary vessels considered the major coronary vessels?

Propagation of cardiac action potentials.

Electrical activation of the muscle cells, termed depolarization, is caused by the movement of ions, including sodium, potassium, calcium, and chloride, across cardiac cell membranes. Deactivation, called repolarization, occurs the same way. (Movement of ions across cell membranes is described in Chapter 1; electrical activation of muscle cells is described in Chapter 38.)

Movement of ions into and out of the cell creates an electrical (voltage) difference across the cell membrane, called the membrane potential. The resting membrane potential of myocardial cells is between −80 and −90 millivolts (mV), whereas that of the SA node is between −50 and −60 mV and that of the AV node is between −60 and −70 mV. During depolarization, the inside of the cell becomes less negatively charged. In cardiac cells, as in other excitable cells, when the resting membrane potential (in millivolts) becomes more negative with depolarization and reaches the threshold potential for cardiac cells, a cardiac action potential is fired. Table 23-2 summarizes the intracellular and extracellular ionic concentrations of cardiac muscle. Drugs that alter the movement of these ions (e.g., calcium) have profound effects on the action potential and can alter heart rate. The various phases of the cardiac action potential are related to changes in the permeability of the cell membrane to sodium, potassium, chloride, and calcium. Threshold is the point at which the cell membrane's selective permeability to these ions is temporarily disrupted, leading to an “all or nothing” depolarization. If the resting membrane potential becomes more negative because of a decrease in extracellular potassium concentration (hypokalemia), it is termed hyperpolarization.

*mM, Millimolar (millimoles per kilogram).

A **refractory period**, during which no new cardiac action potential can be initiated by a stimulus, follows depolarization. This effective or absolute refractory period corresponds to the time needed for the reopening of channels that permit sodium and calcium influx into the cells. A relative refractory period occurs near the end of repolarization, following the effective refractory period. During this time, the membrane can be depolarized again but only by a greater-than-normal stimulus. Abnormal refractory periods as a result of disease can cause abnormal heart rhythms or dysrhythmias, including ventricular fibrillation and cardiac arrest (see **Chapter 24**).

The electrocardiogram.

An electrocardiogram originates from myocardial cell electrical activity as recorded by skin electrodes and is the summation of all the cardiac action potentials (**Figure 23-10**). The **P wave** represents atrial depolarization. The **PR interval** is a measure of time from the onset of atrial activation to the onset of ventricular activation (normally 0.12 to 0.20 second). The PR interval represents the time necessary for electrical activity to travel from the sinus node through the atrium, AV node, and His-Purkinje system to activate ventricular myocardial cells. The **QRS complex** represents the sum of all ventricular muscle cell depolarization. The configuration and amplitude of the QRS complex may vary considerably among individuals. The duration is normally between 0.06 and 0.10 second. During the **ST interval**, the entire ventricular myocardium is depolarized. The **QT interval** is sometimes called the “electrical systole” of the ventricles. It lasts about 0.4 second but varies inversely with the heart rate. The **T wave** represents ventricular repolarization.
Automaticity.

**Automaticity**, or the property of generating spontaneous depolarization to threshold, enables the SA and AV nodes to generate cardiac action potentials without any external stimulus. Cells capable of spontaneous depolarization are called **automatic cells**. The automatic cells of the cardiac conduction system can stimulate the heart to beat even when it is transplanted and thus has no innervation. Spontaneous depolarization is possible in automatic cells because the membrane potential of these special cells does not actually “rest” during return to the resting membrane potential. Instead, it slowly depolarizes toward threshold during the diastolic phase of the cardiac cycle. Because threshold is approached during diastole, return to the resting membrane potential in automatic cells is called **diastolic depolarization**. The electrical impulse normally begins in the SA node because its cells depolarize more rapidly than other automatic cells.

Rhythmicity.

**Rhythmicity** is the regular generation of an action potential by the heart's conduction system. The SA node sets the pace because normally it has the fastest rate. The SA node depolarizes spontaneously 60 to 100 times per minute. If the SA node is damaged, the AV node can become the heart's pacemaker at a rate of about 40 to 60 spontaneous depolarizations per minute. Eventually, however, conduction cells in the atria usually take over from the AV node. Purkinje fibers are capable of spontaneous depolarization but at an even slower rate than the AV node.

**Quick Check 23-3**

1. What are the pathways of conduction through the heart?
2. What does each of the electrocardiogram waves (P, Q, R, S, T) represent?
3. Define automaticity and rhythmicity.

**Cardiac Innervation**

Although the heart's nodes and conduction system are able to generate action
potentials independently, the autonomic nervous system influences both the rate of 
impulse generation (firing), depolarization, and repolarization of the myocardium; 
and the strength of atrial and ventricular contraction. Autonomic neural 
transmission produces changes in the heart and circulatory system faster than 
metabolic or humoral agents. Speed is important, for example, in stimulating the 
heart to increase its pumping action during times of stress and fear—the so-called 
fight or flight response—or with increased physical activity. Although increased 
delivery of oxygen, glucose, hormones, and other blood-borne factors sustains 
increased cardiac activity, the rapid initiation of increased activity depends on the 
sympathetic and parasympathetic fibers of the autonomic nervous system.

**Sympathetic and parasympathetic nerves.**

Sympathetic and parasympathetic nerve fibers innervate all parts of the atria and 
ventricles and the SA and AV nodes. In general, sympathetic stimulation increases 
electrical conductivity and the strength of myocardial contraction, and vagal 
parasympathetic nerve activity does the opposite, slowing the conduction of action 
potentials through the heart and reducing the strength of contraction. Thus the 
sympathetic and parasympathetic nerves affect the speed of the cardiac cycle (heart 
rate, or beats per minute) and the sympathetic nerves also influence the diameter of 
the coronary vessels (Figure 23-11). Sympathetic nervous activity enhances 
myocardial performance. Stimulation of the SA node by the sympathetic nervous 
system rapidly increases heart rate. Furthermore, neurally released norepinephrine 
or circulating catecholamines interact with β-adrenergic receptors on the cardiac 
cell membranes. The overall effect is an increased influx of Ca^{++}, which increases 
the contractile strength of the heart and increases the speed of electrical impulses 
through the heart muscle and the nodes.\(^8\) Finally, increased sympathetic discharge 
dilates the coronary vessels by causing the release of vasodilating metabolites 
resulting from increased myocardial contraction.\(^7\)
The parasympathetic nervous system affects the heart through the vagus nerve, which releases acetylcholine. Acetylcholine causes decreased heart rate and slows conduction through the AV node.

**Myocardial Cells**

Cardiomyocytes are composed of long, narrow fibers that contain bundles of longitudinally arranged myofibrils; a nucleus (cardiac muscle); mitochondria; an internal membrane system (the sarcoplasmic reticulum); cytoplasm (sarcoplasm); and a plasma membrane (the sarcolemma), which encloses the cell. Cardiac and skeletal muscle cells also have an “external” membrane system made up of transverse tubules (T tubules) formed by inward pouching of the sarcolemma. The sarcoplasmic reticulum forms a network of channels that surrounds the muscle fiber.
Because the myofibrils in both cardiac and skeletal fibers consist of alternating light and dark bands of protein, the fibers appear striped, or striated. The dark and light bands of the myofibrils create repeating longitudinal units, called sarcomeres, which are between 1.6 and 2.2 μm long (Figures 23-12 and 23-13). Length of these sarcomeres determines the limits of myocardial stretch at the end of diastole and subsequently the force of contraction during systole. Alterations in sarcomere size are seen in both physiologic and pathologic myocardial hypertrophy (see Health Alert: Regression of Myocardial Hypertrophy).

**Health Alert**

**Regression of Myocardial Hypertrophy**

Hypertrophy, or enlargement, of the heart may occur through growth in either the length or the width of the sarcomeres in both normal and disease conditions. When normal stimuli, such as physical activity or pregnancy, cause hypertrophy, myocardial contractility is increased; and when the stimulus is removed, regression of the hypertrophy occurs. Conversely, disease-related hypertrophy caused by conditions such as hypertension or myocardial infarction results in reduced contractility and often heart failure. It has long been thought that this pathologic hypertrophy was not reversible but new research has shown that reversal may be possible.

When patients with hypertrophic heart failure awaiting a heart transplant were treated by the placement of a left ventricular assist device, regression of the ventricular hypertrophy was observed, occasionally to the point that heart transplant was not required. Research on the mechanisms involved in regression has shown that gene activation, several signaling pathways, angiogenesis, and autophagy are all involved. The hope is that identification of these mechanisms will lead to new and more effective pharmaceutical treatments for heart failure that currently is associated with a poor long-term prognosis.

Unlike other types of muscle fibers, cardiac muscle fibers are typically branched with junctions, called intercalated disks, between adjacent myocytes. Like skeletal muscle cells, cardiac muscle cells contain sarcoplasmic reticula and T tubules, although these structures are not as highly organized as in skeletal muscle fibers.
Differences between cardiac and skeletal muscle reflect heart function. Cardiac cells are arranged in branching networks throughout the myocardium, whereas skeletal muscle cells tend to be arranged in parallel units throughout the length of the muscle. Cardiac fibers have only one nucleus, whereas skeletal muscle cells have many nuclei. Other differences enable cardiac fibers to:

1. *Transmit action potentials quickly from cell to cell*. Electrical impulses are transmitted rapidly from cardiac fiber to cardiac fiber because the network of fibers connects at **intercalated disks**, which are thickened portions of the sarcolemma. The intercalated disks contain three junctions: desmosomes or macula adherens;
fascia adherens, which mechanically attach one cell to another; and gap junctions, also known as tight junctions, which allow the electrical impulse to spread from cell to cell through a low-resistance pathway (see Chapter 1). Changes in the function of these junctional elements may cause an increased risk of arrhythmias. 

2. Maintain high levels of energy synthesis. Unlike skeletal muscle, the heart cannot rest and is in constant need of energy, which is supplied by molecules such as adenosine triphosphate (ATP). Therefore, the cytoplasm surrounding the bundles of myofibrils in each cardiomyocyte contains a large number of mitochondria (25% to 33% of cell volume). Cardiac muscle cells have more mitochondria than do skeletal muscle cells to provide the necessary respiratory enzymes for aerobic metabolism and supply quantities of ATP sufficient for the constant action of the myocardium.

3. Gain access to more ions, particularly sodium and potassium, in the extracellular environment. Cardiac fibers contain more T tubules than do skeletal muscle fibers (see Figure 23-12). This increased closeness to the T tubules gives each myofibril in the myocardium faster access to molecules needed for the transmission of action potentials, a process that involves transport of sodium and potassium through the walls of the T tubules. Because the T tubule system is continuous with the extracellular space and the interstitial fluid, it facilitates the rapid transmission of the electrical impulses from the surface of the sarcolemma to the myofibrils inside the fiber. This rapid transmission activates all the myofibrils of one fiber simultaneously. The sarcoplasmic reticulum is located around the myofibrils. As an action potential is transmitted through the T tubules, it induces the sarcoplasmic reticulum to release its stored calcium, thus activating the contractile proteins actin and myosin.

Actin, myosin, and the troponin-tropomyosin complex.
Within each myocardial sarcomere are myosin molecules that resemble golf clubs with two large, ovoid heads at one end of the shaft (Figure 23-14, B). The two heads contain an actin binding site and a site of ATPase activity. Thick filaments of myosin overlapping with thinner actin molecules form the central dark band of the sarcomere called the anisotropic or A band (see Figures 23-13 and 23-14). A thick filament has about 200 myosin molecules bundled together with their outward-facing heads named cross-bridges because they can form force-generating bridges by binding with exposed actin molecules, resulting in contraction (Figure 23-14, A). Actin molecules are part of the thin filaments (see Figures 23-13 and 23-14). The light bands, called isotropic or I bands, of the sarcomere contain only actin molecules and no myosin (see Figure 23-13). Thin filaments of actin extend from
each side of the Z line, a dense fibrous structure at the center of each I band. The area from one dark Z line to the next Z line defines one sarcomere. The center of the sarcomere is the H zone, a less dense region with a central thin, dark M line.9

A single tropomyosin molecule (a relaxing protein) lies alongside seven actin molecules. Troponin, another relaxing protein, associates with the tropomyosin molecule, forming the troponin-tropomyosin complex (see Figures 23-14, A, and 23-15). The troponin complex itself has three components. Troponin T aids in the
binding of the troponin complex to actin and tropomyosin; troponin I inhibits the ATPase of actomyosin; and troponin C contains binding sites for the calcium ions involved in contraction. Troponin T and I molecules are released into the bloodstream during myocardial injury and are measured to evaluate if a myocardial infarction or other damage has occurred. When troponin and tropomyosin cover the myosin binding sites on actin, the cross-bridges release calcium and the myocardium relaxes. The sarcomere also contains a giant elastic protein, titin, which attaches myosin to the Z line, acts as a spring, and influences myocardial stiffness. Titin structure impacts myocardial diastolic filling and has been found to play a role in heart failure.

Myocardial metabolism.

Cardiomyocytes depend on the constant production of ATP, which is synthesized within the mitochondria mainly from glucose, fatty acids, and lactate. If the myocardium is underperfused because of coronary artery disease, anaerobic metabolism must be used for energy (see Chapter 1). Energy produced by metabolic processes fuels muscle contraction and relaxation, electrical excitation, membrane transport, and synthesis of large molecules. Normally, the amount of ATP produced supplies sufficient energy to pump blood throughout the system.

Cardiac work is expressed as myocardial oxygen consumption ($\text{MVO}_2$), which is closely correlated with total cardiac energy requirements. $\text{MVO}_2$ is determined by three major factors: (1) amount of wall stress during systole, estimated by

**FIGURE 23-15** Cross-Bridge Theory of Muscle Contraction. A, Each myosin cross-bridge in the thick filament moves into a resting position after an adenosine triphosphate (ATP) molecule binds and transfers its energy. B, Calcium ions released from the sarcoplasmic reticulum bind to troponin in the thin filament, allowing tropomyosin to shift from its position blocking the active sites of actin molecules. C, Each myosin cross-bridge then binds to an active site on a thin filament, displacing the remnants of ATP hydrolysis—adenosine diphosphate (ADP) and inorganic phosphate (Pi). D, The release of stored energy from step A provides the force needed for each cross-bridge to move back to its original position, pulling actin along with it. Each cross-bridge will remain bound to actin until another ATP molecule binds to it and pulls it back into its resting position (A). (Adapted from Thibodeau GA, Patton KT: Anatomy & physiology, ed 4, St Louis, 1999, Mosby)
measuring the systolic blood pressure; (2) duration of systolic wall tension, measured indirectly by the heart rate; and (3) contractile state of the myocardium, which is not measured clinically.

The coronary arteries deliver oxygen (O$_2$) to the myocardium. Approximately 70% to 75% of this oxygen is used immediately by cardiac muscle, leaving little O$_2$ in reserve. Since the O$_2$ content of the blood and the amount of O$_2$ extracted from the blood cannot be increased under normal circumstances, any increased energy needs can be met only by increasing coronary blood flow. $\text{MV}_2$ increases with exercise and decreases with hypotension and hypothermia. As myocardial metabolism and consumption of O$_2$ increase, the local concentration of local vasoactive metabolic factors increases. Some of these, such as adenosine, nitric oxide, and prostaglandins, dilate coronary arterioles, thus increasing coronary blood flow.$^{11}$

**Myocardial Contraction and Relaxation**

**Myocardial contractility** is a change in developed tension at a given resting fiber length, which basically is the ability of the heart muscle to shorten. At the molecular level, thin filaments of actin slide over thick filaments of myosin, called the cross-bridge theory of muscle contraction. Anatomically, contraction occurs when the sarcomere shortens, so adjacent Z lines move closer together (see **Figure 23-13**). The degree of shortening depends on the amount of overlap between the thick and thin filaments.

**Calcium and excitation-contraction coupling.**

**Excitation-contraction coupling** is the process by which an action potential arriving at the muscle fiber plasma membrane triggers the cycle, leading to cross-bridge formation and contraction. Cycle activation depends on calcium availability, and the amount of force developed is regulated by how much the concentration of calcium ions increases within the cardiomyocytes. Calcium enters the myocardial cell from the interstitial fluid after electrical excitation that increases membrane calcium permeability. Two types of calcium channels (L-type, T-type) are found in cardiac tissues.$^9$ The L-type, or long-lasting, channels predominate and are the channels blocked by calcium channel–blocking drugs (verapamil, nifedipine, diltiazem).$^9$ The T-type, or transient, channels are much less abundant in the heart. T-type channels are not blocked by currently available calcium channel–blocking drugs; therefore T-type channel blockers are being investigated.$^{12}$ Calcium entering the cell triggers the release of additional calcium from the two storage sites within
the sarcomere—the sarcoplasmic reticulum and tubule system. Calcium ions then diffuse toward the myofibrils, where they bind with troponin.

The calcium-troponin complex interaction facilitates the contraction process. In the resting state, troponin I is bound to actin and the tropomyosin molecule covers the sites where the myosin heads bind to actin, thereby preventing interaction between actin and myosin. Calcium binds to troponin C, which ultimately results in tropomyosin moving troponin I, thus uncovering the binding sites on the myosin heads. Myosin and actin can now form cross-bridges, and ATP can be dephosphorylated to adenosine diphosphate (ADP). Under these circumstances, sliding of the thick and thin filaments can occur, and the muscle contracts.⁹

**Myocardial relaxation.**

Relaxation is as vital to optimal cardiac function as contraction; and calcium, troponin, and tropomyosin also facilitate relaxation. After contraction, free calcium ions are actively pumped out of the cell back into the interstitial fluid or taken back into storage by the sarcoplasmic reticulum and tubule system. As the concentration of calcium within the sarcomere decreases, troponin releases its bound calcium. The tropomyosin complex moves and blocks the active sites on the actin molecule, preventing cross-bridge formation with the myosin heads. If the ability of the myocardium to relax is impaired, it can lead to increased diastolic filling pressures and eventually heart failure.¹³

---

**Quick Check 23-4**

1. What features distinguish myocardial cells from skeletal cells?

2. Describe the interactions of actin, myosin, and the troponin-tropomyosin complex in controlling heart function.

3. Define excitation-contraction coupling.

**Factors Affecting Cardiac Output**

Cardiac performance can be evaluated by measuring the cardiac output. **Cardiac output** is calculated by multiplying heart rate in beats per minute (beats/min) by **stroke volume** in liters per beat. Normal adult cardiac output is about 5 L/minute at rest given a heart rate of about 70 beats/min and a normal stroke volume of about 70 ml.⁷
With each heartbeat, the ventricles eject much of their blood volume, and the amount ejected per beat is called the **ejection fraction**. The ejection fraction is estimated by echocardiography, computed tomography (CT) scan, nuclear medicine scan, or cardiac catheterization and is calculated by dividing stroke volume by end-diastolic volume. The end-diastolic volume of the normal ventricle is about 70 to 80 ml/m², and the normal ejection fraction of the resting heart measured with gated myocardial perfusion imaging was 66% ± 8% for women and 58% ± 8% for men.\(^\text{14}\)

The ejection fraction is increased by factors that increase contractility, such as increased sympathetic nervous system activity. A decrease in ejection fraction may indicate ventricular failure. The effects of aging on cardiovascular function are summarized in Table 23-3.

*Changes in healthy men and women up to age 80 years as compared to those 20 years of age.

The factors that determine cardiac output are (1) preload, (2) afterload, (3) myocardial contractility, and (4) heart rate. Preload, afterload, and contractility all affect stroke volume.

### Preload

**Preload** is the volume and pressure inside the ventricle at the end of diastole (**ventricular end-diastolic volume [VEDV]** and **pressure [VEDP]**). Preload is determined by two primary factors: (1) the amount of venous blood returning to the ventricle during diastole and (2) the amount of blood left in the ventricle after systole (**end-systolic volume**). Venous return is dependent on blood volume and flow through the venous system and the atrioventricular valves. End-systolic volume is dependent on the strength of ventricular contraction and the resistance to ventricular emptying. Clinically, preload is estimated by measuring the central
venous pressure (CVP) for the right side of the heart and the pulmonary artery wedge pressure for the left side. Normal values for these two estimates are 1 to 5 mm Hg and 4 to 12 mm Hg, respectively.\textsuperscript{15}

Laplace law states that wall tension generated in the wall of the ventricle (or any chamber or vessel) to produce a given intraventricular pressure depends directly on ventricular size or internal radius and inversely on ventricular wall thickness. Ventricular end-diastolic volume, which determines the size of the ventricle and the stretch of the cardiac muscle fibers, therefore affects the tension (or force) for contraction. The Frank-Starling law of the heart indicates that the volume of blood in the heart at the end of diastole, as the volume determines the length of its muscle fibers, is directly related to the force of contraction during the next systole. Muscle fibers have an optimal resting length from which to generate the maximum amount of contractile strength. Within a physiologic range of muscle stretching, increased preload increases stroke volume (and therefore cardiac output and stroke work) (Figure 23-16, curve \textit{B}). Excessive ventricular filling and preload (increased VEDV) stretches the heart muscle beyond optimal length and stroke volume begins to fall. Factors that increase contractility cause the heart to operate on a higher length-tension curve (Figure 23-16, curve \textit{A}). Factors that decrease contractility (Figure 23-16, curve \textit{C}) cause the heart to operate at a lower length-tension curve. Figure 23-17 illustrates the relationship between VEDV and stroke volume, cardiac output, and stroke work.

\begin{figure}
\centering
\includegraphics[width=\textwidth]{figure23-16}
\caption{Frank-Starling Law of the Heart. Relationship between length and tension in heart. End-diastolic volume determines end-diastolic length of ventricular muscle fibers and is proportional to tension generated during systole, as well as to cardiac output, stroke volume, and stroke work. A change in myocardial contractility causes the heart to perform on a different length-tension curve. \textit{A}, increased contractility; \textit{B}, normal contractility; \textit{C}, heart failure or decreased contractility. (See text for further explanation.)}
\end{figure}
Increases in preload (VEDV) may not only cause a decline in stroke volume but also result in increases in VEDP. These changes can lead to heart failure (see Chapter 24). Increased VEDP causes pressures to increase or “back up” into the pulmonary or systemic venous circulation, thus increasing the movement of plasma out through vessel walls, causing fluid to accumulate in lung tissues (pulmonary edema; see Chapter 27) or in peripheral tissues (peripheral edema).

**Afterload**

Left ventricular afterload is the resistance to ejection of blood from the left ventricle. It is the load the muscle must move during contraction. Aortic systolic pressure is an index of afterload. Pressure in the ventricle must exceed aortic pressure before blood can be pumped out during systole. Low aortic pressures (decreased afterload) enable the heart to contract more rapidly and efficiently, whereas high aortic pressures (increased afterload) slow contraction and cause higher workloads against which the heart must function to eject blood. Increased aortic pressure is usually the result of increased systemic vascular resistance (SVR), sometimes referred to as total peripheral resistance (TPR). In individuals with hypertension, increased TPR means that afterload is chronically elevated,
resulting in increased ventricular workload and hypertrophy of the myocardium. In some individuals, changes in afterload are the result of aortic valvular disease (see Figure 23-17). SVR is calculated by dividing mean arterial pressure by cardiac output; the normal range is 700 dyne/sec/cm$^{-5}$.\textsuperscript{7,15}

**Myocardial Contractility**

**Stroke volume**, or the volume of blood ejected per beat during systole, also depends on the force of contraction, myocardial contractility, or the degree of myocardial fiber shortening. Three major factors determine the force of contraction (see Figure 23-17):

1. *Changes in the stretching of the ventricular myocardium caused by changes in VEDV (preload)*. As discussed previously, increased venous return to the heart distends the ventricle, thus increasing preload, which increases the stroke volume and, subsequently, cardiac output, up to a certain point. However, an excessive increase in preload leads to decreased stroke volume.

2. *Alterations in the inotropic stimuli of the ventricles*. Hormones, neurotransmitters, or medications that affect contractility are called inotropic agents. The most important endogenous positive inotropic agents are epinephrine and norepinephrine released from the sympathetic nervous system. Other positive inotropes include thyroid hormone and dopamine. The most important negative inotropic agent is acetylcholine released from the vagus nerve. Many medications have positive or negative inotropic properties that can have profound effects on cardiac function. In sepsis, a variety of cytokines including tumor necrosis factor-alpha (TNF-α), and interleukin-1β have been shown to impair myocardial contractility.\textsuperscript{16}

3. *Adequacy of myocardial oxygen supply*. Oxygen and carbon dioxide levels (tensions) in the coronary blood also influence contractility. With severe hypoxemia (arterial oxygen saturation less than 50%), contractility is decreased. With less severe hypoxemia (saturation more than 50%), contractility is stimulated. Moderate degrees of hypoxemia may increase contractility by enhancing the myocardial response to circulating catecholamines.\textsuperscript{17}

Preload, afterload, and contractility all interact with one another to determine stroke volume and cardiac output. Changes in any one of these factors can result in deleterious effects on the others, resulting in heart failure (see Chapter 24).
Heart Rate

As described previously, SA node activity is the primary determinant of the heart rate. The average heart rate in healthy adults is about 70 beats/min. This rate diminishes by 10 to 20 beats/min during sleep and can accelerate to more than 100 beats/min during muscular activity or emotional excitement. In well-conditioned athletes, resting heart rate is normally about 50 to 60 beats/min. In highly trained or elite athletes, the resting heart rate can be below 50 beats/min; these athletes also have a greater stroke volume and lower peripheral resistance in active muscles than they had before training. The control of heart rate includes activity of the central nervous system, autonomic nervous system, neural reflexes, atrial receptors, and hormones (see Figure 23-17).

Cardiovascular control centers in the brain.

The cardiovascular vasomotor control center is in the medulla and pons areas of the brainstem with additional areas in the hypothalamus, cerebral cortex, and thalamus. The hypothalamic centers regulate cardiovascular responses to changes in temperature, the cerebral cortex centers adjust cardiac reaction to a variety of emotional states, and the brainstem control center regulates heart rate and blood pressure (see Figure 23-11).

The nerve fibers from the cardiovascular control center synapse with autonomic neurons that influence the rate of firing of the SA node. As previously discussed, increased heart rate occurs with sympathetic (adrenergic) stimulation. When the parasympathetic nerves to the heart are stimulated (primarily via the vagus nerve), heart rate slows and the sympathetic nerves to the heart, arterioles, and veins are inhibited. At rest, the heart rate in healthy individuals is primarily under the control of parasympathetic stimulation. Administration of drugs that block parasympathetic function (anticholinergic) or physical interruption of the vagus nerve causes significant tachycardia (abnormally fast heart rate) because this inhibitory parasympathetic influence is lost.

Neural reflexes.

Output from the baroreceptor reflexes influences short-term regulation of the vascular smooth muscle of resistance arteries, myocardial contractility, and heart rate, all components of blood pressure control. The baroreceptors or pressoreceptors are located in the aortic arch and carotid arteries. If blood pressure decreases, the baroreceptor reflex accelerates heart rate, increases myocardial contractility, and increases vascular smooth muscle contraction in the arterioles, thus raising blood pressure. This reflex is critical to maintaining adequate tissue
perfusion. When blood pressure increases, the baroreceptors increase their rate of discharge, sending neural impulses over a branch of the glossopharyngeal nerve (ninth cranial nerve) and through the vagus nerve to the cardiovascular control centers in the medulla. These reflexes increase parasympathetic activity and decrease sympathetic activity, causing the resistance arteries to dilate, decreasing myocardial contractility and heart rate. The role of baroreceptors in influencing blood pressure is discussed in more detail later in this chapter.

**Atrial receptors.**

Mechanoreceptors that influence heart rate exist in both atria.\(^{18}\) They are located where the veins, venae cavae, and pulmonary veins enter their respective atria. **Bainbridge reflex** is the name for the changes in the heart rate that may occur after intravenous infusions of blood or other fluid. The change in heart rate is thought to be caused by a reflex mediated by these atrial volume receptors that are innervated by the vagus nerve (volume receptors are thought to respond to increased plasma volume). Although this reflex can be elicited in humans, its relevance is uncertain at this time.\(^ {19}\)

Stimulation of these atrial receptors also increases urine volume, presumably because of a neurally mediated reduction in antidiuretic hormone. In addition, peptides of the atrial natriuretic family are released from atrial tissue in response to the increases in blood volume. These peptides have diuretic and natriuretic (salt excretion) properties, resulting in decreased blood volume and pressure. The atrial natriuretic peptides also have been shown to relax vascular smooth muscle and oppose myocardial hypertrophy, leading to measurement of blood levels to evaluate clinical status and raising interest in their use as therapeutic agents.\(^ {20}\)

**Hormones and biochemicals.**

Hormones and other biochemically active substances affect the arteries, arterioles, venules, capillaries, and contractility of the myocardium. Norepinephrine, mainly released as a neurotransmitter from the adrenal medulla, dilates vessels of the liver and skeletal muscle and also causes an increase in myocardial contractility. Some adrenocortical hormones, such as hydrocortisone, potentiate the effects of the catecholamines—norepinephrine and epinephrine.

Thyroid hormones enhance sympathetic activity and increase cardiac output. Growth hormone, working together with insulin-like growth factor-1 (IGF-1), also has been shown to increase myocardial contractility.\(^ {21}\) Decreases in levels of growth hormone or thyroid hormone may result in bradycardia (heart rate below 60 beats/min), reduced cardiac output, and low blood pressure. (Other hormones are
discussed in the Regulation of Blood Pressure section.)

The Systemic Circulation

The arteries and veins of the systemic circulation are illustrated in Figure 23-18. Oxygenated blood leaves the left side of the heart through the aorta and flows into the systemic arteries. These arteries branch into small arterioles, which branch into the smallest vessels, the capillaries, where nutrient and waste product exchange between the blood and tissues occurs. Blood from the capillaries then enters tiny venules that join to form the larger veins, which return venous blood to the right heart. Peripheral vascular system is the term used to describe the part of the systemic circulation that supplies the skin and the extremities, particularly the legs and feet.
**Structure of Blood Vessels**

Blood vessel walls are composed of three layers: (1) the **tunica intima** (innermost, or intimal, layer), (2) the **tunica media** (middle, or medial, layer), and (3) the **tunica externa** or **adventitia** (outermost, or external, layer), which also contains nerves and lymphatic vessels. These layers are illustrated in Figure 23-19. Blood vessel walls vary in thickness depending on the thickness or absence of one or more of these three layers. Cells of the larger vessel walls are nourished by the **vasa vasorum**, small vessels located in the tunica externa.

**Arterial Vessels**

An **artery** is a thick-walled pulsating blood vessel transporting blood away from the heart. In the systemic circulation, arteries carry oxygenated blood. Arterial walls are composed of elastic connective tissue, fibrous connective tissue, and smooth...
muscle. **Elastic arteries**, such as the aorta, the branches of the aorta, and the trunk of the pulmonary artery, have a thick tunica media with more elastic fibers than smooth muscle fibers. Elasticity allows the vessel to absorb energy and stretch as blood is ejected from the heart during systole. During diastole, elasticity promotes recoil of the arteries, maintaining blood pressure within the vessels.

**Muscular arteries**, medium and small size arteries, are farther from the heart than the elastic arteries. They contain more muscle fibers and fewer elastic fibers than the elastic arteries and they function to distribute blood to arterioles throughout the body. Because their smooth muscle can contract or relax, they play a role in blood flow control and in directing flow to body parts with the highest need at any point in time. Contraction narrows the vessel **lumen** (the internal cavity of the vessel), which diminishes flow through the vessel (**vasoconstriction**). When the smooth muscle layer relaxes, more blood flows through the vessel lumen (**vasodilation**).

An artery becomes an arteriole where the diameter of its lumen narrows to less than 0.5 mm. **Arterioles** are mainly composed of smooth muscle and regulate the flow of blood into the capillaries by constricting or dilating to either slow or increase the flow of blood into the capillaries (**Figure 23-20**). The thick smooth muscle layer of the arterioles is a major determinant of the resistance blood encounters as it flows through the systemic circulation.
The capillary network is composed of connective channels called metarterioles, and “true” capillaries (see Figure 23-20). Metarterioles have discontinuous smooth muscle cells in their tunica media whereas capillaries have no smooth muscle cells. There is a ring of smooth muscle called the precapillary sphincter at the point where capillaries branch from metarterioles. As the sphincters contract and relax, they regulate blood flow through the capillary beds. The precapillary sphincters help to maintain arterial pressure and regulate selective flow to vascular beds.

Capillaries are composed solely of a layer of endothelial cells surrounded by a basement membrane. Their thin walls and unique structure make possible the rapid exchange of water; small (low molecular weight) soluble molecules; some larger molecules, such as albumin; and cells of the innate and adaptive components of the immune system between the blood and the interstitial fluid. In some capillaries, the endothelial cells contain oval windows or pores termed fenestrations covered by a thin diaphragm.
Substances pass between the capillary lumen and the interstitial fluid (1) through junctions between endothelial cells, (2) through fenestrations in endothelial cells, (3) in vesicles moved by active transport across the endothelial cell membrane, or (4) by diffusion through the endothelial cell membrane. A single capillary may be only 0.5 to 1 mm in length and 0.01 mm in diameter, but the capillaries are so numerous their total surface area may be more than 600 m² (about 100 football fields).

**Endothelium**

The vascular **endothelium** is important to several body functions and is sometimes considered a separate endocrine organ. All tissues depend on a blood supply and the blood supply depends on **endothelial cells**, which form the lining, or endothelium, of the blood vessel (Figure 23-21). In addition to substance transport, the vascular endothelium has important roles in coagulation, antithrombogenesis, and fibrinolysis; immune system function; tissue and vessel growth and wound healing; and vasomotion, the contraction and relaxation of vessels. Table 23-4 summarizes some of the more important endothelial functions. Endothelial injury and dysfunction are central processes in many of the most common and serious cardiovascular disorders, including hypertension and atherosclerosis (see Chapter 24).

### Veins

Compared with arteries, **veins** are thin walled with more fibrous connective tissue and have a larger diameter (see Figure 23-19). Veins also are more numerous than arteries. The smallest venules downstream from the capillaries have an endothelial lining and are surrounded by connective tissue. The largest venules have some smooth muscle fibers in their thin tunica media. The venous tunica externa has less elastic tissue than that in arteries, so veins do not recoil as much or as rapidly after distention. Like arteries, veins receive nourishment from tiny vasa vasorum.

Veins contain valves to facilitate the one-way flow of blood toward the heart (Figure 23-22). These valves are folds of the tunica intima and resemble the semilunar valves of the heart. When a person stands up, contraction of the skeletal muscles of the legs compresses the deep veins of the legs and assists the flow of blood toward the heart. This important mechanism of venous return is called the **muscle pump** (Figure 23-22, B).
Factors Affecting Blood Flow

**Blood flow**, the amount of fluid moved per unit of time, is usually expressed as liters or milliliters per minute (L/min or ml/min). Factors the influence blood flow include pressure, resistance, velocity, turbulent versus laminar flow, and compliance, with the most important of these being pressure and resistance.

**Pressure and Resistance**

**Pressure** in a liquid system is the force exerted on the liquid per unit area and is expressed clinically as millimeters of mercury (mm Hg), or torr (1 torr = 1 mm Hg). Blood flow to an organ depends partly on the pressure difference between the arterial and venous vessels supplying that organ. Fluid moves from the arterial “side” of the capillaries where the pressure is higher to the venous side where the pressure is lower.

**Resistance** is the opposition to blood flow. Most opposition to blood flow results from the diameter and length of the vessels. Changes in blood flow through an
organ result from changes in the vascular resistance within the organ because of increases or decreases in vessel diameter and the opening or closing of vascular channels. Resistance in a vessel is inversely related to blood flow—that is, increased resistance leads to decreased blood flow. Poiseuille law indicates that resistance is directly related to tube length and blood viscosity and inversely related to the radius of the tube to the fourth power ($r^4$). Because blood flow is inversely related to resistance, the greater the resistance the lower the blood flow will be. Resistance to flow cannot be measured directly, but it can be calculated if the pressure difference and flow volumes are known. Resistance to blood flow in a single vessel is determined by the radius and length of the blood vessel and by the blood viscosity.

Clinically, the most important factor determining resistance in a single vessel is the **radius** or **diameter** of the vessel's lumen. Small changes in the lumen's radius or diameter lead to large changes in vascular resistance. Clinically, vasoconstriction will contribute to an increase in resistance whereas vasodilation will cause a decrease in resistance that may be reflected by a fall in blood pressure. Because vessel length is relatively constant whereas lumen size is quite variable, length is not as important as lumen size in determining flow through a single vessel. Because viscosity is relatively constant, blood vessel radius is usually the key factor in determining total peripheral resistance. An exception to this rule is when red blood cell volume, measured as hematocrit, is elevated, which is relatively rare. Conditions with elevated hematocrits include a lack of body water, cyanotic congenital heart disease (see Chapter 25), or polycythemia (see Chapter 21), and can lead to increased cardiac work as a result of increased vascular resistance.

Resistance to flow through a **system of vessels**, or **total resistance**, depends not only on characteristics of individual vessels but also on whether the vessels are arranged in series or in parallel and on the total cross-sectional area of the system. Vessels arranged in parallel provide less resistance than vessels arranged in series. Blood flowing through the distributing arteries, beginning with branches off the aorta and ending at arterioles in the capillary bed, encounters more resistance than blood flowing through the capillary bed itself, where flow is distributed among many short, tiny branches arranged in parallel (see Figure 23-23). The total cross-sectional area of the arteriolar system is greater than that of the arterial system, yet the greater number of arterioles arranged in series leads to great resistance to flow in the arteriolar system. In contrast, the capillary system has a larger number of vessels arranged in parallel than the arteriolar system, and the total cross-sectional area is much greater; thus there is lower resistance overall through the capillary system. The resulting slow velocity of flow in each capillary is optimal for capillary-tissue exchange.
**Velocity**

**Blood velocity or speed** is the *distance* blood travels in a unit of time, usually centimeters per second (cm/sec). It is directly related to blood flow (*amount* of blood moved per unit of time) and inversely related to the cross-sectional area of the vessel in which the blood is flowing ([Figure 23-23](#)). As blood moves from the aorta to the capillaries, the total cross-sectional area of the vessels increases and the velocity decreases.
Blood flows with great speed in the large arteries. However, branching of arterial vessels increases the total cross-sectional area of the arterioles and capillaries, reducing the flow rate. When capillaries merge into venules and venules merge into veins, the total cross-sectional area decreases, causing the flow rate to increase. (From Patton KT, Thibodeau GA. Anatomy & physiology, ed 9, St Louis, 2016, Elsevier.)

Laminar Versus Turbulent Flow

Flow through a tubular system can be either laminar or turbulent. Blood flow
through the vessels, except where vessels split or branch, is usually \textit{laminar}. In \textbf{laminar flow}, concentric layers of molecules move “straight ahead” with each layer flowing at a slightly different velocity (Figure 23-24). The cohesive attraction between the fluid and the vessel wall prevents the molecules of blood that are in contact with the wall from moving at all. The next thin layer of blood is able to slide slowly past the stationary layer and so on until, at the center, the blood velocity is greatest. Large vessels have room for a large center layer; therefore they have less resistance to flow and greater flow and velocity than smaller vessels.
Where flow is obstructed, the vessel turns, or blood flows over rough surfaces, the flow becomes **turbulent** with whorls or eddy currents that produce noise, causing a murmur to be heard on auscultation. Resistance increases with turbulence, which frequently occurs in areas with atherosclerotic plaque (see Chapter 24).

**Vascular Compliance**

**Vascular compliance** is the increase in volume a vessel can accommodate for a given increase in pressure. Compliance depends on factors related to the nature of a vessel wall, such as the ratio of elastic fibers to muscle fibers in the wall. Elastic
arteries are more compliant than muscular arteries. The veins are more compliant than either type of artery, and they can serve as storage areas for the circulatory system.

Compliance determines a vessel's response to pressure changes. For example, a large volume of blood can be accommodated by the venous system with only a small increase in pressure. In the less compliant arterial system, where smaller volumes and higher pressures are normal, even small changes in blood volume can cause significant changes in arterial pressure.

Stiffness is the opposite of compliance. Several conditions and disorders can cause stiffness, with the most common being aging and atherosclerosis (see Chapter 24).

Quick Check 23-6

1. What is the function of the arterioles?

2. Identify the functions of the endothelium.

3. Why does the total cross-sectional area in the capillary system lower the resistance to flow?

Regulation of Blood Pressure

Arterial Pressure

Arterial blood pressure is determined by the cardiac output multiplied by the peripheral resistance (Figure 23-25). The systolic blood pressure is the highest arterial blood pressure following ventricular contraction or systole. The diastolic blood pressure is the lowest arterial blood pressure that occurs during ventricular filling or diastole. The mean arterial pressure (MAP), which is the average pressure in the arteries throughout the cardiac cycle, depends on the elastic properties of the arterial walls and the mean volume of blood in the arterial system. MAP can be approximated from the measured values of the systolic ($P_s$) and diastolic ($P_d$) pressures as follows:

$$\text{MAP} = P_d + \frac{1}{3}(P_s - P_d)$$
The normal range for MAP is 70 to 110 mm Hg.\textsuperscript{23} The difference between the systolic pressure and diastolic pressure ($P_s - P_d$) is called the pulsue pressure and typically is between 40 and 50 mm Hg.\textsuperscript{7} Pulse pressure is directly related to arterial wall stiffness and stroke volume.

During a wide range of physiologic conditions, including changes in body position, muscular activity, and circulating blood volume, arterial pressure is regulated within a fairly narrow range to maintain tissue perfusion, or blood supply to the capillary beds. The major factors and relationships that regulate arterial blood pressure are summarized in Figure 23-25.

**Effects of Cardiac Output**

The cardiac output (minute volume) of the heart can be changed by alterations in heart rate, stroke volume (volume of blood ejected during each ventricular contraction), or both. An increase in cardiac output without a decrease in peripheral resistance will cause mean arterial pressure and flow rate to increase. The higher arterial pressure increases blood flow through the arterioles. On the other hand, a decrease in the cardiac output causes a drop in the mean arterial blood pressure and arteriolar flow if peripheral resistance stays constant.
**Effects of Total Peripheral Resistance**

Total resistance in the systemic circulation, known as either systemic vascular resistance or *total peripheral resistance*, is primarily a function of arteriolar diameter. If cardiac output remains constant, arteriolar constriction raises mean arterial pressure by reducing the flow of blood into the capillaries, whereas arteriolar dilation has the opposite effect. Reflex control of total cardiac output and peripheral resistance includes (1) sympathetic stimulation of heart, arterioles, and veins; and (2) parasympathetic stimulation of the heart (Figure 23-26). The cardiovascular center in the medulla receives input from arterial baroreceptors and chemoreceptors throughout the vascular system and then modifies vagal and sympathetic output to control heart rate and contractility, plus vascular diameter. Vasoconstriction is regulated by an area of the brainstem that maintains a constant (tonic) output of norepinephrine from sympathetic fibers in the peripheral arterioles. This tonic activity is essential for maintenance of blood pressure.
Baroreceptors.

As discussed previously, baroreceptors are stretch receptors located predominantly in the aorta and in the carotid sinus (see Figure 23-26, A). They respond to changes in smooth muscle fiber length by altering their rate of discharge and supply sensory information to the cardiovascular center in the brainstem. When activated
(stretched), the baroreceptors decrease cardiac output by lowering heart rate and stroke volume) and peripheral resistance, and thus lower blood pressure. (Postural changes and the baroreceptor reflex are discussed in Chapter 24.)

**Arterial chemoreceptors.**

Specialized areas within the aortic arch and carotid arteries are sensitive to concentrations of oxygen, carbon dioxide, and hydrogen ions (pH) in the blood (see Figure 23-26, B). Although these chemoreceptors are most important for respiratory control, they also transmit impulses to the medullary cardiovascular centers that regulate blood pressure. A decrease in arterial oxygen concentration or an increase in carbon dioxide concentration contributes to an increase in heart rate, stroke volume, and blood pressure, whereas an increase in carbon dioxide concentration causes decreases in these variables. The major chemoreceptive reflex is caused by alterations in arterial oxygen concentration. The effects of altered pH or carbon dioxide levels are minor.

**Effect of Hormones**

Hormones influence blood pressure regulation through their effects on vascular smooth muscle and blood volume. By constricting or dilating the arterioles in organs, hormones can (1) increase or decrease the flow in response to the body's needs, (2) redistribute blood volume during hemorrhage or shock, and (3) regulate heat loss. The key vasoconstrictor hormones include angiotensin II, vasopressin (or antidiuretic hormone), epinephrine, and norepinephrine. The main vasodilator hormones are the atrial natriuretic hormones. By causing fluid retention or loss, aldosterone, vasopressin, and the natriuretic hormones can influence stroke volume and thus blood pressure.

A variety of other factors, including adipokines and insulin, may be related to the hypertension that occurs with chronic conditions, such as adiposity and diabetes mellitus; but these factors have not been clearly demonstrated to play a role in blood pressure regulation in healthy individuals. Some research has suggested that the risk of cardiovascular disease and hypertension that often co-occurs with diabetes mellitus is more closely related to insulin resistance than to insulin levels. **Adrenomedullin (ADM)** is a vasodilating peptide present in cardiovascular, pulmonary, renal, and other tissues. Because increases in ADM levels are associated with heart failure and myocardial infarction, ADM levels may be useful for risk categorization in people with these conditions.

**Vasoconstrictor hormones.**
The vasoconstrictor hormones include epinephrine; norepinephrine; angiotensin II, which is part of the renin-angiotensin-aldosterone system; and vasopressin (also known as antidiuretic hormone). **Epinephrine**, the catecholamine hormone released from the adrenal medulla, causes vasoconstriction in most vascular beds except the coronary, liver, and skeletal muscle circulations. Norepinephrine mainly acts as a neurotransmitter; however, some also is released from the adrenal medulla. When released into the circulation, it is a more potent vasoconstrictor than epinephrine. Although angiotensin II and vasopressin are vasoconstrictors they are not thought to have a major role in blood pressure control in normal circumstances.

Vasopressin and aldosterone also affect blood pressure by increasing blood volume through their influence on fluid reabsorption in the kidney and by stimulating thirst. Vasopressin causes the reabsorption of water from tubular fluid in the distal tubule and collecting duct of the nephron. Aldosterone, the end product of the renin-angiotensin-aldosterone system, stimulates the reabsorption of sodium, chloride, and water from the same locations in the kidney (Figure 23-27; also see Chapters 5 and 18).
Vasodilator hormones.

The natriuretic peptides (NPs) or hormones (see Figure 23-27), including atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), C-type natriuretic peptide (CNP), and urodilatin, function as both vasodilators and regulators of sodium and water excretion (natriuresis and diuresis). Increased pressure or diastolic volume in the heart stimulates the release of these peptide hormones.
Increased levels of BNP predict increased risk of a poor outcome in heart failure, pulmonary embolism, valvular heart disease, and chronic coronary artery disease.  

**Effects of Other Mediators**

A variety of other mediators have been demonstrated to cause arteriolar vasodilation or vasoconstriction. Some of the vasodilating mediators include nitric oxide (NO), ADM, the endothelins, and prostacyclin. These mediators are being investigated to determine if they or their inhibitors might be useful drugs for the treatment of cardiovascular diseases or if their levels might be useful in determining the prognosis of persons with known disease.

**Nitric oxide (NO),** an intercellular and intracellular signaling molecule produced in endothelial cells, has a variety of roles in vascular function including acting as a vasodilator and inhibitor of smooth muscle proliferation. NO also has been called endothelium-derived relaxing factor (EDRF). One way that diabetes may contribute to hypertension is through inhibition of NO production by impeding a family of enzymes—the nitric oxide synthases. Understanding the role of NO in producing vasodilation explains why sublingual nitroglycerin has been a useful treatment for coronary artery spasm.

ADM, a peptide with powerful vasodilatory activity, is present in numerous tissues. It is a member of the calcitonin gene–related peptide family. Although it has been found to have numerous cardiovascular effects, including a role in fetal cardiovascular system development and vasodilation, its exact role in adult human cardiovascular function and disease is unclear. Some research indicates that elevated adrenomedullin levels may be useful disease indicators.

The endothelins are a family of three peptides (ET-1, ET-2, and ET-3) and four receptors produced in cells in the vascular smooth muscle, the endothelium, the kidneys, and other organs. Understanding the physiologic and pathologic roles of these peptides has been complicated by the fact that endothelin binding to the type A receptor causes vasodilation and natriuresis, whereas binding to type B receptor causes the opposite response—vasoconstriction plus sodium and water retention. Inhibitors to endothelin-1 have been approved for the treatment of pulmonary hypertension.

Prostacyclin is a vasodilator that is produced by the actions of cyclooxygenases (COX-1 and COX-2) on arachidonic acid. It also has the additional properties of opposing clot formation (antithrombotic), decreasing platelet activity, and inhibiting the release of growth factors from macrophages and the endothelial cells. Nonsteroidal anti-inflammatory drugs (NSAIDs) that inhibit these cyclooxygenases have been associated with cardiovascular disease risk in healthy people and in those
with a known cardiovascular disease.\textsuperscript{33,34}

**Venous Pressure**

The main determinants of venous blood pressure are (1) the volume of fluid within the veins and (2) the compliance (distensibility) of the vessel walls. The venous system typically accommodates about 66\% of the total blood volume at any time, with venous pressure averaging less than 10 mm Hg. The systemic arteries accommodate about 11\% of the total blood volume, with an average arterial pressure (blood pressure) of about 100 mm Hg; the remainder of the blood volume is within the heart, capillaries, and pulmonary circulation.\textsuperscript{23}

The sympathetic nervous system controls venous compliance. The walls of the veins are highly innervated by sympathetic fibers that control venous smooth muscle. Rather than constriction that would occur in the arteries, smooth muscle contraction in the veins results in stiffening of the vessel walls. This stiffening reduces venous distensibility and increases venous blood pressure, thus forcing more blood through the veins and into the right heart.

Two other mechanisms that increase venous pressure and venous return to the heart are (1) the skeletal muscle pump and (2) the respiratory pump. During skeletal muscle contraction, the veins within the muscles are partially compressed, causing decreased venous capacity and increased return to the heart (see Figure 23-26). The respiratory pump acts during inspiration, when the veins of the abdomen are partially compressed by the downward movement of the diaphragm. Increased abdominal pressure moves blood toward the heart.

**Regulation of the Coronary Circulation**

Coronary blood flow is directly proportional to the perfusion pressure and inversely proportional to the vascular resistance of the coronary bed. Coronary perfusion pressure is the difference between pressure in the aorta and pressure in the coronary vessels. Thus, aortic pressure is the driving pressure for the arteries and arterioles that perfuse the myocardium. Vasodilation and vasoconstriction maintain coronary blood flow despite stresses imposed by the constant contraction and relaxation of the heart muscle and despite shifts (within a physiologic range) of coronary perfusion pressure.

Several unique anatomic factors influence coronary blood flow. Because of their anatomic location, the aortic valve cusps can obstruct coronary blood flow by occluding the openings of the coronary arteries during systole. Also during systole, the coronary arteries are compressed by ventricular contraction. The resulting systolic compressive effect is particularly evident in the subendocardial layers of
the left ventricular wall and can greatly increase resistance to coronary blood flow with the result that most left ventricular coronary blood flow occurs during diastole. During the period of systolic compression, when flow is slowed or stopped, myoglobin, a protein in heart muscle that binds oxygen, provides the supply of oxygen to the myocardium. Myoglobin's oxygen levels are replenished during diastole.

**Autoregulation**

Autoregulation (automatic self-regulation) enables organs to regulate blood flow by altering the resistance (diameter) in their arterioles. Autoregulation in the coronary circulation maintains the blood flow at a nearly constant rate at perfusion pressures (mean arterial pressure) between 60 and 140 mm Hg when other influencing factors are held constant. Thus autoregulation helps to ensure constant coronary blood flow despite shifts in the perfusion pressure within the stated range.

Given that blood flow is directly related to pressure and inversely related to resistance, for flow to stay constant as pressure decreases resistance also has to decrease; therefore the mechanisms underlying autoregulation must be related to control of smooth muscle contraction in the arteriolar walls. Although the exact mechanisms underlying autoregulation are unknown, research has indicated that factors influencing calcium release with the myocardium are involved and perhaps also the accumulation of vasodilatory products of metabolism, such as adenosine.\(^{18,35}\)

**Autonomic Regulation**

Although the coronary vessels, themselves, contain sympathetic (\(\alpha\)- and \(\beta\)-adrenergic) and parasympathetic neural receptors, coronary blood flow during regular activity is regulated locally by the factors that cause autoregulation. During exercise, however, the vasodilating effects of \(\beta_2\)-receptors on the smaller coronary resistance arteries are responsible for about 25% of any increase in blood flow. At the same time, \(\alpha\)-adrenergic receptors in larger arteries cause vasoconstriction to direct the blood flow to the inner layers of the myocardium.\(^{18}\)

**Quick Check 23-7**

1. Why is capillary flow increased with increased mean arterial pressure?
2. Why is angiotensin significant in blood flow?
3. Identify the factors regulating blood pressure.

4. Define natriuretic peptides and adrenomedullin.
The Lymphatic System

The lymphatic system is a one-way network of lymphatic vessels and the lymph nodes (Figures 23-28 and 23-29) that is important for immune function, fluid balance, and transport of lipids, hormones, and cytokines. Every day about 3 liters of fluid filters out of venous capillaries in body tissues and is not reabsorbed. This fluid becomes the lymph that is carried by the lymphatic vessels to the chest, where it enters the venous circulation. The lymphatic vessels run in the same sheaths with the arteries and veins. (Lymph nodes and lymphoid tissues are described in Chapters 6 and 8.) In this pumpless system, a series of valves ensures one-way flow of the excess interstitial fluid (now called lymph) toward the heart. The lymphatic capillaries are closed at the distal ends, as shown in Figure 23-30.
FIGURE 23-28  Role of the Lymphatic System in Fluid Balance. Fluid from plasma flowing through the capillaries moves into interstitial spaces. Although most of this interstitial fluid is either absorbed by tissue cells or reabsorbed by blood capillaries, some of the fluid tends to accumulate in the interstitial spaces. This lymph then diffuses into the lymphatic vessels that carry it to the lymph nodes and then into the systemic venous blood. Green is used to diagram the lymphatic vessels although the lymphatic vessels, particularly the smaller ones, are almost transparent. (Modified from Thibodeau GA, Patton KT: Structure & function of the body, ed 13, St Louis, 2008, Elsevier.)
FIGURE 23-29  Principle Organs of the Lymphatic System.  (From VanMeter KC, Hubert R.J. Microbiology for the healthcare professional, St Louis, 2010, Mosby)
Lymph consists primarily of water and small amounts of dissolved proteins, mostly albumin, that are too large to be reabsorbed into the less permeable blood capillaries. Lymph also carries two types of immune system cells: lymphocytes and
antigen-presenting cells. The antigen-presenting cells are carried to the next lymph node in the system while lymphocytes traffic between lymph nodes. Once within the lymphatic system, lymph travels through lymphatic venules and veins that drain into one of two large ducts in the thorax: the right lymphatic duct and the thoracic duct. The right lymphatic duct drains lymph from the right arm and the right side of the head and thorax, whereas the larger thoracic duct receives lymph from the rest of the body (see Figure 23-29). The right lymphatic duct and the thoracic duct drain lymph into the right and left subclavian veins, respectively.

Lymphatic veins are thin walled like the veins of the cardiovascular system. In larger lymphatic veins, endothelial flaps form valves similar to those in blood-carrying veins (see Figure 23-30). The valves allow lymph to flow in only one direction as lymphatic vessels are compressed intermittently by skeletal muscle contraction, pulsatile expansion of the artery in the same sheath, and contraction of the smooth muscles in the walls of the lymphatic vessels.

As lymph is transported toward the heart, it is filtered through thousands of bean-shaped lymph nodes clustered along the lymphatic vessels (see Figure 23-29). Lymph enters the nodes through afferent lymphatic vessels, filters through the sinuses in the node, and leaves by way of efferent lymphatic vessels. Lymph flows slowly through a node, allowing phagocytosis of foreign substances within the node and delivery of lymphocytes. (Phagocytosis is described in Chapter 7.)

Quick Check 23-8

1. Why is the lymphatic system considered a circulatory system?
2. What happens to lymph in lymph nodes?
Did You Understand?

The Circulatory System

1. The circulatory system is part of the body's transport and communication systems. It delivers oxygen, nutrients, metabolites, hormones, neurochemicals, proteins, and blood cells including lymphocytes and leukocytes throughout the body and carries metabolic wastes to the kidneys, lungs, and liver for excretion.

2. The circulatory system consists of the heart and the blood and lymphatic vessels and is made up of two separate, but conjoined serially connected pump systems: the pulmonary circulation and the systemic circulation. The lymphatic system is a one-way network consisting of lymphatic vessels and lymph nodes.

3. The low-pressure pulmonary circulation is driven by the right side of the heart; its function is to deliver blood to the lungs for oxygenation.

4. The higher pressure systemic circulation is driven by the left side of the heart and functions to provide oxygenated blood, nutrients, and other key substances to body tissues and transport waste products to the lungs, kidneys, and liver for excretion.

5. The lymphatic vessels collect fluids from the interstitium and return the fluids to the circulatory system; lymphatic vessels also deliver antigens, microorganisms, and cells to the lymph nodes.

The Heart

1. The heart consists of four chambers (two atria and two ventricles), four valves (two atrioventricular valves and two semilunar valves), a muscular wall, a fibrous skeleton, a conduction system, nerve fibers, systemic vessels (the coronary circulation), and openings where the great vessels enter the atria and ventricles.

2. The heart wall, which encloses the heart and divides it into chambers, is made up of three layers: the epicardium (outer layer), the myocardium (muscular layer), and the endocardium (inner lining). The heart lies within the pericardium, a double-walled sac.

3. The myocardial layer of the two atria, which receive blood entering the heart, is thinner than the myocardial layer of the ventricles, which have to be stronger to
squeeze blood out of the heart.

4. The right and left sides of the heart are separated by portions of the heart wall called the *interatrial septum* and the *interventricular septum*.

5. Deoxygenated (venous) blood from the systemic circulation enters the right atrium through the superior and inferior vena cavae. From the right atrium, the blood passes through the right atrioventricular (tricuspid) valve into the right ventricle. In the ventricle, the blood flows from the inflow tract to the outflow tract and then through the pulmonary semilunar valve (pulmonary valve) into the pulmonary artery, which delivers it to the lungs for oxygenation.

6. Oxygenated blood from the lungs enters the left atrium through the four pulmonary veins (two from the left lung and two from the right lung). From the left atrium, the blood passes through the left atrioventricular valve (mitral valve) into the left ventricle. In the ventricle, the blood flows from the inflow tract to the outflow tract and then through the aortic semilunar valve (aortic valve) into the aorta, which delivers it to systemic arteries of the entire body.

7. There are four heart valves. The atrioventricular valves ensure one-way flow of blood from the atria to the ventricles. The semilunar valves ensure one-way blood flow from the right ventricle to the pulmonary artery and from the left ventricle to the aorta.

8. Oxygenated blood enters the coronary arteries through openings from the aorta, and deoxygenated blood from the coronary veins enters the right atrium through the coronary sinus.

9. The pumping action of the heart consists of two phases: diastole, during which the myocardium relaxes and the ventricles fill with blood; and systole, during which the myocardium contracts, forcing blood out of the ventricles. A cardiac cycle consists of one systolic contraction and the diastolic relaxation that follows it. Each cardiac cycle represents one heartbeat.

10. The conduction system of the heart generates and transmits electrical impulses (cardiac action potentials) that stimulate systolic contractions. The autonomic nerves (sympathetic and parasympathetic fibers) can adjust heart rate and force of contraction, but they do not originate the heartbeat.

11. The normal electrocardiogram is the sum of all cardiac action potentials. The P
wave represents atrial depolarization; the QRS complex is the sum of all ventricular cell depolarizations. The ST interval occurs when the entire ventricular myocardium is depolarized.

12. Cardiac action potentials are generated by the sinoatrial node at a rate of 60 to 100 impulses per minute. The impulses can travel through the conduction system of the heart, stimulating myocardial contraction as they go.

13. Cells of the cardiac conduction system possess the properties of automaticity and rhythmicity. Automatic cells return to threshold and depolarize rhythmically without an outside stimulus. The cells of the sinoatrial node depolarize faster than other automatic cells, making it the natural pacemaker of the heart. If the sinoatrial node is disabled, the next fastest pacemaker, the atrioventricular node, takes over.

14. Each cardiac action potential travels from the sinoatrial node to the atrioventricular node to the bundle of His (atrioventricular bundle), through the bundle branches, and finally to the Purkinje fibers and ventricular myocardium, where the impulse stops. It is prevented from reversing its path by the refractory period of cells that have just been polarized. The refractory period ensures that diastole (relaxation) will occur, thereby completing the cardiac cycle.

15. Adrenergic receptor number, type, and function govern autonomic (sympathetic) regulation of heart rate, contractile force, and the dilation or constriction of coronary arteries. The presence of specific receptors on the myocardium and coronary vessels determines the effects of the neurotransmitters norepinephrine and epinephrine.

16. Unique features that distinguish myocardial cells from skeletal cells enable myocardial cells to transmit action potentials faster (through intercalated disks), synthesize more ATP (because of a large number of mitochondria), and have readier access to ions in the interstitium (because of an abundance of transverse tubules). These combined differences enable the myocardium to work constantly, which is not required by skeletal muscle.

17. Cross-bridges between actin and myosin enable contraction. Calcium ions interacting with the troponin complex help initiate the contraction process. Subsequently, myocardial relaxation begins as troponin releases calcium ions.

18. Cardiac performance is affected by preload, afterload, myocardial contractility, and heart rate.
19. Preload, or pressure generated in the ventricles at the end of diastole, depends on the amount of blood in the ventricle. Afterload is the resistance to ejection of the blood from the ventricle. Afterload depends on pressure in the aorta.

20. Myocardial stretch determines the force of myocardial contraction; thus the greater the stretch, the stronger the contraction up to a certain point. This relationship is known as the Frank-Starling law of the heart.

21. Contractility is the potential for myocardial fiber shortening during systole. It is determined by the amount of stretch during diastole (i.e., preload) and by sympathetic stimulation of the ventricles.

22. Heart rate is determined by the sinoatrial node and by components of the autonomic nervous system, including cardiovascular control centers in the brain, receptors in the aorta and carotid arteries, and hormones, including catecholamines (epinephrine, norepinephrine).

The Systemic Circulation

1. Blood flows from the left ventricle into the aorta and from the aorta into arteries that eventually branch into arterioles and capillaries, the smallest of the arterial vessels. Oxygen, nutrients, and other substances needed for cellular metabolism pass from the capillaries into the interstitium, where they are taken up by the cells. Capillaries also absorb metabolic waste products from the interstitium.

2. Venules, the smallest veins, receive capillary blood. From the venules, the venous blood flows into larger and larger veins until it reaches the venae cavae, through which it enters the right atrium.

3. Vessel walls have three layers: the tunica intima (inner layer), the tunica media (middle layer), and the tunica externa (the outer layer).

4. Layers of the vessel wall differ in thickness and composition from vessel to vessel, depending on the vessel's size and location within the circulatory system. In general, the tunica media of arteries close to the heart has more elastic fibers because these arteries must be able to distend during systole and recoil during diastole. Distributing arteries farther from the heart contain more smooth muscle fibers because they constrict and dilate to control blood pressure and volume within specific capillary beds.
5. Blood flow into the capillary beds is controlled by the contraction and relaxation of smooth muscle bands (precapillary sphincters) at junctions between metarterioles and capillaries.

6. Endothelial cells line the blood vessels. The endothelium is a life-support tissue; it functions as a filter (altering permeability), changes in vasomotion (constriction and dilation), and is involved in clotting and inflammation.

7. Blood flow through the veins is assisted by the contraction of skeletal muscles (the muscle pump), and backward flow is prevented by one-way valves, which are particularly important in the deep veins of the legs.

8. Blood flow is affected by blood pressure, resistance to flow within the vessels, blood consistency (which affects velocity), anatomic features that may cause turbulent or laminar flow, and compliance (distensibility) of the vessels.

9. Poiseuille law describes the relationship of blood flow, pressure, and resistance as the difference between pressure at the inflow end of the vessel and pressure at the outflow end divided by resistance within the vessel.

10. The greater a vessel's length and the blood's viscosity and the narrower the radius of the vessel's lumen, the greater the resistance within the vessel.

11. Total peripheral resistance, or the resistance to flow within the entire systemic circulatory system, depends on the combined lengths and radii of all the vessels within the system and on whether the vessels are arranged in series (greater resistance) or in parallel (lesser resistance).

12. Blood flow is also influenced by neural stimulation (vasoconstriction or vasodilation) and by autonomic features that cause turbulence within the vascular lumen (e.g., protrusions from the vessel wall, twists and turns, vessel branching).

13. Arterial blood pressure is influenced and regulated by factors that affect cardiac output (heart rate, stroke volume), total resistance within the system, and blood volume.

14. Antidiuretic hormone, the renin-angiotensin-aldosterone system, and natriuretic peptides can all alter blood volume and thus blood pressure.

15. Venous blood pressure is influenced by blood volume within the venous system
and compliance of the venous walls.

16. Blood flow through the coronary circulation is governed by the same principles as flow through other vascular beds plus two adaptations dictated by cardiac dynamics. First, blood flows into the coronary arteries during diastole rather than systole, because during systole the cusps of the aortic semilunar valve block the openings of the coronary arteries. Second, systolic contraction inhibits coronary artery flow by compressing the coronary arteries.

17. Autoregulation enables the coronary vessels to maintain optimal perfusion pressure despite systolic compression.

18. Myoglobin in heart muscle stores oxygen for use during the systolic phase of the cardiac cycle.

The Lymphatic System

1. The vessels of the lymphatic system run in the same sheaths as the arteries and veins.

2. Lymph (interstitial fluid) is absorbed by lymphatic venules in the capillary beds and travels through ever larger lymphatic veins until it empties through the right lymphatic duct or thoracic duct into the right or left subclavian veins, respectively.

3. As lymph travels toward the thoracic ducts, it passes through thousands of lymph nodes clustered around the lymphatic veins. The lymph nodes are sites of immune function and are ideally placed to sample antigens and cells carried by the lymph from the periphery of the body into the central circulation.

Our understanding of the pathophysiology of cardiovascular diseases is evolving rapidly. Neurohumoral, genetic, inflammatory, and metabolic factors are now the focus. This new information is leading to improvements in prevention and treatment.
Diseases of the Veins

Varicose Veins and Chronic Venous Insufficiency

A varicose vein is a vein in which blood has pooled, producing distended, tortuous, and palpable vessels (Figure 24-1). Veins are thin-walled, highly distensible vessels with valves to prevent backflow and pooling of blood (see Figure 23-26). Varicose veins typically involve the saphenous veins of the leg and are caused by (1) trauma to the saphenous veins that damages one or more valves or (2) gradual venous distention caused by the action of gravity on blood in the legs.

If a valve is damaged, a section of the vein is subjected to the pressure of a larger volume of blood under the influence of gravity. Altered connective tissue proteins and proteolytic enzyme activity also play a role in remodeling of the vessel wall. The vein swells as it becomes engorged and surrounding tissue becomes edematous because increased hydrostatic pressure pushes plasma through the stretched vessel wall. Venous distention can develop over time in individuals who habitually stand for long periods, wear constricting garments, or cross the legs at the knees, which diminishes the action of the muscle pump (see Figure 23-27). Risk factors also
include age, female gender, a family history of varicose veins, obesity, pregnancy, deep venous thrombosis, and previous leg injury. Eventually the pressure in the vein damages venous valves, rendering them incompetent and unable to maintain normal venous pressure.

Varicose veins and valvular incompetence can progress to chronic venous insufficiency, especially in obese individuals. **Chronic venous insufficiency (CVI)** is inadequate venous return over a long period. Venous hypertension, circulatory stasis, and tissue hypoxia cause an inflammatory reaction in vessels and tissue leading to fibrosclerotic remodeling of the skin and then to ulceration. Symptoms include edema of the lower extremities and hyperpigmentation of the skin of the feet and ankles. Edema in these areas may extend to the knees. Circulation to the extremities can become so sluggish that the metabolic demands of the cells to obtain oxygen and nutrients and to remove wastes are barely met. Any trauma or pressure can therefore lower the oxygen supply and cause cell death and necrosis (**venous stasis ulcers**) (Figure 24-2). Infection can occur because poor circulation impairs the delivery of the cells and biochemicals necessary for the immune and inflammatory responses. This same sluggish circulation makes infection following reparative surgery a significant risk.

Treatment of varicose veins and CVI begins conservatively, and excellent wound healing results have followed noninvasive treatments such as elevating the legs, wearing compression stockings, and performing physical exercise. Invasive
management includes endovenous ablation, sclerotherapy or surgical ligation, conservative vein resection, and vein stripping.\textsuperscript{3}

**Thrombus Formation in Veins**

A **thrombus** is a blood clot that remains attached to a vessel wall (see Figure 21-20). A detached thrombus is a **thromboembolus**. Venous thrombi are more common than arterial thrombi because flow and pressure are lower in the veins than in the arteries. **Deep venous thrombosis (DVT)** occurs primarily in the lower extremity. Three factors (triad of Virchow) promote venous thrombosis: (1) venous stasis (e.g., immobility, age, congestive heart failure), (2) venous endothelial damage (e.g., trauma, intravenous medications), and (3) hypercoagulable states (e.g., inherited disorders, malignancy, pregnancy, use of oral contraceptives or hormone replacement therapy). Orthopedic trauma or surgery, spinal cord injury, and obstetric/gynecologic conditions can be associated with up to a 100% likelihood of DVT. Numerous genetic abnormalities are associated with an increased risk for venous thrombosis primarily related to states of hypercoagulability. These inherited abnormalities include factor V Leiden mutation, prothrombin mutations, and deficiencies of protein C, protein S, and antithrombin; these abnormalities are commonly found in individuals who develop thrombi in the absence of the usual risk factors.\textsuperscript{4}

Accumulation of clotting factors and platelets leads to thrombus formation in the vein, often near a venous valve. Inflammation around the thrombus promotes further platelet aggregation, and the thrombus propagates or grows proximally. This inflammation may cause pain and redness, but because the vein is deep in the leg, it is usually not accompanied by clinical symptoms or signs. If the thrombus creates significant obstruction to venous blood flow, increased pressure in the vein behind the clot may lead to edema of the extremity. Most thrombi will eventually dissolve without treatment; however, untreated DVT is associated with a high risk of embolization of a part of the clot to the lung (pulmonary embolism) (see Chapter 27). Persistent venous obstruction may lead to chronic venous insufficiency and post-thrombotic syndrome with associated pain, edema, and ulceration of the affected limb.\textsuperscript{5}

Because DVT is usually asymptomatic and difficult to detect clinically, prevention is important in at-risk individuals and includes early ambulation, pneumatic devices, and prophylactic anticoagulation. If thrombosis does occur, diagnosis is confirmed by a combination of serum D-dimer measurement and Doppler ultrasonography. Management most often consists of anticoagulation therapy using heparin (low-molecular-weight heparin) and warfarin.\textsuperscript{6} New oral anticoagulant therapies, such as
factor Xa inhibitors and direct thrombin inhibitors, have been shown to have a more favorable benefit-to-risk ratio and are rapidly becoming the treatments of choice.\textsuperscript{7} Thrombolytic therapy or placement of an inferior vena cava filter may be indicated in selected individuals.\textsuperscript{4,6}

**Superior Vena Cava Syndrome**

**Superior vena cava syndrome (SVCS)** is a progressive occlusion of the superior vena cava (SVC) that leads to venous distention in the upper extremities and head. Causes include bronchogenic cancer (75\% of cases) followed by lymphomas and metastasis of other cancers.\textsuperscript{8} Other less common causes include tuberculosis, mediastinal fibrosis, and cystic fibrosis. Invasive therapies (pacemaker wires, central venous catheters, and pulmonary artery catheters) with associated thrombosis now account for nearly 40\% of cases.\textsuperscript{9} The SVC is a relatively low-pressure vessel that lies in the closed thoracic compartment; therefore tissue expansion can easily compress the SVC. The right mainstem bronchus abuts the SVC so that cancers occurring in this bronchus may exert pressure on the SVC. Additionally, the SVC is surrounded by lymph nodes and lymph chains that commonly become involved in thoracic cancers and compress the SVC during tumor growth. Because onset of SVCS is most often slow, collateral venous drainage to the azygos vein usually has time to develop.

Clinical manifestations of SVCS are edema and venous distention in the upper extremities and face, including the ocular beds. Affected persons complain of a feeling of fullness in the head or tightness of shirt collars, necklaces, and rings. Cerebral edema may cause headache, visual disturbance, and impaired consciousness. The skin of the face and arms may become purple and taut, and capillary refill time is prolonged. Respiratory distress may be present because of edema of bronchial structures or compression of the bronchus by a carcinoma. In infants, SVCS can lead to hydrocephalus.

Diagnosis is made by chest x-ray, Doppler studies, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound. Because of its slow onset and the development of collateral venous drainage, SVCS is generally not a vascular emergency, but it is an oncologic emergency. Treatment for malignant disorders can include radiation therapy, surgery, chemotherapy, and the administration of diuretics, steroids, and anticoagulants, as necessary. Treatment for nonmalignant causes may include bypass surgery using various grafts, thrombolysis (both locally and systemically), balloon angioplasty, and placement of intravascular stents.\textsuperscript{8}

2. What are the major risk factors for DVT?
3. Name three causes of superior vena cava syndrome.
Diseases of the Arteries

Hypertension

Hypertension is consistent elevation of systemic arterial blood pressure. Hypertension (HTN) is the most common primary diagnosis in the United States. One in three Americans has hypertension, and more than two thirds of those older than age 60 are affected. The chance of developing primary hypertension increases with age. Although hypertension is usually considered an adult health problem, it is important to remember that hypertension does occur in children and is being diagnosed with increasing frequency (see Chapter 25). The prevalence of HTN is higher in blacks and in those with diabetes. Hypertension is defined by the Eighth Joint National Committee Report as a sustained systolic blood pressure of 140 mm Hg or greater or a diastolic pressure of 90 mm Hg or greater (Table 24-1). Normal blood pressure is associated with the lowest cardiovascular risk, whereas those who fall into the prehypertension category (which includes between 25% and 37% of the U.S. population) are at risk for developing hypertension and many associated cardiovascular complications unless lifestyle modification and treatment are instituted. All stages of hypertension are associated with increased risk for target organ disease events, such as myocardial infarction, kidney disease, and stroke; thus both stage I and stage II hypertension need effective long-term therapy.

Most cases of hypertension are diagnosed as primary hypertension (also called essential or idiopathic hypertension). From 92% to 95% of hypertensive individuals have primary disease. Secondary hypertension is caused by an underlying disorder such as renal disease. This form of hypertension accounts for only 5% to 8% of cases.

Factors Associated with Primary Hypertension

A specific cause for primary hypertension has not been identified, and a combination of genetic and environmental factors is thought to be responsible for
its development. Genetic predisposition to hypertension is thought to be polygenic and associated with epigenetic changes influenced by diet and lifestyle.\textsuperscript{12} Inherited defects are associated with renal sodium excretion, insulin and insulin sensitivity, activity of the sympathetic nervous system (SNS) and the renin-angiotensin-aldosterone system (RAAS), and cell membrane sodium or calcium transport.\textsuperscript{13} Factors associated with primary hypertension relate to age, gender, race, and dietary factors (see \textit{Risk Factors: Primary Hypertension}). Many of these factors are also risk factors for other cardiovascular disorders. In fact, obesity, hypertension, dyslipidemia, and glucose intolerance often are found together in a condition called the metabolic syndrome (see \textit{Chapter 19}).

\textbf{Risk Factors}

\textbf{Primary Hypertension}

- Family history
- Advancing age
- Cigarette smoking
- Obesity
- Heavy alcohol consumption
- Gender (men > women before age 55, women > men after 55)
- Black race
- High dietary sodium intake
- Low dietary intake of potassium, calcium, magnesium
- Glucose intolerance

\textbf{Pathophysiology}

Hypertension results from a sustained increase in peripheral resistance (arteriolar vasoconstriction), an increase in circulating blood volume, or both.
Primary Hypertension

Primary hypertension is the result of an extremely complicated interaction of genetics and the environment mediated by a host of neurohumoral effects. Multiple pathophysiologic mechanisms mediate these effects, including the sympathetic nervous system (SNS), the renin-angiotensin-aldosterone system (RAAS), and natriuretic peptides. Inflammation, endothelial dysfunction, obesity-related hormones, and insulin resistance also contribute to both increased peripheral resistance and increased blood volume. Increased vascular volume is related to a decrease in renal excretion of salt, often referred to as a shift in the pressure-natriuresis relationship (Figure 24-3). This means that for a given blood pressure, individuals with hypertension tend to secrete less salt in their urine.

FIGURE 24-3  Factors That Cause a Shift in the Pressure-Natriuresis Relationship. Numerous factors have been implicated in the pathogenesis of sodium retention in individuals with hypertension. These factors cause less renal excretion of salt than would normally occur with increased blood pressure. This is called a shift in the pressure-natriuresis relationship and is thought to be a central process in the pathogenesis of primary hypertension. RAAS, Renin-angiotensin-aldosterone system; SNS, sympathetic nervous system.

The sympathetic nervous system has been implicated in both the development and the maintenance of elevated blood pressure and plays a role in hypertensive end-organ damage. Increased SNS activity causes increased heart rate and systemic vasoconstriction, thus raising the blood pressure. Additional mechanisms of SNS-
induced hypertension include structural changes in blood vessels (vascular remodeling), renal sodium retention (shift in pressure-natriuresis curve), insulin resistance, increased renin and angiotensin levels, and procoagulant effects.\textsuperscript{15}

In hypertensive individuals, overactivity of the RAAS contributes to salt and water retention and increased vascular resistance (see Figure 23-27). High levels of angiotensin II contribute to endothelial dysfunction, insulin resistance, and platelet aggregation and play an important role in the complications associated with the metabolic syndrome.\textsuperscript{16} Further, angiotensin II mediates \textit{arteriolar remodeling}, which is structural change in the vessel wall that results in permanent increases in peripheral resistance and contributes to atherogenesis\textsuperscript{17} (see Figure 23-33). Angiotensin II is associated with end-organ effects of hypertension, including atherosclerosis, renal disease, cardiac hypertrophy, and heart failure.\textsuperscript{18,19} Finally, aldosterone not only contributes to sodium retention by the kidney but also has other deleterious effects on the cardiovascular system and contributes to insulin resistance.\textsuperscript{20} Medications, such as angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), oppose the activity of the RAAS and are effective in reducing blood pressure and protecting against target organ damage.\textsuperscript{21} A second RAAS also has been described. This system uses ACE2 to create angiotensin 1-7, Ang(1-7), which has cardiovascular, cerebrovascular, and metabolic protective effects.\textsuperscript{22} Its discovery may lead to new and more effective medications\textsuperscript{23} (see \textit{Health Alert: The Renin-Angiotensin-Aldosterone System (RAAS) and Cardiovascular Disease}).

\textbf{Health Alert}

\textbf{The Renin-Angiotensin-Aldosterone System (RAAS) and Cardiovascular Disease}

The RAAS has multiple effects on the cardiovascular system. There are two primary RAA systems. The best known includes the release of renin, the synthesis of angiotensin II (Ang II) through angiotensin-converting enzyme (ACE), stimulation of the AT1 receptor (AT1R), and secretion of aldosterone. Ang II causes systemic vasoconstriction and renal salt and water retention, and stimulates tissue growth and inflammation. When present in abnormal amounts, Ang II contributes to insulin resistance, remodeling of blood vessels, atherogenesis, and decreased release of endothelial vasodilators and anticoagulants. In the heart, Ang II and aldosterone contribute to hypertensive hypertrophy and fibrosis of heart muscle, decreased contractility, and an increased susceptibility to arrhythmias and heart
failure. In the kidney these hormones cause a shift in the pressure-natriuresis curve, inflammation, and glomerular remodeling and are a major contributor to renal failure in individuals with hypertension and diabetes. Drugs that block this RAAS include ACE inhibitors, direct renin inhibitors, Ang II receptor blockers (ARBs), and aldosterone inhibitors. These medications are used widely in managing hypertension, myocardial infarction, and heart failure to lower blood pressure and to protect and improve cardiovascular and renal function. In contrast, the second RAAS serves a counterregulatory system. Activation of a second ACE pathway (ACE2) leads to the synthesis of angiotensin 1-7 from Ang II. Angiotensin 1-7 stimulates Mas receptors in the brain, blood vessels, heart, kidney, gut, pancreas, and inflammatory cells and has vasodilatory, antiproliferative, antifibrotic, and antithrombotic effects. These protective effects lead to lower blood pressure, less vascular inflammation and clotting, and decreased tissue remodeling and damage to target organ tissues. This pathway appears to be especially important in protecting renal tissue and improving insulin sensitivity in those with diabetes and hypertension. Research is underway to develop pharmacologic interventions, such as synthetic Mas agonists, Ang1-7 formulations, and ACE2 activators that will stimulate these protective RAAS pathways. More recently, additional RAAS pathways have been identified that play a role in proto-oncogene stimulation, hypothalamic function, and central nervous system function.

Populations with high dietary sodium intake have long been shown to have an increased incidence of hypertension. Low dietary potassium, calcium, and magnesium intakes also are risk factors because without their intake, sodium is retained. The natriuretic hormones modulate renal sodium (Na+) excretion and require adequate potassium, calcium, and magnesium to function properly. The natriuretic hormones include atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), C-type natriuretic peptide (CNP), and urodilatin. Dysfunction of these hormones, along with alterations in the RAA system and the SNS, causes an increase in vascular tone and a shift in the pressure-natriuresis relationship. When there is inadequate natriuretic function, serum levels of the natriuretic peptides are increased. In hypertension, increased ANP and BNP levels are linked to an increased risk for ventricular hypertrophy, atherosclerosis, and heart failure. Salt retention
leads to water retention and increased blood volume, which contributes to an increase in blood pressure. Subtle renal injury results, with renal vasoconstriction and tissue ischemia. Tissue ischemia causes inflammation of the kidney and contributes to dysfunction of the glomeruli and tubules, which promotes additional sodium retention. Salt restriction combined with adequate intake of dietary potassium, magnesium, and calcium has been linked to improved natriuretic peptide function.\textsuperscript{26}

Inflammation plays a role in the pathogenesis of hypertension. One proposed mechanism for initiating hypertension-related inflammation is \textit{peripheral vascular resistance–mediated ischemic cellular injury} and the release of \textbf{damage-associated molecular patterns (DAMPs)} that activate Toll-like receptors on immune cells\textsuperscript{27} (see \textit{Chapter 5}). Activation of innate and adaptive immunity results in damage to endothelial cells.\textsuperscript{26} Endothelial injury and tissue ischemia result in the release of vasoactive inflammatory cytokines. Although many of these cytokines (e.g., histamine, prostaglandins) have vasodilatory actions in acute inflammatory injury, chronic inflammation leads to decreased production of vasodilators (such as nitric oxide), vascular remodeling, and smooth muscle contraction. Inflammation also contributes to insulin resistance, decreased natriuresis, and autonomic dysfunction (increased SNS activity).\textsuperscript{29-31}

Obesity is recognized as an important risk factor for hypertension in both adults and children and contributes to many of the neurohumoral, metabolic, renal, and cardiovascular processes that cause hypertension.\textsuperscript{32} Obesity causes changes in the adipokines (i.e., leptin and adiponectin) and also is associated with increased activity of the SNS and the RAAS.\textsuperscript{33} Obesity is linked to inflammation, endothelial dysfunction, and insulin resistance and an increased risk for cardiovascular complications from hypertension\textsuperscript{32} (see \textit{Health Alert: Obesity and Hypertension}).

\textbf{Health Alert}

\textbf{Obesity and Hypertension}

Obesity is a well-known risk factor for hypertension. Obesity and increased caloric intake contribute to adipocyte dysfunction and ectopic fat deposition throughout the cardiovascular system. These dysfunctional adipocytes release inflammatory mediators that contribute to vascular remodeling and endothelial dysfunction with decreased endogenous vasodilator release. Adipocytes secrete adipokines, including leptin and adiponectin. The primary function of leptin is to interact with the hypothalamus to control body weight and fat deposition through appetite
inhibition and increased metabolic rate. However, chronically high levels of leptin associated with obesity result in resistance to these weight-reducing functions and have been found to increase sympathetic nervous system activity, decrease renal sodium excretion, promote inflammation, and stimulate myocyte hypertrophy. Adiponectin is a protein that is produced by adipose tissue but is reduced in obesity. Decreased adiponectin is associated with insulin resistance, decreased endothelial-derived nitric oxide (vasodilator) production, and activation of the sympathetic nervous and renin-angiotensin-aldosterone systems. Other less studied adipokines that are altered in obesity-related cardiovascular diseases include resistin, omentin, visfatin, and perivascular adipose tissue–derived relaxing factor. Taken together, these obesity-related changes result in vasoconstriction, salt and water retention, and renal dysfunction that may contribute to the development of hypertension. Obesity-related microvascular dysfunction is linked to the pathogenesis both of hypertension and of hypertension-related target organ damage. Obesity also is linked with insulin resistance, which contributes to vascular dysfunction and the development of sustained hypertension. Weight loss is an essential treatment for obesity-related hypertension and has beneficial effects on these pathogenic pathways. In severe obesity, bariatric surgery has been shown to cause long-standing remission of hypertension in up to 93% of individuals. Further studies aimed at achieving a better understanding of these mechanisms may lead to new treatments for obesity-related hypertension.

Finally, insulin resistance is common in hypertension, even in individuals without clinical diabetes. Insulin resistance is associated with decreased endothelial release of nitric oxide and other vasodilators. It also affects renal function and causes renal salt and water retention. Insulin resistance is associated with overactivity of the sympathetic nervous system and the renin-angiotensin-aldosterone system. It is interesting to note that in many individuals with diabetes treated with drugs that increase insulin sensitivity, blood pressure often declines, even in the absence of antihypertensive drugs. The interactions between obesity, hypertension, insulin resistance, and lipid disorders in the metabolic syndrome result in a high risk of cardiovascular disease.

It is likely that primary hypertension is an interaction between many of these factors leading to sustained increases in blood volume and peripheral resistance. The pathophysiology of primary hypertension is summarized in Figure 24-4.
Secondary Hypertension

Secondary hypertension is caused by an underlying disease process or medication that raises peripheral vascular resistance or cardiac output. Examples include renal vascular or parenchymal disease, adrenocortical tumors, adrenomedullary tumors (pheochromocytoma), and drugs (oral contraceptives, corticosteroids, antihistamines). If the cause is identified and removed before permanent structural
changes occur, blood pressure returns to normal.

**Complicated Hypertension**

As hypertension becomes more severe and chronic, tissue damage can occur in the blood vessels and tissues leading to target organ damage in the heart, kidney, brain, and eyes. Cardiovascular complications of sustained hypertension include left ventricular hypertrophy, angina pectoris, heart failure, coronary artery disease, myocardial infarction, and sudden death. Myocardial hypertrophy in response to hypertension is mediated by several neurohormonal substances, including catecholamines from the SNS and angiotensin II. Hypertrophy is characterized by changes in the myocyte proteins, apoptosis of myocytes, and deposition of collagen in heart muscle, which causes it to become thickened, scarred, and less able to relax during diastole, leading to heart failure with preserved ejection fraction. In addition, the increased size of the heart muscle increases demand for oxygen delivery over time, the contractility of the heart is impaired, and the individual is at increased risk for myocardial infarction and heart failure with reduced ejection fraction. Vascular complications include the formation, dissection, and rupture of aneurysms (outpouchings in vessel walls) and atherosclerosis leading to vessel occlusion.

Renal complications of complicated hypertension include parenchymal damage, nephrosclerosis, renal arteriosclerosis, and renal insufficiency or failure. Microalbuminuria (small amounts of protein in the urine) occurs in 10% to 25% of individuals with primary hypertension and is now recognized as an early sign of impending renal dysfunction and significantly increased risk for cardiovascular events, especially in those who also have diabetes. Complications specific to the retina include retinal vascular sclerosis, exudation, and hemorrhage. Cerebrovascular complications include transient ischemia, stroke, cerebral thrombosis, aneurysm, hemorrhage, and dementia. The pathologic effects of complicated hypertension are summarized in Table 24-2.
### Hypertensive crisis (or malignant hypertension)

Hypertensive crisis (or malignant hypertension) is rapidly progressive hypertension in which diastolic pressure is usually greater than 140 mm Hg. It can occur in those with primary hypertension, but the reason why some people develop this complication and others do not is unknown. Other causes include complications of pregnancy, cocaine or amphetamine use, reaction to certain medications, adrenal tumors, and alcohol withdrawal. High arterial pressure renders the cerebral arterioles incapable of regulating blood flow to the cerebral capillary beds. High hydrostatic pressures in the capillaries cause vascular fluid to exude into the interstitial space. If blood pressure is not reduced, cerebral edema and cerebral dysfunction (encephalopathy) increase until death occurs. Organ damage resulting from malignant hypertension is life-threatening. Besides encephalopathy, hypertensive crisis can cause papilledema, cardiac failure, uremia, retinopathy, and cerebrovascular accident and is considered a medical emergency.\(^{38}\)

### Clinical manifestations

The early stages of hypertension have no clinical manifestations other than elevated blood pressure; for this reason, hypertension is called a silent disease. Some hypertensive individuals never have signs, symptoms, or complications, whereas others become very ill, and hypertension can be a cause of death. Still other individuals have anatomic and physiologic damage caused by past hypertensive disease, despite current blood pressure measurements being within normal ranges. If elevated blood pressure is not detected and treated, it becomes established and may begin to accelerate its effects on tissues when the individual is 30 to 50 years of age. This sets the stage for the complications of hypertension that begin to appear during the fourth, fifth, and sixth decades of life.

Most clinical manifestations of hypertensive disease are caused by complications that damage organs and tissues outside the vascular system. Besides elevated blood pressure...
pressure, the signs and symptoms therefore tend to be specific for the organs or tissues affected. Evidence of heart disease, renal insufficiency, central nervous system dysfunction, impaired vision, impaired mobility, vascular occlusion, or edema can all be caused by sustained hypertension.

**Evaluation and treatment**

A single elevated blood pressure reading does not mean that a person has hypertension. Diagnosis requires the measurement of blood pressure on at least two separate occasions, averaging two readings at least 2 minutes apart, with the following conditions: the person is seated, the arm is supported at heart level, the person must be at rest for at least 5 minutes, and the person should not have smoked or ingested any caffeine in the previous 30 minutes. Diagnostic tests for further evaluation of hypertension include 24-hour blood pressure monitoring in selected individuals, complete blood count, urinalysis, biochemical blood profile (measures levels of plasma glucose, sodium, potassium, calcium, magnesium, creatinine, cholesterol, and triglycerides), and an electrocardiogram (ECG). Individuals who have elevated blood pressure are assumed to have primary hypertension unless their history, physical examination, or initial diagnostic screening indicates secondary hypertension. Once the diagnosis is made, a careful evaluation for other cardiovascular risk factors and for end-organ damage should be done.

Treatment of primary hypertension depends on its severity. JNC 8 recommendations begin with lifestyle modification as important for preventing and treating hypertension. Important lifestyle modifications include following an exercise program, making dietary modifications, stopping smoking, and losing weight. Reducing salt intake is an important dietary modification and has been shown to significantly reduce blood pressure in both hypertensive and normotensive individuals. Pharmacologic treatment of hypertension reduces the risk of end-organ damage and prevents major diseases, such as myocardial infarction and stroke. Recommendations in the JNC 8 report suggest that treatment should begin with thiazide diuretics alone or in combination with angiotensin II (Ang II) blockers (ACE inhibitors or angiotensin receptor blockers) or calcium channel blockers. Beta-blockers were found to have a higher rate of stroke than Ang II blockers and are no longer recommended as first-line medications. Individuals with heart failure, chronic kidney disease, or a history of myocardial infarction or stroke should begin antihypertensive treatment with an ACE inhibitor or ARB. Some individuals require two or more drugs for blood pressure control. JNC 8 raised the treatment goal for adults 18 to 59 years of age without comorbidities or in those >60 years of age with diabetes or chronic kidney disease to <140/90 mm Hg, and for adults >60 years of age who do not have diabetes or
chronic kidney disease to <150/90 mm Hg, which resulted in an overall decrease in the number of individuals requiring treatment compared with previous recommendations. In individuals with refractive hypertension, catheter-based renal denervation can result in significant reductions in blood pressure, but many questions remain pertaining to long-term safety, mechanisms of action, and selection of appropriate candidates for the procedure. Careful follow-up to support continued adherence, determine the response, and monitor for potential side effects of these medications is important.

**Orthostatic (Postural) Hypotension**

The term orthostatic (postural) hypotension (OH) refers to a decrease in systolic blood pressure of at least 20 mm Hg or a decrease in diastolic blood pressure of at least 10 mm Hg within 3 minutes of moving to a standing position. Idiopathic, or primary, orthostatic hypotension implies no known initial cause. This kind of OH is often called “neurogenic” and is usually the result of primary neurologic disorders or secondary to conditions that affect autonomic function. It affects men more often than women and usually occurs between the ages of 40 and 70 years. Up to 18% of older adults may be affected by primary orthostatic hypotension, and it is a significant risk factor for falls and associated injury, with increased mortality.

Recently, OH has been implicated in contributing to depression and dementia. Normally when an individual stands, the gravitational changes on the circulation are compensated by such mechanisms as baroreceptor-mediated reflex arteriolar and venous constriction and increased heart rate. Other compensatory mechanisms include mechanical factors, such as the closure of valves in the venous system, contraction of the leg muscles, and a decrease in intrathoracic pressure. The normally increased sympathetic activity during upright posture is mediated through a stretch receptor (baroreceptor) reflex that responds to shifts in volume caused by postural changes. This reflex promptly increases heart rate and constricts the systemic arterioles. Thus, arterial blood pressure is maintained. These mechanisms are dysfunctional or inadequate in individuals with orthostatic hypotension; consequently, upon standing, blood pools and normal arterial pressure cannot be maintained.

Orthostatic hypotension may be acute or chronic. Acute orthostatic hypotension is caused when the normal regulatory mechanisms are sluggish as a result of (1) altered body chemistry, (2) drug action (e.g., antihypertensives, antidepressants), (3) prolonged immobility caused by illness, (4) starvation, (5) physical exhaustion, (6) any condition that produces volume depletion (e.g., dehydration, diuresis, potassium or sodium depletion), or (7) any condition that results in venous pooling (e.g.,
pregnancy, extensive varicosities of the lower extremities). Elderly persons are particularly susceptible to this type of orthostatic hypotension.

**Chronic orthostatic hypotension** may be (1) secondary to a specific disease or (2) idiopathic or primary. The diseases that cause secondary orthostatic hypotension are endocrine disorders (e.g., adrenal insufficiency, diabetes), metabolic disorders (e.g., porphyria), or diseases of the central or peripheral nervous systems (e.g., Parkinson disease, multiple system atrophy, intracranial tumors, cerebral infarcts, Wernicke encephalopathy, peripheral neuropathies). Cardiovascular autonomic neuropathy is a common cause of orthostatic hypotension in persons with diabetes and is a serious and often overlooked complication. In addition to cardiovascular symptoms, associated impotence and bowel and bladder dysfunction are common.

Orthostatic hypotension is often accompanied by dizziness, blurring or loss of vision, and syncope or fainting caused by insufficient vasomotor compensation and reduction of blood flow through the brain. Although no curative treatment is available for idiopathic orthostatic hypotension, often it can be managed adequately with a combination of nondrug and drug therapies—increasing fluid and salt intake, wearing thigh-high stockings, and taking mineralocorticoids and vasoconstrictors.44,46

---

**Aneurysm**

An **aneurysm** is a localized dilation or outpouching of a vessel wall or cardiac chamber (Figure 24-5). The law of Laplace (discussed in detail in Chapter 23) can provide an understanding of the hemodynamics of an aneurysm. **True aneurysms** involve all three layers of the arterial wall and are best described as a weakening of the vessel wall (Figure 24-6, A). Most are fusiform and circumferential, whereas **saccular aneurysms** are basically spherical in shape. **False aneurysm** is an extravascular hematoma that communicates with the intravascular space. A common cause of this type of lesion is a leak between a vascular graft and a natural artery.
Aneurysm. A three-dimensional CT scan shows the aneurysm (A) involves the ascending thoracic aorta. D, Descending aorta; LV, left ventricle.
Aneurysms most commonly occur in the thoracic or abdominal aorta. The aorta is particularly susceptible to aneurysm formation because of constant stress on the vessel wall and the absence of penetrating vasa vasorum in the media layer. Genetic and environmental risk factors (such as smoking and diet) are implicated in the pathogenesis of aortic aneurysms. Atherosclerosis is the most common cause of arterial aneurysms because plaque formation erodes the vessel wall and contributes to inflammation and release of proteinases that can further weaken the vessel. Hypertension also contributes to aneurysm formation by increasing wall stress. Collagen-vascular disorders (e.g., Marfan syndrome), syphilis, and other infections that affect arterial walls also can cause aneurysms.

Cardiac aneurysms most commonly form after myocardial infarction when intraventricular tension stretches the noncontracting infarcted muscle. The stretching produces infarct expansion, a weak and thin layer of necrotic muscle, and fibrous tissue that bulges with each systole.

Clinical manifestations depend on where the aneurysm is located. Aortic aneurysms often are asymptomatic until they rupture, and then cause severe pain and hypotension. Thoracic aortic aneurysms can cause dysphagia (difficulty swallowing) and dyspnea (breathlessness). An aneurysm that impairs flow to an extremity causes symptoms of ischemia. Cerebral aneurysms, which often occur in the circle of Willis, are associated with signs and symptoms of increased
intracranial pressure. Signs and symptoms of stroke occur when cerebral aneurysms leak. (Cerebral aneurysms are described in Chapter 16.) Aneurysms in the heart present with dysrhythmias, heart failure, and embolism of clots to the brain or other vital organs.

Aortic aneurysms can be complicated by the acute aortic syndromes, which include aortic dissection, hemorrhage into the vessel wall, or vessel rupture. Dissection of the layers of the arterial wall occurs when there is a tear in the intima and blood enters the wall of the artery (see Figure 24-6, B). Dissections can involve any part of the aorta (ascending, arch, or descending) and can disrupt flow through arterial branches, thus creating a surgical emergency.

The diagnosis of an aneurysm is usually confirmed by ultrasonography, computed tomography, magnetic resonance imaging, or angiography. Medical treatment is indicated for slow-growing aortic aneurysms, particularly in early stages, and includes cessation of smoking, reduction of blood pressure and blood volume, and implementation of β-adrenergic blockade. For those aneurysms that are dilating rapidly or have become large, surgical treatment is indicated and usually includes replacement with a prosthetic graft. Endovascular surgical techniques are commonly used for aneurysm repair and management of acute aortic rupture.  

**Thrombus Formation**

As in venous thrombosis, arterial thrombi tend to develop when intravascular conditions promote activation of coagulation, or when there is stasis of blood flow. These conditions include those in which there is intimal irritation or roughening (such as in surgical procedures), inflammation, traumatic injury, infection, low blood pressures, or obstructions that cause blood stasis and pooling within the vessels. (Mechanisms of coagulation are described in Chapter 20.) Inflammation of the endothelium leads to activation of the clotting cascade, causing platelets to adhere readily. An anatomic change in an artery (such as an aneurysm) can contribute to thrombus formation, particularly if the change results in a pooling of arterial blood. Thrombi also form on heart valves altered by calcification or bacterial vegetation. Valvular thrombi are most commonly associated with inflammation of the endocardium (endocarditis) and rheumatic heart disease. Widespread arterial thrombus formation can occur in shock, particularly shock resulting from septicemia. In septic shock, systemic inflammation activates the intrinsic and extrinsic pathways of coagulation, resulting in microvascular thrombosis throughout the systemic arterial circulation.

Arterial thrombi pose two potential threats to the circulation. First, the thrombus may grow large enough to occlude the artery, causing ischemia in tissue supplied by
the artery. Second, the thrombus may dislodge, becoming a thromboembolus that travels through the vascular system until it occludes flow into a distal systemic vascular bed.

Diagnosis of arterial thrombi is usually accomplished through the use of Doppler ultrasonography and angiography. Pharmacologic treatment involves the administration of heparin, warfarin derivatives, thrombin inhibitors, or thrombolytics. A balloon-tipped catheter also can be used to remove or compress an arterial thrombus. Various combinations of drug and catheter therapies are sometimes used concurrently.

**Embolism**

**Embolism** is the obstruction of a vessel by an *embolus*—a bolus of matter circulating in the bloodstream. The embolus may consist of a dislodged thrombus; an air bubble; an aggregate of amniotic fluid; an aggregate of fat, bacteria, or cancer cells; or a foreign substance. An embolus travels in the bloodstream until it reaches a vessel through which it cannot pass. No matter how tiny it is, an embolus will eventually lodge in a systemic or pulmonary vessel determined by its source. Pulmonary emboli originate on the venous side (mostly from the deep veins of the legs) of the systemic circulation or in the right heart; arterial emboli most commonly originate in the left heart and are associated with thrombi after myocardial infarction, valvular disease, left heart failure, endocarditis, and dysrhythmias.

Embolism causes ischemia or infarction in tissues distal to the obstruction, producing organ dysfunction and pain. Infarction and subsequent necrosis of a central organ are life-threatening. For example, occlusion of a coronary artery will cause a myocardial infarction, whereas occlusion of a cerebral artery causes a stroke (see Chapter 16). The types of emboli are summarized in Table 24-3.

**Peripheral Vascular Disease**

**Thromboangiitis Obliterans (Buerger Disease)**

*Thromboangiitis obliterans (Buerger disease)* is an inflammatory disease of the peripheral arteries. It is strongly associated with smoking. Thromboangiitis obliterans is an autoimmune condition characterized by the formation of thrombi filled with inflammatory and immune cells. Inflammatory cytokines and toxic oxygen free radicals contribute to accompanying vasospasm. Over time, these thrombi become organized and fibrotic and result in permanent occlusion and obliteration of portions of small- and medium-sized arteries in the feet and sometimes in the hands. Although collateral vessels develop in Buerger disease, they are inadequate to supply the extremities with blood. These collateral vessels have a characteristic corkscrew shape, thought to be a result of dilated vasa vasorum in the affected artery.

The chief symptom of thromboangiitis obliterans is pain and tenderness of the affected part, usually affecting more than one extremity. Clinical manifestations are caused by sluggish blood flow and include rubor (redness of the skin), which is caused by dilated capillaries under the skin, and cyanosis, which is caused by tissue ischemia. Chronic ischemia causes the skin to thin and become shiny and the nails to become thickened and malformed. In advanced disease, profound ischemia of the extremities resulting from vessel obliteration can cause gangrene necessitating amputation. Buerger disease has also been associated with cerebrovascular disease (stroke), mesenteric disease, and rheumatic symptoms (joint pain).

Diagnosis of thromboangiitis obliterans is made by identification of the
following common features—age <45 years, smoking history, evidence of peripheral ischemia—and by exclusion of other causes of arterial insufficiency. The most important part of treatment is cessation of cigarette smoking. If the person continues to smoke, the likelihood of recurrence of the disease and gangrene requiring amputation is high. Other measures are aimed at improving circulation to the foot or hand. Vasodilators are prescribed to alleviate vasospasm, and the individual receives instruction in exercises that use gravity to improve blood flow.

Raynaud Phenomenon

Raynaud phenomenon is characterized by attacks of vasospasm in the small arteries and arterioles of the fingers and, less commonly, the toes. Primary Raynaud phenomenon is a common primary vasospastic disorder of unknown origin. Secondary Raynaud phenomenon is associated with systemic diseases, particularly collagen vascular disease (scleroderma), vasculitis, malignancy, pulmonary hypertension, chemotherapy, cocaine use, hypothyroidism, thoracic outlet syndrome, trauma, serum sickness, or long-term exposure to environmental conditions such as cold temperatures or vibrating machinery in the workplace. Blood vessels in affected individuals demonstrate endothelial dysfunction with an imbalance in endothelium-derived vasodilators (e.g., nitric oxide) and vasoconstrictors (e.g., endothelin-1). Platelet activation also may play a role, and autoantibodies have been identified in some individuals. It tends to affect young women and is characterized by vasospastic attacks triggered by brief exposure to cold, vibration, or emotional stress. Genetic predisposition may play a role in its development.

The clinical manifestations of the vasospastic attacks of either disorder are changes in skin color and sensation caused by ischemia. Vasospasm occurs with varying frequency and severity and causes pallor, numbness, and the sensation of coldness in the digits. Attacks tend to be bilateral, and manifestations usually begin at the tips of the digits and progress to the proximal phalanges. Sluggish blood flow resulting from ischemia may cause the skin to appear cyanotic. Rubor, throbbing pain, and paresthesias follow as blood flow returns. Skin color returns to normal after the attack, but frequent, prolonged attacks interfere with cellular metabolism, causing the skin of the fingertips to thicken and the nails to become brittle. In severe, chronic Raynaud phenomenon, ischemia can eventually cause ulceration and gangrene.

Once evident, the clinical manifestations confirm the diagnosis of Raynaud phenomenon; however, nailfold capillaroscopy is a more sensitive method of diagnosis and can improve management and follow-up of individuals with
associated collagen-vascular disorders. Treatment for Raynaud phenomenon consists of removing the stimulus or treating the primary disease process. Treatment of Raynaud phenomenon begins with avoidance of stimuli that trigger attacks (e.g., cold temperatures, emotional stress) and cessation of cigarette smoking to eliminate the vasoconstricting effects of nicotine. If attacks of vasospasm become frequent or prolonged, vasodilators, such as calcium channel blockers, nitric oxide agonists, alpha-blockers, prostaglandin analogs, or endothelin antagonists, are administered. Sympathectomy may be indicated in severe cases, but may not be effective. If ischemia leads to ulceration and gangrene, amputation may be necessary.

Quick Check 24-4

1. What is Buerger disease, and why does it occur?

2. Compare the physical manifestations of Buerger disease and Raynaud phenomenon.

Atherosclerosis

Arteriosclerosis is a condition characterized by thickening and hardening of the vessel wall. Atherosclerosis is a form of arteriosclerosis that is caused by the accumulation of lipid-laden macrophages within the arterial wall, which leads to the formation of a lesion called a plaque. Atherosclerosis is not a single disease entity but rather a pathologic process that can affect vascular systems throughout the body, resulting in ischemic syndromes that can vary widely in their severity and clinical manifestations. It is the leading cause of coronary artery and cerebrovascular disease. (Atherosclerosis of the coronary arteries is described later in this chapter, and atherosclerosis of the cerebral arteries is described in Chapter 16.)

Pathophysiology

Atherosclerosis begins with injury to the endothelial cells that line artery walls. Pathologically, the lesions progress from endothelial injury and dysfunction to fatty streak to fibrotic plaque to complicated lesion (Figure 24-7). Possible causes of endothelial injury include the common risk factors for atherosclerosis, such as smoking, hypertension, diabetes, increased levels of low-density lipoprotein (LDL), decreased levels of high-density lipoprotein (HDL), and autoimmunity. Other “nontraditional” risk factors include increased serum markers for inflammation and
thrombosis (such as high-sensitivity C-reactive protein [hs-CRP], troponin I, adipokines, infection, and air pollution). These risk factors are discussed in more detail in the following section on coronary artery disease (see p. 610).
FIGURE 24-7 Progression of Atherosclerosis. A, Damaged endothelium. B, Diagram of fatty streak and lipid core formation (see Figure 24-8 for a diagram of oxidized low-density lipoprotein [LDL]). C, Diagram of fibrous plaque. Raised plaques are visible; some are yellow; others are white. D, Diagram of complicated lesion; thrombus is red; collagen is blue. Plaque is
Injured endothelial cells become inflamed. Inflammation plays a fundamental role in mediating the steps in the initiation and progression of atherogenesis. Inflamed endothelial cells cannot make normal amounts of antithrombic and vasodilating cytokines. Evidence is accumulating that microRNAs (short pieces of RNA that regulate posttranscriptional gene expression) are activated by many of the risk factors for atherosclerosis and impact endothelial cell responses to injury.

The next step in atherogenesis occurs when inflamed endothelial cells express adhesion molecules that bind macrophages and other inflammatory and immune cells (Figure 24-8). Macrophages are activated by binding to damage-associated molecular patterns (DAMPs) released from injured cells, and release numerous inflammatory cytokines (e.g., tumor necrosis factor-alpha [TNF-α], interferons, interleukins, and C-reactive protein) and enzymes that further injure the vessel wall. Toxic oxygen free radicals generated by the inflammatory process cause oxidation (i.e., addition of oxygen) of LDL that has accumulated in the vessel intima. Hyperlipidemia, diabetes, smoking, and hypertension contribute to LDL oxidation and its accumulation in the vessel wall. Oxidized LDL causes additional adhesion molecule expression with the recruitment of monocytes that differentiate into macrophages. These macrophages penetrate into the intima, where they engulf oxidized LDL. These lipid-laden macrophages are now called foam cells, and when they accumulate in significant amounts, they form a lesion called a fatty streak (Figures 24-8 and 24-9). These lesions can be found in the walls of arteries of most people, even young children. Once formed, fatty streaks produce more toxic oxygen free radicals, recruit T cells leading to autoimmunity, and secrete additional inflammatory mediators resulting in progressive damage to the vessel wall.
Low-Density Lipoprotein Oxidation. (1) Low-density lipoprotein (LDL) enters the arterial intima through an intact endothelium. In hypercholesterolemia, the influx of LDL exceeds the eliminating capacity and an extracellular pool of LDL is formed. This is enhanced by association of LDL with the extracellular matrix. (2) Intimal LDL is oxidized through the action of oxygen free radicals formed by enzymatic or nonenzymatic reactions. (3) This generates proinflammatory lipids that induce endothelial expression of the adhesion molecule; vascular cell adhesion molecule-1 activates complement and stimulates chemokine secretion. All of these factors cause adhesion and entry of mononuclear leukocytes, particularly monocytes and T lymphocytes. (4) Monocytes differentiate into macrophages. Macrophages up-regulate and internalize oxidized LDL and transform into foam cells. Macrophage update of oxidized LDL also leads to presentation of its fragments to antigen-specific T cells. (5) This induces an autoimmune reaction that leads to production of proinflammatory cytokines. Such cytokines include interferon-gamma, tumor necrosis factor-alpha, and interleukin-1, which act on endothelial cells to stimulate expression of adhesion molecules and procoagulant activity; on macrophages to activate proteases, endocytosis, nitric oxide (NO), and cytokines; and on smooth muscle cells (SMCs) to induce NO production and inhibit growth, collagen, and actin expression. (Modified from Crawford MH et al: Cardiology, ed 3, London, 2010, Mosby)
Macrophages also release growth factors that stimulate smooth muscle cell proliferation. Smooth muscle cells in the region of endothelial injury proliferate, produce collagen, and migrate over the fatty streak, forming a fibrous plaque (see Figure 24-9). The fibrous plaque may calcify, protrude into the vessel lumen, and obstruct blood flow to distal tissues (especially during exercise), which may cause symptoms (e.g., angina or intermittent claudication).

Many plaques, however, are “unstable,” meaning they are prone to rupture even before they affect blood flow significantly and are clinically silent until they rupture. Plaque rupture occurs because of innate and adaptive immune responses to tissue injury including activation of proteinases (matrix metalloproteinases and cathepsins) and apoptosis of cells within the plaque, and can be accelerated by bleeding within the lesion (plaque hemorrhage). Plaques that have ruptured are called complicated plaques. Once rupture occurs, exposure of underlying tissue results in platelet adhesion, initiation of the clotting cascade, and rapid thrombus formation. The thrombus may suddenly occlude the affected vessel, resulting in ischemia and infarction. Aspirin or other antithrombotic agents are used to prevent this complication of atherosclerotic disease.

Clinical manifestations
Atherosclerosis presents with symptoms and signs that result from inadequate perfusion of tissues because of obstruction of the vessels that supply them. Partial vessel obstruction may lead to transient ischemic events, often associated with
exercise or stress. As the lesion becomes complicated, increasing obstruction with superimposed thrombosis may result in tissue infarction. Obstruction of peripheral arteries can cause significant pain and disability. Coronary artery disease (CAD) caused by atherosclerosis is the major cause of myocardial ischemia and is one of the most important health issues in the United States. Atherosclerotic obstruction of the vessels supplying the brain is the major cause of stroke. Similarly, any part of the body may become ischemic when its blood supply is compromised by atherosclerotic lesions. Often, more than one vessel will become involved with this disease process such that an individual may present with symptoms from several ischemic tissues at the same time, and disease in one area may indicate that the individual is at risk for ischemic complications elsewhere.

**Evaluation and treatment**

In evaluating individuals for the presence of atherosclerosis, obtaining a complete health history (including risk factors and symptoms of ischemia) is essential. Physical examination may reveal arterial bruits and evidence of decreased blood flow to tissues. Laboratory data that include measurement of levels of lipids, blood glucose, and hs-CRP are also indicated. Judicious use of x-ray films, electrocardiography, ultrasonography, nuclear scanning, CT, MRI, and angiography may be necessary to identify affected vessels, particularly coronary vessels. New modalities aimed at identifying vulnerable plaques before the rupture are being evaluated.

Current management of atherosclerosis is focused on detection and treatment of preclinical lesions with drugs aimed at stabilizing and reversing plaques before they rupture. Once a lesion obstructs blood flow, the primary goal in the management of atherosclerosis is to restore adequate blood flow to the affected tissues. If an individual has presented with acute ischemia (e.g., myocardial infarction, stroke), interventions are specific to the diseased area (discussed further under those topics). In situations in which the disease process does not require immediate intervention, management focuses on reduction of risk factors and prevention of plaque progression. This includes implementation of an exercise program, cessation of smoking, and control of hypertension and diabetes where appropriate while reducing LDL cholesterol level by diet or medications, or both. Management of atherosclerotic risk factors is discussed further starting on p. 614.

**Peripheral Artery Disease**

**Peripheral artery disease (PAD)** refers to atherosclerotic disease of arteries that perfuse the limbs, especially the lower extremities. PAD affects an estimated 8.5
million Americans aged >40 years. The risk factors for PAD are the same as those previously described for atherosclerosis, but it is especially prevalent in elderly individuals with diabetes and has a very strong link with smoking.

Lower extremity ischemia resulting from arterial obstruction in PAD can be gradual or acute. In most individuals, gradually increasing obstruction to arterial blood flow to the legs caused by atherosclerosis in the iliofemoral vessels can result in pain with ambulation called intermittent claudication. If a thrombus forms over the atherosclerotic lesion, complete obstruction of blood flow can occur acutely, causing severe pain, loss of pulses, and skin color changes in the affected extremity.

Although individuals with PAD have an increased mortality, more than two thirds of adults with PAD are asymptomatic even in severe cases. Therefore evaluation for PAD requires a careful history and physical examination that focuses on finding evidence of atherosclerotic disease (e.g., bruits), determining a difference in blood pressure measured at the ankle versus the arm (ankle-brachial index), and measuring blood flow using noninvasive Doppler. Treatment includes risk factor reduction (smoking cessation and treatment of diabetes, hypertension, and dyslipidemia) and antiplatelet therapy. Symptomatic PAD should be managed with vasodilators in combination with antiplatelet or antithrombotic medications (aspirin, cilostazol, ticlopidine, or clopidogrel), and cholesterol-lowering medications. Aerobic exercise is a crucial part of therapy. If acute or refractory symptoms occur, emergent percutaneous or surgical revascularization may be indicated. Newer treatment modalities that are being explored include autologous stem cell therapies and angiogenesis.

Coronary Artery Disease, Myocardial Ischemia, and Acute Coronary Syndromes

Coronary artery disease, myocardial ischemia, and myocardial infarction form a pathophysiologic continuum that impairs the pumping ability of the heart by depriving the heart muscle of blood-borne oxygen and nutrients. The earliest lesions of the continuum are those of coronary artery disease (CAD), which is usually caused by atherosclerosis (see Figure 24-9). CAD can diminish the myocardial blood supply until deprivation impairs myocardial metabolism enough to cause ischemia, a local state in which the cells are temporarily deprived of blood supply. The cells remain alive but cannot function normally. Persistent ischemia or the complete occlusion of a coronary artery causes the acute coronary syndromes including infarction, or irreversible myocardial damage. Infarction constitutes the potentially fatal event known as a heart attack.
Development of Coronary Artery Disease

Coronary artery disease affects approximately 6.5% of people in the United States, with an estimated 122,000 deaths caused by myocardial infarction each year.10 Fortunately, the incidence and mortality statistics for CAD have been decreasing over the past 15 years because of more aggressive recognition, prevention, and treatment. Risk factors for CAD are the same as those for atherosclerosis and can be categorized as conventional (major) versus nontraditional (novel) and as modifiable versus nonmodifiable. The plethora of new information obtained about the conventional risk factors has markedly improved prevention and management of CAD. In addition, nontraditional risk factors have been identified that have provided insight into the pathogenesis of CAD and may lead to more effective interventions in the future.

Conventional or major risk factors for CAD that are nonmodifiable include (1) advanced age, (2) male gender or women after menopause, and (3) family history. Aging and menopause are associated with increased exposure to risk factors and poor endothelial healing. Family history may contribute to CAD through genetics and shared environmental exposures. Many gene polymorphisms have been associated with CAD and its risk factors. Modifiable major risks include (1) dyslipidemia, (2) hypertension, (3) cigarette smoking, (4) diabetes and insulin resistance, (5) obesity, (6) sedentary lifestyle, and (7) atherogenic diet. Fortunately, modification of these factors can dramatically reduce the risk for CAD.

Dyslipidemia.

The link between CAD and abnormal levels of lipoproteins is well documented. The term lipoprotein refers to lipids, phospholipids, cholesterol, and triglycerides bound to carrier proteins. Lipids (cholesterol in particular) are required by most cells for the manufacture and repair of plasma membranes. Cholesterol is also a necessary component for the manufacture of such essential substances as bile acids and steroid hormones. Although cholesterol can easily be obtained from dietary fat intake, most body cells also can manufacture cholesterol.

The cycle of lipid metabolism is complex. Dietary fat is packaged into particles known as chylomicrons in the small intestine. Chylomicrons are required for absorption of fat and function by transporting exogenous lipid from the intestine to the liver and peripheral cells. Chylomicrons are the least dense of the lipoproteins and primarily contain triglyceride. Some of the triglyceride may be removed and either stored by adipose tissue or used by muscle as an energy source. The chylomicron remnants, composed mainly of cholesterol, are taken up by the liver. A series of chemical reactions in the liver results in the production of several
lipoproteins that vary in density and function. These include very-low-density lipoproteins (VLDLs), primarily triglyceride and protein; low-density lipoproteins (LDLs), mostly cholesterol and protein; and high-density lipoproteins (HDLs), mainly phospholipids and protein.

**Dyslipidemia** (or **dyslipoproteinemia**) refers to abnormal concentrations of serum lipoproteins. It has been defined by the Third Report of the National Cholesterol Education Program\(^6\) ([Table 24-4](#)), although more recent guidelines place less emphasis on specific serum lipoprotein levels.\(^6\) It is estimated that nearly half of the U.S. population has some form of dyslipidemia, especially among white and Asian populations.\(^10\) These abnormalities are the result of a combination of genetic and dietary factors. Primary or familial dyslipoproteinemias result from genetic defects that cause abnormalities in lipid-metabolizing enzymes and abnormal cellular lipid receptors. Secondary causes of dyslipidemia include the existence of several common systemic disorders, such as diabetes, hypothyroidism, pancreatitis, and renal nephrosis, as well as the use of certain medications, such as some diuretics, glucocorticoids, interferons, and antiretrovirals.

*All units are mg/dl.

LDL is responsible for the delivery of cholesterol to the tissues, and an increased serum concentration of LDL is a strong indicator of coronary risk. Serum levels of LDL are normally controlled by hepatic receptors that bind LDL and limit liver synthesis of this lipoprotein. High dietary intake of cholesterol and saturated fats, in combination with a genetic predisposition to accumulations of LDL in the serum (e.g., dysfunction of the hepatic LDL receptor), result in high levels of LDL in the bloodstream. LDL migration into the vessel wall, oxidation, and phagocytosis by macrophages are key steps in the pathogenesis of atherosclerosis (see [Figure 24-8](#)). LDL also plays a role in endothelial injury, inflammation, and immune responses that have been identified as being important in atherogenesis.\(^56\) The term **LDL** actually describes several types of LDL molecules. Measurement of LDL subfractions allows for a better prediction of coronary risk. For example, LDL-C
measurements allow for the detection of the small, dense LDL particles that are the most atherogenic, and apolipoprotein B (structural protein found in both LDL and VLDL) levels are a very strong predictor of future coronary events. New guidelines from the American Heart Association and the American College of Cardiology focus on treating dyslipidemia in the context of other risk factors (see Health Alert: New Insights and Guidelines into the Management of Dyslipidemia for the Prevention of Coronary Artery Disease).

**Health Alert**

**New Insights and Guidelines into the Management of Dyslipidemia for the Prevention of Coronary Artery Disease**

Despite a wealth of evidence that lowering LDL levels decreases the risk for coronary events in individuals with known CAD (secondary prevention), primary prevention of cardiovascular disease through pharmacologic modulation of lipid levels remains controversial. Although many clinical trials and meta-analyses have shown a reduction in primary cardiovascular events with the use of the 3-hydroxy-3-methyl-glutaryl-CoA (HMG-CoA) reductase drugs (statins) in men, other studies have provided mixed results, especially in women. In addition, statin use is linked to several significant complications including muscle soreness, elevation in liver enzymes, and diabetes. There is concern that these complications are being underreported, especially in pharmaceutical company–sponsored research reports. In 2013 the Cochrane Database and the American Heart Association/American College of Cardiology Expert Blood Cholesterol Panel released two comprehensive analyses that documented the effectiveness of statins for primary prevention of coronary events. New guidelines help to weigh the benefits versus risks and guide the intensity of therapy by linking recommendations for statin use with the presence of other risk factors, such as diabetes and age. In contrast, efforts at reducing cardiovascular risk through pharmacologically increased high-density lipoprotein (HDL) levels have failed to demonstrate benefit. New information suggests that the functionality of HDL and its subparticles is more important to reducing risk than is the serum level, and studies are now underway to explore how HDL might be functionality optimized. It is clear from these studies that, despite decades of research, there is still much work needed to fully understand the proper role of medications in the prevention of cardiovascular disease. In the meantime, improved diet and exercise remain the foundation for reducing coronary risk.

Low levels of HDL cholesterol also are a strong indicator of coronary risk. HDL is responsible for “reverse cholesterol transport,” which returns excess cholesterol from the tissues to the liver for processing or elimination in the bile. HDL also participates in endothelial repair and decreases thrombosis. It can be fractionated into several particle densities (HDL-2 and HDL-3) that have different effects on vascular function. Exercise, weight loss, fish oil consumption, and moderate alcohol use result in modest increases in HDL level. Despite the wealth of evidence that HDL plays an important role in preventing atherosclerotic coronary disease, studies have suggested that raising overall levels of HDL is not adequate to prevent cardiovascular disease. Niacin and fibrates are drugs that can cause modest increases in HDL levels that are not correlated with an improvement in cardiovascular risk in individuals without documented coronary disease (primary prevention). Drugs that are aimed specifically at increasing HDL levels include recombinant apolipoprotein A-I (ApoA-I) mimetics, thiazolidinediones (used to treat diabetes), and cholesteryl ester transfer protein inhibitors, but they have not been shown to be effective in preventing heart disease. Recent studies suggest that it is not the serum levels of HDL that are key to determining CAD risk, but rather HDL functionality, which is harder to measure.66,67

Other lipoproteins associated with increased cardiovascular risk include elevated levels of serum VLDLs (triglycerides) and increased lipoprotein(a) levels. Triglycerides are associated with an increased risk for CAD, especially in combination with other risk factors such as diabetes. Lipoprotein(a) (Lp[a]) is a genetically determined molecular complex between LDL and a serum glycoprotein called apolipoprotein A and has been shown to be an important risk factor for atherosclerosis, especially in women.

**Hypertension.**

Hypertension is responsible for a twofold to threefold increased risk of atherosclerotic cardiovascular disease. It contributes to endothelial injury, a key step in atherogenesis (see p. 607). It also can cause myocardial hypertrophy, which increases myocardial demand for coronary flow. Overactivity of the SNS and RAAS commonly found in hypertension also contributes to the genesis of CAD.

**Cigarette smoking.**

Both direct and passive (environmental) smoking increase the risk of CAD.
Smoking has a direct effect on endothelial cells and the generation of oxygen free radicals that contribute to atherogenesis. Nicotine stimulates the release of catecholamines (epinephrine and norepinephrine), which increase heart rate and peripheral vascular constriction. As a result, blood pressure increases, as do cardiac workload and oxygen demand. Cigarette smoking is associated with an increase in LDL levels and a decrease in HDL levels. The risk of CAD increases with heavy smoking and decreases when smoking is stopped.

**Diabetes mellitus.**

Insulin resistance and diabetes mellitus are extremely important risk factors for CAD. Insulin resistance and diabetes have multiple effects on the cardiovascular system including damage to the endothelium, thickening of the vessel wall, increased inflammation, increased thrombosis, glycation of vascular proteins, and decreased production of endothelial-derived vasodilators, such as nitric oxide. Diabetes also is associated with dyslipidemia (see Chapter 19). Good diabetic control is linked to reduced risk for CAD.

**Obesity/sedentary lifestyle.**

It is estimated that 65% of the adult population in the United States is overweight or obese, and an estimated 47 million U.S. residents have a combination of obesity, dyslipidemia, hypertension, and insulin resistance, called the **metabolic syndrome**, which is associated with an even higher risk for CAD events. Abdominal obesity has the strongest link with increased CAD risk and is related to inflammation, insulin resistance, decreased HDL level, increased blood pressure, and fewer changes in hormones called adipokines (leptin and adiponectin). A sedentary lifestyle not only increases the risk of obesity but also has an independent effect on increasing CAD risk. Physical activity and weight loss offer substantial reductions in risk factors for CAD. There is emerging evidence that bariatric surgery procedures, such as gastric bypass, can provide sustained improvement in risk factors for cardiovascular disease, such as hypertension, dyslipidemia, and diabetes.

**Atherogenic diet.**

Diet plays a complex role in atherogenic risk. Diets high in salt, fats, trans-fats, and carbohydrates have all been implicated. There are many recommendations regarding diet modification to reduce coronary risk; one of the most effective is called the Mediterranean Diet (see Health Alert: Mediterranean Diet).
**Health Alert**

**Mediterranean Diet**

A number of different kinds of studies—observational cohort, secondary prevention trial, and recent randomized intervention trials—show the Mediterranean diet patterns are associated with a reduced cardiovascular disease risk and cardiovascular events. The traditional Mediterranean diet is characterized by a high intake of olive oil, fruits, nuts, vegetables, and cereals; moderate intake of fish and poultry; low intake of dairy products, red meat, processed meats, and sweets; and moderate intake of wine consumed with meals. A large prospective cohort study showed adherence to the Mediterranean diet was associated with a decrease in incidence of fatal and nonfatal coronary heart disease (CHD) in initially healthy middle-aged individuals. A recent large randomized trial (the Prevención con Dieta Mediterránea Study [PREDIMED]) among individuals at high cardiovascular risk showed that a Mediterranean diet supplemented with extra-virgin olive oil or nuts reduced the incidence of major cardiovascular events, especially stroke. The beneficial effects of the Mediterranean diet are hypothesized to include modulation of all of the following—inflammation and oxidative stress, glucose metabolism, lipid profile, and lipoprotein particle characteristics—and also favorable changes to the vascular endothelium. Additionally, effects may include a favorable interaction between diet and gene polymorphisms related to cardiovascular risk factors and events.

**Nontraditional risk factors.**

Nontraditional, or novel, risk factors for CAD include increased serum markers for inflammation and thrombosis (troponin I, adipokines, infection, and air pollution). The amount of risk conferred by these relatively newly identified factors is still being explored.

**Markers of inflammation and thrombosis.**

Of the numerous markers of inflammation that have been linked to an increase in CAD risk (hs-CRP, fibrinogen, protein C, plasminogen activator inhibitor), the relationship between serum levels of hs-CRP and CAD has been explored in the
greatest depth. **High-sensitivity C-reactive protein (hs-CRP)** is a protein mostly synthesized in the liver and is used as an indirect measure of atherosclerotic plaque–related inflammation. An elevated serum level of hs-CRP is strongly correlated with an increased risk for coronary events, but is a nonspecific measure of inflammation and may indicate the presence of other inflammatory conditions. The primary use of hs-CRP is as an aid to decision-making about pharmacologic interventions for individuals with other risk factors for coronary disease. Other markers of inflammation associated with CAD include the erythrocyte sedimentation rate and concentrations of von Willebrand factor, interleukin-6, interleukin-18, tumor necrosis factor, fibrinogen, and CD 40 ligand. Interestingly, the long-term use of some anti-inflammatories, such as ibuprofen, has been linked to increased (rather than decreased) risk for CAD because of their potentiation of clotting in certain tissues.

**Troponin I.**

Troponin I (TnI) is a serum protein whose measurement is used as a sensitive and specific diagnostic test to help identify myocardial injury during acute coronary syndromes. Highly sensitive TnI assays are used in individuals without a history of CAD to assess risk for future CHD events, mortality, and heart failure.

**Adipokines.**

Adipokines are a group of hormones released from adipose cells. Obesity causes increased levels of leptin, which is implicated in hypertension and diabetes, and decreased levels of adiponectin, which is a hormone that functions to protect the vascular endothelium and is anti-inflammatory. Other adipokines also have been linked to inflammation in endothelial cells. Weight loss, exercise, and healthy diet improve adipokine levels.

**Infection.**

Infections with various microorganisms, including *Chlamydia pneumoniae*, *Helicobacter pylori*, and cytomegalovirus, have been linked to an increased risk for CAD, although cause and effect have not been proven. Periodontal disease also has been linked to an increased risk for CAD. One hypothesis is that systemic infection results in increased inflammation of vessels and, therefore, contributes to vascular disease. Unfortunately, the use of antibiotics for the prevention and treatment of CAD has not yielded consistently positive results.

**Air pollution.**

Exposure to air pollution, especially roadway exposures, is strongly correlated with
coronary risk. It is postulated that toxins in pollution contribute to macrophage activation, oxidation of LDL, thrombosis, and inflammation of vessel walls.79

Myocardial Ischemia

Pathophysiology
The coronary arteries normally supply blood flow sufficient to meet the demands of the myocardium as it labors under varying workloads. Oxygen is extracted from these vessels with maximal efficiency. If demand increases, healthy coronary arteries can dilate to increase the flow of oxygenated blood to the myocardium. Narrowing of a major coronary artery by more than 50% impairs blood flow enough to hamper cellular metabolism when myocardial demand increases.

Myocardial ischemia develops if the flow or oxygen content of coronary blood is insufficient to meet the metabolic demands of myocardial cells (Figure 24-10). Imbalances between coronary blood supply and myocardial demand can result from a number of conditions. The most common cause of decreased coronary blood flow and resultant myocardial ischemia is the formation of atherosclerotic plaques in the coronary circulation. As the plaque increases in size, it may partially occlude the vessel lumina, thus limiting coronary flow and causing ischemia especially during exercise. As discussed earlier in this chapter, some plaques are “unstable,” meaning they are prone to ulceration or rupture. When this ulceration or rupture occurs, underlying tissues of the vessel wall are exposed, resulting in platelet adhesion and thrombus formation (see Figures 24-7 and 24-15). Thrombus formation can suddenly stop blood supply to the heart muscle, resulting in acute myocardial ischemia, and if the vessel obstruction cannot be reversed rapidly, ischemia will progress to infarction. Myocardial ischemia also can result from other causes of decreased blood and oxygen delivery to the myocardium, such as coronary spasm, hypotension, dysrhythmias, and decreased oxygen-carrying capacity of the blood (e.g., anemia, hypoxemia). Common causes of increased myocardial demand for blood include tachycardia, exercise, hypertension (hypertrophy), and valvular disease.
Myocardial cells become ischemic within 10 seconds of coronary occlusion, thus hampering pump function and depriving the myocardium of a glucose source necessary for aerobic metabolism. Anaerobic processes take over, and lactic acid accumulates. After several minutes, the heart cells lose the ability to contract and cardiac output decreases. Cardiac cells remain viable for approximately 20 minutes under ischemic conditions. If blood flow is restored, aerobic metabolism resumes, contractility is restored, and cellular repair begins. If perfusion is not restored, then myocardial infarction occurs (see Figure 24-10).

**Clinical manifestations**

Individuals with reversible myocardial ischemia present clinically in several ways. Chronic coronary obstruction results in recurrent predictable chest pain called *stable angina*. Abnormal vasospasm of coronary vessels results in unpredictable chest pain called *Prinzmetal angina*. Myocardial ischemia that does not cause detectable symptoms is called *silent ischemia*.

1. **Stable angina pectoris.** Angina is chest pain caused by myocardial ischemia. Stable angina is caused by gradual luminal narrowing and hardening of the arterial walls, with associated inflammation, endothelial cell dysfunction, and a decrease in endogenous vasodilators. These changes are more prevalent in individuals with obesity, diabetes, and dyslipidemia. Affected vessels cannot dilate in response to increased myocardial demand associated with physical exertion or emotional stress. With rest, blood flow is restored and necrosis of myocardial cells does not occur. Angina pectoris is typically experienced as transient substernal chest discomfort, ranging from a sensation of heaviness or pressure to moderately severe pain. Individuals often describe the sensation by clenching a fist over the left sternal border. The discomfort may be mistaken for indigestion. The pain is caused by the

![Figure 24-10](https://example.com/fig24-10.png)
buildup of lactic acid or abnormal stretching of the ischemic myocardium that irritates myocardial nerve fibers. These afferent sympathetic fibers enter the spinal cord from levels C3 to T4, accounting for a variety of locations and radiation patterns of anginal pain. Discomfort may radiate to the neck, lower jaw, left arm, and left shoulder, or occasionally to the back or down the right arm. Pallor, diaphoresis, and dyspnea may be associated with the pain. The pain is usually relieved by rest and nitrates. However, myocardial ischemia in women may not present with typical anginal pain. Common symptoms in women include atypical chest pain, palpitations, sense of unease, and severe fatigue. In addition, it is estimated that half of women with stable angina do not have obstructive coronary artery disease, but rather have “microvascular angina” that results from vasoconstriction of small coronary arterioles deep in the myocardium (see Health Alert: Women and Microvascular Angina).

Health Alert

Women and Microvascular Angina

More women in the United States die from coronary artery disease (CAD) and stroke than from all cancers combined, and women have a higher rate of CAD-related mortality than men. Women with myocardial ischemia often have either no symptoms or atypical symptoms, such as palpitations, anxiety, weakness, and fatigue. Additionally, many women with angina are found to have cardiac ischemia yet no evidence of obstructive coronary artery disease on cardiac catheterization, a condition sometimes called cardiac syndrome x. Evidence is accumulating that nearly half of women with myocardial ischemia suffer from coronary microvascular disease, a condition often called microvascular angina (MVA). Small intramyocardial arterioles constrict in MVA, causing ischemic pain that is less predictable than with typical epicardial CAD. The pathophysiology is complex and still being elucidated, but there is strong evidence that endothelial dysfunction, decreased endogenous vasodilators, inflammation, changes in adipokines, and platelet activation are contributing factors. Managing MVA can be challenging; for example, women with this condition have less coronary microvascular dilation in response to nitrates than do those without MVA. Aggressive interventions to reduce modifiable risk factors for CAD are an important component of management, especially smoking cessation, exercise, and diabetes management. The combination of nonnitrate vasodilators, such as calcium channel blockers with HMG-CoA reductase inhibitors (statins), also has been shown to be effective in many women,
and new drugs, such as ranolazine and ivabradine, have shown promise in the treatment of MVA.

2. **Prinzmetal angina.** Prinzmetal angina (also called variant angina) is chest pain attributable to transient ischemia of the myocardium that occurs unpredictably and often at rest. Pain is caused by vasospasm of one or more major coronary arteries with or without associated atherosclerosis. The pain often occurs at night during rapid eye movement sleep and may have a cyclic pattern of occurrence. The angina may result from decreased vagal activity, hyperactivity of the sympathetic nervous system, or decreased nitric oxide activity. Other causes include altered calcium channel function in arterial smooth muscle or impaired production or release of inflammatory mediators, such as serotonin, histamine, endothelin, or thromboxane. Serum markers of inflammation, such as CRP and interleukin-6 (IL-6), are elevated in individuals with this form of angina. Prinzmetal angina is usually a benign condition, but can occasionally cause serious dysrhythmias, especially if treatment is withdrawn; therefore calcium channel blockers or long-acting nitrates, or both, should be continued even if clinical remission is achieved.

3. **Silent ischemia** and mental stress–induced ischemia. Myocardial ischemia may not cause detectable symptoms such as angina. Ischemia can be totally asymptomatic and referred to as silent ischemia, or individuals may complain of fatigue, dyspnea, or a feeling of unease. Some individuals only have silent ischemia, and episodes of silent ischemia are common in individuals who also experience angina. One proposed mechanism for the absence of angina in silent myocardial ischemia is the presence of a global or regional abnormality in left ventricular sympathetic afferent innervation. The most common cause of autonomic dysfunction leading to silent ischemia is diabetes mellitus. Other causes include surgical denervation during coronary artery bypass grafting (CABG) or cardiac transplantation, or following ischemic local nerve injury by myocardial infarction. Also of interest is silent ischemia occurring in some individuals during mental stress (Figures 24-11 and 24-12). Chronic stress has been linked to an increase in the number of inflammatory cytokines and a hypercoagulable state that may contribute to acute ischemic events. Silent ischemia can be detected by stress radionucleotide imaging. Detection and management of silent ischemia caused by coronary disease is
important because it is an indicator of increased risk for serious cardiovascular events.86

**FIGURE 24-11** Mental Stress and Angiogram of Coronary Arteries. A, Baseline. B, Transient total occlusion of left anterior descending branch of the left coronary artery after mental stress. C, After nitrates and nifedipine, artery reopened to same diameter as baseline. (Modified from Stern S, editor: Silent myocardial ischemia, St Louis, 1998, Mosby.)

**FIGURE 24-12** Pathophysiologic Model of the Effects of Acute Stress as a Trigger of Cardiac Clinical Events. Acting via the central and autonomic nervous systems, stress can produce a cascade of physiologic responses that may lead to myocardial ischemia, especially in persons with coronary artery disease, potentially fatal dysrhythmia, plaque rupture, or coronary thrombosis. LV, Left ventricular; MI, myocardial infarction; VF, ventricular fibrillation; VT, ventricular tachycardia. (From Krantz DS et al: Mental stress as a trigger of myocardial ischemia and infarction. In Deedwania PC, Tofler GH, editors: Triggers and timing of cardiac events, ed 2, London, 1996, Saunders.)
**Evaluation and treatment**

Many individuals with reversible myocardial ischemia will have a normal physical examination between events. Physical examination of those experiencing myocardial ischemia may disclose rapid pulse rate or extra heart sounds (gallops or murmurs), and pulmonary congestion indicating impaired left ventricular function. The presence of xanthelasmas (small fat deposits) around the eyelids or arcus senilis of the eyes (a yellow lipid ring around the cornea) suggests severe dyslipidemia and possible atherosclerosis. The presence of peripheral or carotid artery bruits suggests probable atherosclerotic disease and increases the likelihood that CAD is present.

Electrocardiography is a critical tool for the diagnosis of myocardial ischemia. Ischemic cells distort the electrical impulses that are measured across the myocardium during an **electrocardiogram (ECG)**. Because many individuals have normal ECGs when there is no pain, diagnosis requires that an ECG be performed during an attack of angina or during exercise stress testing. The ST segment and the T wave segments of the ECG respectively correlate with ventricular contraction and relaxation (see Figure 23-10). Transient ST segment depression and T wave inversion are characteristic signs of ischemia that involves only the inner wall of the myocardium (subendocardial ischemia). ST elevation is indicative of ischemia involving the full myocardial wall (transmural ischemia) (Figure 24-13). The ECG tracings correlate with different parts of the myocardium and, therefore, can give some indication of which coronary artery is involved.

Stress radionuclide imaging is indicated to detect ischemic changes in asymptomatic individuals with multiple risk factors for coronary disease, such as diabetes and dyslipidemia, and for older individuals who plan to start vigorous exercise. Currently, the diagnostic modality of choice for the diagnosis of...
myocardial ischemia is single photon emission computerized tomography (SPECT), which is effective at identifying ischemia and estimating coronary risk.\textsuperscript{87} Stress echocardiography is another technique used to diagnose CAD. Unfortunately these tests cannot detect the presence of vulnerable plaques that are the cause of the majority of acute coronary syndromes; therefore new diagnostic techniques are being evaluated.\textsuperscript{58} Noninvasive tests for evaluating coronary atherosclerotic lesions include measurement of coronary artery calcium concentration by computed tomography (CT), noninvasive coronary angiography using electron beam CT, protein-weighted magnetic resonance imaging, and intravascular ultrasound; however, the sensitivity and specificity of these tests vary widely.\textsuperscript{87} Coronary angiography helps determine the anatomic extent of CAD, but the procedure is expensive and carries some risk. It is used primarily to determine whether possible percutaneous coronary intervention (PCI) or coronary artery bypass graft (CABG) surgery is warranted for individuals whose noninvasive studies suggest severe disease.

The primary aims of therapy for myocardial ischemia and stable angina are to increase coronary blood flow and to reduce myocardial oxygen consumption. Recommendations for appropriate diet, exercise, and risk reduction strategies have been widely distributed and the use of lipid-lowering statins has been shown to be effective for both primary and secondary prevention of coronary artery disease.\textsuperscript{65,88} Coronary blood flow is improved by reversing vasoconstriction, reducing plaque growth and rupture, and preventing clotting. Myocardial oxygen demand is reduced by manipulation of blood pressure, heart rate, contractility, and left ventricular volume. Several classes of drugs are useful for increasing coronary flow and decreasing myocardial demand, especially nitrates, beta-blockers, and calcium channel blockers.\textsuperscript{87,89} Ranolazine represents a relatively new class of antianginal drugs known as sodium ion channel inhibitors and has been found to improve exercise tolerance, lessen anginal symptoms, and reduce the need for nitrates in many individuals with chronic stable angina.\textsuperscript{90}

\textbf{Percutaneous coronary intervention (PCI)} is a procedure whereby stenotic (narrowed) coronary vessels are dilated with a catheter. Indications for PCI in stable angina include persistent symptoms despite optimal medical therapy or severe disease that indicates a high risk for infarction.\textsuperscript{87} Restenosis of the artery is the major complication of the procedure; however, placement of a coronary stent can reduce this risk. Pharmacologic treatment with antithrombotics, such as aspirin, clopidogrel, or glycoprotein IIb/IIIa receptor antagonists, after stenting also can improve outcomes.

Severe CAD can be surgically treated by a coronary artery bypass graft (CABG), usually using the saphenous vein from the lower leg. In selected individuals, a
modified CABG procedure called minimally invasive direct coronary artery bypass (MIDCAB) can be used with much less surgical morbidity and more rapid recovery.

Quick Check 24-5

1. Define atherosclerosis, and briefly describe how it develops.

2. Why do hypertension and dyslipidemia increase the likelihood of developing coronary artery disease?

3. Discuss the relationships among myocardial ischemia, angina, and silent ischemia.

Acute Coronary Syndromes

The process of atherosclerotic plaque progression can be gradual. However, when there is sudden coronary obstruction caused by thrombus formation over a ruptured or ulcerated atherosclerotic plaque, the acute coronary syndromes result (Figure 24-14). **Unstable angina** is the result of reversible myocardial ischemia and is a harbinger of impending infarction. **Myocardial infarction (MI)** results when there is prolonged ischemia causing irreversible damage to the heart muscle. MI can be further subdivided into **non-ST elevation MI (non-STEMI)** and **ST elevation MI (STEMI)**. Sudden cardiac death can occur as a result of any of the acute coronary syndromes.
An atherosclerotic plaque that is prone to rupture is called “unstable” and has a core that is especially rich in deposited oxidized LDL and a thin fibrous cap (Figure 24-15). These unstable plaques may not extend into the lumen of the vessel and may be clinically silent until they rupture. Plaque disruption (ulceration or rupture) occurs because of the effects of shear forces, inflammation with release of multiple inflammatory mediators, secretion of macrophage-derived degradative enzymes, and apoptosis of cells at the edges of the lesions. Exposure of the plaque substrate activates the clotting cascade. In addition, platelet activation results in the release of coagulants and exposure of platelet glycoprotein IIb/IIIa surface receptors, resulting in further platelet aggregation and adherence. The resulting thrombus can form very quickly (Figure 24-16, A). Vessel obstruction is further exacerbated by the release of vasoconstrictors, such as thromboxane A₂ and endothelin. The thrombus
may shatter before permanent myocyte damage has occurred (unstable angina) or it may cause prolonged ischemia with infarction of the heart muscle (myocardial infarction) (Figure 24-16, B).

**FIGURE 24-15** Pathogenesis of Unstable Plaques and Thrombus Formation.
Unstable angina.

Unstable angina is a form of acute coronary syndrome that results from reversible myocardial ischemia. It is important to recognize this syndrome because it signals that the atherosclerotic plaque has become complicated, and infarction may soon follow. Unstable angina occurs when a fairly small fissuring or superficial erosion of the plaque leads to transient episodes of thrombotic vessel occlusion and vasoconstriction at the site of plaque damage. This thrombus is labile and occludes the vessel for no more than 10 to 20 minutes, with return of perfusion before significant myocardial necrosis occurs. Unstable angina presents as new-onset angina, angina that is occurring at rest, or angina that is increasing in severity or frequency (Box 24-1). Individuals may experience increased dyspnea, diaphoresis, and anxiety as the angina worsens. Physical examination may reveal evidence of ischemic myocardial dysfunction such as pulmonary congestion. The ECG most commonly shows ST segment depression and T wave inversion during pain that resolve as the pain is relieved. Unstable angina has traditionally been diagnosed by ECG changes without serum cardiac isoenzyme evidence of myocyte necrosis. However, the advent of highly sensitive measurements of myocardial damage (hs-troponin I) that can identify tiny amounts of enzymes released from damaged myocytes has blurred the distinction between unstable angina and myocardial infarction. Therefore, the current guidelines for the management of unstable angina and non-STEMI are identical. Management of unstable angina requires immediate hospitalization with administration of oxygen, aspirin (if not contraindicated), nitrates, and morphine if pain is still present. Additional antithrombotic therapy with clopidogrel or glycoprotein IIb/IIIa platelet receptor
antagonists may be indicated. Beta-blockers and ACE inhibitors also may be used. Anticoagulants (such as low-molecular-weight heparin) or direct thrombin inhibitors (e.g., fondaparinux) also can be given. Rapid intervention with PCI also may be indicated.

Box 24-1

Three Principal Presentations of Unstable Angina

1. Rest angina—Angina occurring at rest and prolonged, usually >20 minutes

2. New-onset angina—New-onset angina of at least CCS Class III severity

3. Increasing angina—Previously diagnosed angina that has become distinctly more frequent, longer in duration, or lower in threshold (i.e., increased by ≥1 CCS class to at least CCS Class III severity)

CCS, Canadian Cardiovascular Society.

Myocardial infarction.

When coronary blood flow is interrupted for an extended period of time, myocyte necrosis occurs. This results in myocardial infarction (MI). Plaque progression, disruption, and subsequent clot formation are the same for myocardial infarction as they are for unstable angina (see Figures 24-14, 24-15, and 24-16). In this case, however, the thrombus is less labile and occludes the vessel for a prolonged period, such that myocardial ischemia progresses to myocyte necrosis and death. Pathologically, there are two major types of myocardial infarction: subendocardial infarction and transmural infarction. Clinically, however, myocardial infarction is categorized as non-ST segment elevation myocardial infarction (non-STEMI) or ST segment elevation MI (STEMI).

If the thrombus disintegrates before complete distal tissue necrosis has occurred, the infarction will involve only the myocardium directly beneath the endocardium (subendocardial MI) (Figure 24-17). This infarction will usually present with ST segment depression and T wave inversion without Q waves; therefore it is termed non-STEMI. It is especially important to recognize this form of acute coronary
syndrome because recurrent clot formation on the disrupted atherosclerotic plaque is likely. If the thrombus lodges permanently in the vessel, the infarction will extend through the myocardium all the way from endocardium to epicardium, resulting in severe cardiac dysfunction (transmural MI) (see Figure 24-17). **Transmural myocardial infarction** will usually result in marked elevations in the ST segments on ECG, and these individuals are categorized as having ST segment elevation MI, or **STEMI**. Clinically, it is important to identify those individuals with STEMI because they are at highest risk for serious complications and should receive definitive intervention without delay.
FIGURE 24-17  Unstable Angina, non-STEMI, and STEMI. A, Unstable angina. Coronary artery obstruction and thrombus formation lead to ischemia in the surrounding myocardium. B, Non-STEMI with partial thrombus formation. C, STEMI with complete thrombus formation and myocardial infarction.
Pathophysiology

After 8 to 10 seconds of decreased blood flow, the affected myocardium becomes cyanotic and cooler. Myocardial oxygen reserves are used quickly (within about 8 seconds) after complete cessation of coronary flow. Glycogen stores decrease as anaerobic metabolism begins. Unfortunately, glycolysis can supply only 65% to 70% of the total myocardial energy requirement and produces much less adenosine triphosphate (ATP) than aerobic processes. Hydrogen ions and lactic acid accumulate. Because myocardial tissues have poor buffering capabilities and myocardial cells are sensitive to low cellular pH, accumulation of these products further compromises the myocardium. Acidosis may make the myocardium more vulnerable to the damaging effects of lysosomal enzymes and may suppress impulse conduction and contractile function, thereby leading to heart failure.

Oxygen deprivation also is accompanied by electrolyte disturbances, specifically the loss of potassium, calcium, and magnesium from cells. Myocardial cells deprived of necessary oxygen and nutrients lose contractility, thereby diminishing the pumping ability of the heart. Ischemia causes the myocardial cells to release catecholamines, predisposing the individual to serious imbalances of sympathetic and parasympathetic function, irregular heartbeats (dysrhythmia), and heart failure. Catecholamines mediate the release of glycogen, glucose, and stored fat from body cells. Therefore plasma concentrations of free fatty acids and glycerol rise within 1 hour after the onset of acute myocardial infarction. Excessive levels of free fatty acids can have a harmful detergent effect on cell membranes. Norepinephrine elevates blood glucose levels through stimulation of liver and skeletal muscle cells and suppresses pancreatic beta-cell activity, which reduces insulin secretion and elevates blood glucose concentration further. Infiltration of inflammatory cells contributes to tissue injury. Angiotensin II is released during myocardial ischemia and contributes to the pathogenesis of myocardial infarction in several ways. First, it results in the systemic effects of peripheral vasoconstriction and fluid retention, which increase myocardial workload. Second, it is a growth factor for vascular smooth muscle cells, myocytes, and cardiac fibroblasts, resulting in structural changes in the myocardium called remodeling. Finally, angiotensin II promotes catecholamine release and causes coronary artery spasm.

Ischemic injury can be exacerbated by reperfusion injury once blood flow is restored. This process involves the release of toxic oxygen free radicals, calcium flux, and pH changes that cause a sustained opening of mitochondrial permeability
transition pores (mPTPs) and contribute to resultant cellular death. Many innovative therapies are being explored to reduce reperfusion injury.\textsuperscript{93}

Cardiac cells can withstand ischemic conditions for about 20 minutes before irreversible hypoxic injury causes cellular death (apoptosis) and tissue necrosis. This results in the release of intracellular enzymes such as creatine phosphokinase MB (CPK-MB) and myocyte proteins such as the troponins through the damaged cell membranes into the interstitial spaces. The lymphatics absorb the enzymes and transport them into the bloodstream, where they can be detected by serologic tests.

Myocardial infarction results in both structural and functional changes of cardiac tissues (Figure 24-18). Gross tissue changes at the area of infarction may not become apparent for several hours, despite almost immediate onset (within 30 to 60 seconds) of electrocardiographic changes. Cardiac tissue surrounding the area of infarction also undergoes changes. \textbf{Myocardial stunning} is a temporary loss of contractile function that persists for hours to days after perfusion has been restored. This pathophysiologic state can occur both with MI and in individuals who suffer ischemia during cardiovascular procedures or during central nervous system trauma. Stunning is caused by the alterations in electrolyte pumps and calcium homeostasis and by the release of toxic oxygen free radicals; it can contribute to heart failure, shock, and dysrhythmias. Recurrent episodes of transient myocardial ischemia (angina) before MI can result in myocyte adaptation to oxygen deprivation with reduced stunning and preservation of myocardium.\textsuperscript{94} This process, termed ischemic preconditioning, is being studied to determine whether it has potential prophylactic or therapeutic uses.\textsuperscript{95} \textbf{Hibernating myocardium} describes tissue that is persistently ischemic and undergoes metabolic adaptation to prolong myocyte survival until perfusion can be restored. PCI or surgery aimed at reperfusion of hibernating myocardium can restore significant cardiac function.\textsuperscript{96} \textbf{Myocardial remodeling} is a process mediated by angiotensin II, aldosterone, catecholamines, adenosine, and inflammatory cytokines that causes myocyte hypertrophy and loss of contractile function in the areas of the heart distant from the site of infarction. Remodeling can be limited through rapid restoration of coronary flow and the use of renin-angiotensin-aldosterone blockers and beta-blockers after MI.\textsuperscript{97}
The severity of functional impairment depends on the size of the lesion and the site of infarction. Functional changes can include (1) decreased cardiac contractility with abnormal wall motion, (2) altered left ventricular compliance, (3) decreased stroke volume, (4) decreased ejection fraction, (5) increased left ventricular end-diastolic pressure, and (6) sinoatrial node malfunction. Life-threatening dysrhythmias and heart failure often follow myocardial infarction.

With infarction, ventricular function is abnormal and the ejection fraction falls, resulting in increases in ventricular end-diastolic volume (VEDV). If the coronary obstruction involves the perfusion to the left ventricle, pulmonary venous congestion ensues; if the right ventricle is ischemic, increases in systemic venous pressures occur.

Myocardial infarction causes a severe inflammatory response that ends with wound repair (see Chapter 6). Damaged cells undergo degradation, fibroblasts proliferate, and scar tissue is synthesized. Many cell types, hormones, and nutrient substrates must be available for optimal healing to proceed. Within 24 hours, leukocytes infiltrate the necrotic area, and proteolytic enzymes from scavenger neutrophils degrade necrotic tissue. The collagen matrix that is deposited is initially weak, mushy, and vulnerable to reinjury. Unfortunately, it is at this time in the recovery period (10 to 14 days after infarction) that individuals feel more like increasing activities and may stress the newly formed scar tissue. After 6 weeks, the necrotic area is completely replaced by scar tissue, which is strong but cannot contract and relax like healthy myocardial tissue.

**Clinical manifestations**

The first symptom of acute myocardial infarction is usually sudden, severe chest pain. The pain is similar to that of angina pectoris but more severe and prolonged. It
may be described as heavy and crushing, such as a “truck sitting on my chest.” Radiation to the neck, jaw, back, shoulder, or left arm is common. Some individuals, especially those who are elderly or have diabetes, experience no pain, thereby having a “silent” infarction. Infarction often simulates a sensation of unrelenting indigestion. Nausea and vomiting may occur because of reflex stimulation of vomiting centers by pain fibers. Vasovagal reflexes from the area of the infarcted myocardium also may affect the gastrointestinal tract.

Various cardiovascular changes are found on physical examination:

1. The sympathetic nervous system is reflexively activated to compensate, resulting in a temporary increase in heart rate and blood pressure.

2. Abnormal extra heart sounds reflect left ventricular dysfunction.

3. Pulmonary findings of congestion including dullness to percussion and inspiratory crackles at the lung bases can occur if the individual develops heart failure.

4. Peripheral vasoconstriction may cause the skin to become cool and clammy.

The number and severity of postinfarction complications depend on the location and extent of necrosis, the individual’s physiologic condition before the infarction, and the availability of swift therapeutic intervention. Sudden cardiac death can occur in individuals with myocardial ischemia even if infarction is absent or minimal, and is a multifactorial problem. Risk factors for sudden death are related to three factors: ischemia, left ventricular dysfunction, and electrical instability. These factors interact with each other (Figure 24-19). Table 24-5 lists the most common complications.
FIGURE 24-19 Three Interacting Factors Related to Sudden Cardiac Death. The three factors are ischemia, left ventricular dysfunction, and electrical instability.

**Evaluation and treatment**

The diagnosis of acute myocardial infarction is made on the basis of history, physical examination, ECG results, and serial cardiac troponin elevations (Box 24-2). The cardiac troponins (troponin I and troponin T) are the most specific indicators of MI. A transient rise in these plasma enzyme levels can confirm the occurrence of MI and indicate its severity. Blood is drawn for troponin level determination as soon as possible after the onset of symptoms, and serial serum levels are assessed for several days. If serologic tests show abnormally high levels of troponin, acute myocardial infarction has occurred. Elevation of troponin level may not occur immediately after infarction and laboratory confirmation that an infarction has occurred may be delayed up to 12 hours.

**Box 24-2**
Universal Definition of Myocardial Infarction

The term *myocardial infarction* should be used when there is evidence of myocardial necrosis in a clinical setting with myocardial ischemia. Under these conditions any one of the following criteria meets the diagnosis for myocardial infarction:

• Detection of rise and/or fall of cardiac biomarkers (preferably troponin) with at least one value above the 99th percentile of the upper reference limit (URL) together with evidence of myocardial ischemia with at least one of the following:

• Symptoms of ischemia

• ECG changes indicative of new ischemia (new ST-T changes or new left bundle branch block [LBBB])

• Development of pathologic Q waves in the ECG

• Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality

• Sudden, unexpected cardiac death, involving cardiac arrest, often with symptoms suggestive of myocardial ischemia, and accompanied by presumably new ST elevation, or new LBBB, and/or evidence of fresh thrombus by coronary angiography and/or at autopsy; but death occurring before blood samples could be obtained, or at a time before the appearance of cardiac biomarkers in the blood.

• For percutaneous coronary interventions (PCIs) in persons with normal baseline troponin values, elevations of cardiac biomarkers greater than the 99th percentile URL are indicative of periprocedural myocardial necrosis. By convention, increases of biomarkers greater than $3 \times 99$th percentile URL have been designated as defining PCI-related myocardial infarction. A subtype related to a documented stent thrombosis is recognized.

• For coronary artery bypass grafting (CABG) in persons with normal baseline troponin values, elevations of cardiac biomarkers greater than the 99th percentile
URL are indicative of periprocedural myocardial necrosis. By convention, increases of biomarkers greater than $5 \times 99$th percentile URL plus either new pathologic Q waves or new LBBB, or angiographically documented new graft or native coronary artery occlusion, or imaging evidence of new loss of viable myocardium have been designated as defining CABG-related myocardial infarction.

- Pathologic findings of an acute myocardial infarction.

Myocardial infarction can occur in various regions of the heart wall and may be described as anterior, inferior, posterior, lateral, subendocardial, or transmural, depending on the anatomic location and extent of tissue damage from infarction. Twelve-lead ECGs help localize the affected area through identification of changes in ST segments and T waves (Figure 24-20). The infarcted myocardium is surrounded by a zone of hypoxic injury, which may progress to necrosis or return to normal, and adjacent to this zone of hypoxic injury is a zone of reversible ischemia (see Figure 24-20). A characteristic Q wave often develops on ECG some hours later in STEMI.

Cardiac troponin I (cTnI) is the most specific indicator of MI, and measurement of its level should be performed on admission to the emergency department. cTnI level elevation is detectable 2 to 4 hours after onset of symptoms. Additional measurements within 6 to 9 hours and again at 12 to 24 hours are recommended if clinical suspicion is high and previous samples were negative. Troponin levels also can be used to estimate infarct size and therefore the likelihood of complications. Additional laboratory data may reveal leukocytosis and elevated C-reactive protein (CRP), both of which indicate inflammation. The individual's blood glucose level is usually elevated and the glucose tolerance level may remain abnormal for several
Acute myocardial infarction requires admission to the hospital, often directly into a coronary care unit. Most guidelines continue to recommend the use of oxygen in acute MI; however, a recent review did not demonstrate a clear benefit of oxygen therapy. The individual should be given an aspirin immediately (ticlopidine if allergic to aspirin). Pain relief is of utmost importance and involves the use of sublingual nitroglycerin and morphine sulfate. Continuous monitoring of cardiac rhythms and enzymatic changes is essential, because the first 24 hours after onset of symptoms is the time of highest risk for sudden death. Non-STEMI is treated in the same way as unstable angina including antithrombotics, anticoagulation or PCI, or both. STEMI is best managed with emergent PCI and antithrombotics. Thrombolytics may be used if PCI is not readily available. Hyperglycemia is treated with insulin. Once the person is stabilized, further management includes ACE inhibitors, beta-blockers, and statins. Individuals who are in shock require aggressive fluid resuscitation, ionotropic drugs, and possible emergent invasive procedures.

Bed rest, followed by gradual return to activities of daily living, reduces the myocardial oxygen demands of the compromised heart. Individuals not receiving thrombolytic or heparin infusion must receive deep venous thrombosis prophylaxis as long as their activity is significantly limited. Stool softeners are given to eliminate the need for straining, which can precipitate bradycardia and can be followed by increased venous return to the heart, causing possible cardiac overload. Education regarding appropriate diet and caffeine intake, smoking cessation, exercise, and other aspects of risk factor reduction is crucial for secondary prevention of recurrent myocardial ischemia.

Quick Check 24-6

1. Describe the coronary artery disease–myocardial ischemia continuum.

2. Describe the pathophysiology of myocardial infarction.

3. What complications are associated with the period after infarction?
Disorders of the Heart Wall

Disorders of the Pericardium

Pericardial disease is a localized manifestation of another disorder, such as infection (bacterial, viral, fungal, rickettsial, or parasitic); trauma or surgery; neoplasm; or a metabolic, immunologic, or vascular disorder (uremia, rheumatoid arthritis, systemic lupus erythematosus, periarteritis nodosa). The pericardial response to injury from these diverse causes may consist of acute pericarditis, pericardial effusion, or constrictive pericarditis.

Acute Pericarditis

Acute pericarditis is acute inflammation of the pericardium. The etiology of acute pericarditis is most often idiopathic or caused by viral infection by coxsackie, influenza, hepatitis, measles, mumps, or varicella viruses. It also is the most common cardiovascular complication of human immunodeficiency virus (HIV) infection. Other causes include myocardial infarction, trauma, neoplasm, surgery, uremia, bacterial infection (especially tuberculosis), connective tissue disease (especially systemic lupus erythematosus and rheumatoid arthritis), or radiation therapy. The pericardial membranes become inflamed and roughened, and a pericardial effusion may develop that can be serous, purulent, or fibrinous (Figure 24-21). Possible sequelae of pericarditis include recurrent pericarditis, pericardial constriction, and cardiac tamponade.
FIGURE 24-21 Acute Pericarditis. Note shaggy coat of fibers covering the surface of heart. (From Damjanov I, Linder J: Pathology: a color atlas, St Louis, 2000, Mosby.)

Symptoms may follow several days of fever and usually begin with the sudden onset of severe retrosternal chest pain that worsens with respiratory movements and when assuming a recumbent position. The pain may radiate to the back as a result of irritation of the phrenic nerve (innervates the trapezius muscles) as it traverses the pericardium. Individuals with acute pericarditis also report dysphagia, restlessness, irritability, anxiety, weakness, and malaise.

Physical examination often discloses low-grade fever (<38°C [<100.4°F]) and sinus tachycardia. A friction rub—a scratchy, grating sound—may be heard at the cardiac apex and left sternal border and is highly suggestive of pericarditis. The rub is caused by the roughened pericardial membranes rubbing against each other. Friction rubs are not always present and may be intermittently heard and transient. Hypotension or the presence of a pulsus paradoxus (a decrease in systolic blood pressure of >10 mm Hg with inspiration) is suggestive of cardiac tamponade, which
can be life-threatening. Electrocardiographic changes may reflect inflammatory processes through PR segment depression and diffuse ST segment elevation without Q waves, and they may remain abnormal for days or even weeks. Ultrasound, CT scanning, and MRI may be used as diagnostic modalities. Acute pericarditis requires at least two of the following four criteria for diagnosis: (1) chest pain characteristics of pericarditis, (2) pericardial rub, (3) characteristic electrocardiographic (ECG) changes, and (4) new or worsening pericardial effusion.

Treatment for uncomplicated acute pericarditis consists of relieving symptoms and includes administration of anti-inflammatory agents, such as salicylates and nonsteroidal anti-inflammatory drugs, and colchicine. Approximately one third of cases will be complicated by the development of idiopathic recurrent pericarditis. Exploration of the underlying cause is important. If pericardial effusion develops, aspiration of the excessive fluid may be necessary.

**Pericardial Effusion**

Pericardial effusion is the accumulation of fluid in the pericardial cavity and can occur in all forms of pericarditis. Most are idiopathic (20%) but other causes, such as neoplasm and infection, must be considered. Analysis of the fluid obtained through pericardiocentesis allows for identification of the likely source of the fluid. The fluid may be a transudate, such as the serous effusion that develops with left heart failure, overhydration, or hypoproteinemia. More often, however, the fluid is an exudate, which reflects pericardial inflammation like that seen with acute pericarditis, heart surgery, some chemotherapeutic agents, infections, and autoimmune disorders such as systemic lupus erythematosus. (Types of exudate are described in Chapter 6.) Exudative effusions also are found in up to 12% of individuals with STEMI. If the fluid is serosanguineous, the underlying cause is likely to be tuberculosis, neoplasm, uremia, or radiation. Idiopathic serosanguineous (cause unknown) effusion is possible, however. Effusions of frank blood are generally related to aneurysms, trauma, or coagulation defects (Figure 24-22). If chyle leaks from the thoracic duct, it may enter the pericardium and lead to cholesterol pericarditis.
Pericardial effusion, even in large amounts, is not necessarily clinically significant, except that it indicates an underlying disorder. If an effusion develops gradually, the pericardium can stretch to accommodate large quantities of fluid without compressing the heart. If the fluid accumulates rapidly, however, even a small amount (50 to 100 ml) may create sufficient pressure to cause cardiac compression, a serious condition known as tamponade. The danger is that pressure exerted by the pericardial fluid eventually will equal diastolic pressure within the heart chambers, which will interfere with right atrial filling during diastole. This causes increased venous pressure, systemic venous congestion, and signs and symptoms of right heart failure (distention of the jugular veins, edema, hepatomegaly). Decreased atrial filling leads to decreased ventricular filling, decreased stroke volume, and reduced cardiac output. Life-threatening circulatory collapse may occur.

An important clinical finding is pulsus paradoxus, in which arterial blood pressure during expiration exceeds arterial pressure during inspiration by more than 10 mm Hg. Pulsus paradoxus in the setting of a pericardial effusion indicates tamponade and reflects impairment of diastolic filling of the left ventricle plus reduction of blood volume within all four cardiac chambers. The presence of a large pericardial effusion or tamponade magnifies the normally insignificant effect of inspiration on intracardiac flow and volume.

Other clinical manifestations of pericardial effusion are distant or muffled heart
sounds, poorly palpable apical pulse, dyspnea on exertion, and dull chest pain. A chest x-ray film may disclose a “water-bottle configuration” of the cardiac silhouette. An echocardiogram can detect an effusion as small as 20 ml and is a reliable and accurate diagnostic test, although CT scans also may be done. Treatment of pericardial effusion or tamponade generally consists of pericardiocentesis (aspiration of excessive pericardial fluid) and treatment of the underlying condition. Persistent pain may be treated with analgesics, anti-inflammatory medications, or steroids. Surgery may be required if the underlying cause of tamponade is trauma or aneurysm. A pericardial “window” may be surgically created to prevent tamponade.

**Constrictive Pericarditis**

Constrictive pericarditis, or restrictive pericarditis (chronic pericarditis), was synonymous with tuberculosis years ago, and tuberculosis continues to be an important cause of pericarditis in immunocompromised individuals. Currently in the United States, this form of pericardial disease is more commonly idiopathic or associated with viral infection, radiation exposure, collagen vascular disorders, sarcoidosis, neoplasm, uremia, or cardiac surgery. In constrictive pericarditis, fibrous scarring with occasional calcification of the pericardium causes the visceral and parietal pericardial layers to adhere, obliterating the pericardial cavity. The fibrotic lesions encase the heart in a rigid shell (Figure 24-23). Like tamponade, constrictive pericarditis compresses the heart and eventually reduces cardiac output. Unlike tamponade, however, constrictive pericarditis always develops gradually.
Symptoms tend to be exercise intolerance, dyspnea on exertion, fatigue, and anorexia. Clinical assessment shows edema, distention of the jugular vein, hepatic congestion, and systemic hypotension. Restricted ventricular filling may cause a pericardial knock (early diastolic sound).

ECG findings include nonspecific ST and T wave abnormalities and atrial fibrillation. Chest x-ray films often disclose prominent pulmonary vessels and calcification of the pericardium. CT, MRI, and transesophageal echocardiography are used to detect pericardial thickening and constriction and to distinguish constrictive pericarditis from restrictive cardiomyopathy. Pericardial biopsy may be needed to determine the etiology.

Initial treatment for constrictive pericarditis consists of restriction of dietary sodium intake and administration of diuretics to improve cardiac output. Management also may include use of anti-inflammatory drugs and treatment of any underlying disorder. If these modalities are unsuccessful, surgical excision of the restrictive pericardium is indicated (pericardial decortication).
Cardiomyopathies

The cardiomyopathies are a diverse group of diseases that primarily affect the myocardium itself. They may, however, be secondary to infectious disease, toxin exposure, systemic connective tissue disease, infiltrative and proliferative disorders, or nutritional deficiencies. Many cases are idiopathic; others are caused by ischemia, hypertension, inherited disorders, infections, toxins, or systemic inflammatory disorders. Some are preceded by myocarditis; however, most individuals with acute myocarditis recover without sequelae. The cardiomyopathies are categorized as dilated (formerly, congestive), hypertrophic, or restrictive, depending on their physiologic effects on the heart (Figure 24-24).
**Dilated cardiomyopathy** is usually the result of ischemic heart disease, valvular disease, diabetes, renal failure, alcohol or drug toxicity, peripartum complications, or infection.\(^\text{100}\) There is a strong genetic basis for dilated cardiomyopathy and it can be associated with inherited disorders, such as muscular dystrophy. It is characterized by impaired systolic function leading to increases in intracardiac volume, ventricular dilation, and heart failure with reduced ejection fraction (Figure 24-25) (see p. 632). Individuals complain of dyspnea, fatigue, and pedal edema. Findings on examination include a displaced apical pulse, \(S_3\) gallop, peripheral edema, jugular venous distention, and pulmonary congestion. Diagnosis is
confirmed by chest x-ray and echocardiogram, and management is focused on reducing blood volume, increasing contractility, and reversing the underlying disorder if possible.\textsuperscript{100} Heart transplant is required in severe cases.

**Hypertrophic cardiomyopathy** refers to two major categories of thickening of the myocardium: (1) hypertrophic obstructive cardiomyopathy (asymmetric septal hypertrophic cardiomyopathy or subaortic stenosis) and (2) hypertensive or valvular hypertrophic cardiomyopathy. **Hypertrophic obstructive cardiomyopathy** is the most commonly inherited cardiac disorder. It is characterized by thickening of the septal wall (Figure 24-26), which may cause outflow obstruction to the left ventricle outflow tract.\textsuperscript{100} Obstruction of left ventricular outflow can occur when the heart rate is increased and the intravascular volume is decreased. This type of hypertrophic cardiomyopathy is a significant risk factor for serious ventricular dysrhythmias and sudden death.\textsuperscript{100,105} There are other conditions that cause hypertrophic changes in the ventricles; **hypertensive** and **valvular hypertrophic cardiomyopathies** are the most common.\textsuperscript{106} These occur because of increased resistance to ventricular ejection, which is commonly seen in individuals with hypertension or valvular stenosis (usually aortic). In this case, hypertrophy of the myocytes is an attempt to compensate for increased myocardial
workload. Long-term dysfunction of the myocytes develops over time, with diastolic dysfunction appearing first and leading eventually to systolic dysfunction of the ventricle (see *Heart Failure*, p. 632). Individuals with hypertrophic cardiomyopathy may be asymptomatic or may complain of angina, syncope, dyspnea on exertion, and palpitations. Examination may reveal extra heart sounds and murmurs. Echocardiography and cardiac catheterization can confirm the diagnosis.

![Hypertrophic Cardiomyopathy](image)

**FIGURE 24-26** Hypertrophic Cardiomyopathy. There is marked left ventricular hypertrophy. This often affects the septum (S). (From Stevens A et al: *Core pathology*, ed 3, London, 2009, Mosby)

**Restrictive cardiomyopathy** is characterized by restrictive filling and increased diastolic pressure of either or both ventricles with normal or near-normal systolic function and wall thickness. It may occur idiopathically or as a cardiac manifestation of systemic diseases, such as amyloidosis, scleroderma, sarcoidosis, lymphoma, and hemochromatosis, or a number of inherited storage diseases. The myocardium becomes rigid and noncompliant, impeding ventricular filling and raising filling pressures during diastole. The most common clinical manifestation of restrictive cardiomyopathy is right heart failure with systemic venous congestion. Cardiomegaly and dysrhythmias are common. A thorough evaluation for the underlying cause should be initiated (and may include myocardial biopsy). Treatment is aimed at the underlying cause. Death occurs as a result of heart failure
or dysrhythmias.

Quick Check 24-7

1. Why does pericarditis develop?

2. What are the cardiomyopathies? List the major disorders.

3. Briefly describe the pathophysiologic effects of the cardiomyopathies.

Disorders of the Endocardium

Valvular Dysfunction

Disorders of the endocardium (the innermost lining of the heart wall) damage the heart valves, which are composed of endocardial tissue. Endocardial damage can be either congenital or acquired. The acquired forms result from inflammatory, ischemic, traumatic, degenerative, or infectious alterations of valvular structure and function. One of the most common causes of acquired valvular dysfunction is degeneration or inflammation of the endocardium secondary to rheumatic heart disease (Table 24-6). Structural alterations of the heart valves are caused by remodeling changes in the valvular extracellular matrix and lead to stenosis, incompetence, or both.
In **valvular stenosis**, the valve orifice is constricted and narrowed, so blood cannot flow forward and the workload of the cardiac chamber proximal to the diseased valve increases (Figure 24-27). Pressure (intraventricular or atrial) rises in the chamber to overcome resistance to flow through the valve, necessitating greater exertion by the myocardium and producing myocardial hypertrophy.

Although all four heart valves may be affected, in adults those of the left heart (mitral and aortic valves) are far more commonly affected than those of the right heart (tricuspid and pulmonic valves). In valvular regurgitation (also called insufficiency or incompetence), the valve leaflets, or cusps, fail to shut completely, permitting blood flow to continue even when the valve is presumably closed (see Figure 24-27). During systole or diastole, some blood leaks back into the chamber proximal to the diseased valve, which increases the volume of blood the heart must pump and increases the workload of both the atrium and the ventricle. Increased volume leads to chamber dilation, and increased workload leads to hypertrophy, both of which are compensatory mechanisms intended to increase the pumping capability of the heart but that lead to cardiac dysfunction over time. Eventually, myocardial contractility diminishes, ejection fraction drops, and diastolic pressure increases, and the ventricles fail from being overworked. Depending on the severity of the valvular dysfunction and the capacity of the heart to compensate, valvular alterations cause a range of symptoms and some degree of incapacitation (see Table 24-6).

In general, valvular disease is diagnosed by transthoracic echocardiography
(TTE), which can be used to assess the severity of valvular obstruction or regurgitation before the onset of symptoms. CT or MRI may be indicated in certain settings. Valvular lesions are staged and appropriate management is determined by using four general categories: (1) at risk, (2) progressive, (3) asymptomatic severe, and (4) symptomatic severe. Management almost always includes careful medical management, valvular repair, or valve replacement followed by long-term anticoagulation therapy and prophylaxis for endocarditis as needed. The purpose of valvular intervention is to improve symptoms and prolong survival, as well as to minimize complications such as asymptomatic irreversible ventricular dysfunction, pulmonary hypertension, stroke, and atrial fibrillation (AF).

**Stenosis**

**Aortic stenosis.**

**Aortic stenosis** is the most common valvular abnormality, affecting nearly 2% of adults older than 65 years of age. It has three common causes: (1) congenital bicuspid valve, (2) degeneration with aging, and (3) inflammatory damage caused by rheumatic heart disease. Aortic stenosis also is associated with many risk factors for coronary artery disease, including hypertension, smoking, and dyslipidemia. Aortic valve degeneration with aging is associated with chronic inflammation, lipoprotein deposition in the tissue, and leaflet calcification. The orifice of the aortic valve narrows, causing resistance to blood flow from the left ventricle into the aorta. Outflow obstruction increases pressure within the left ventricle as it tries to eject blood through the narrowed opening. Left ventricular hypertrophy develops to compensate for the increased workload. Eventually, hypertrophy increases myocardial oxygen demand, which the coronary arteries may not be able to supply. If this occurs, ischemia may cause attacks of angina. In addition, aortic stenosis is frequently accompanied by atherosclerotic coronary disease, further contributing to inadequate coronary perfusion. Untreated aortic stenosis can lead to hypertrophic cardiomyopathy, dysrhythmias, myocardial infarction, and heart failure.
Aortic stenosis usually develops gradually. Classic symptoms include angina, syncope, and dyspnea. Clinical manifestations include decreased stroke volume and narrowed pulse pressure (the difference between systolic and diastolic pressures). Heart rate is often slow, and pulses are delayed. Resistance to flow leads to a crescendo-decrescendo systolic heart murmur heard best at the right parasternal second intercostal space, and may radiate to the neck. Echocardiography can be used to assess the severity of valvular obstruction before the onset of symptoms. Medical management includes vasodilator therapy. Surgical valve replacement with either a mechanical or a bioprosthetic valve is indicated for both symptomatic and asymptomatic individuals with severe stenosis.\textsuperscript{107} Percutaneous placement of a prosthetic valve avoids major heart surgery in selected individuals.\textsuperscript{107,109} Once individuals become symptomatic from aortic stenosis, the prognosis is poor.

**Mitral stenosis.**

**Mitral stenosis** impairs the flow of blood from the left atrium to the left ventricle. Mitral stenosis is the most common form of rheumatic heart disease. Autoimmunity in response to group A β-hemolytic streptococcal M protein antigens leads to inflammation and scarring of the valvular leaflets. Scarring causes the leaflets to become fibrous and fused, and the chordae tendineae cordis become shortened (Figure 24-29).
Impedance to blood flow results in incomplete emptying of the left atrium and elevated atrial pressure as the chamber tries to force blood through the stenotic valve. Continued increases in left atrial volume and pressure cause atrial dilation and hypertrophy. The risk of developing atrial fibrillation and dysrhythmia-induced thrombi is high. As mitral stenosis progresses, symptoms of decreased cardiac output occur, especially during exertion. Continued elevation of left atrial pressure and volume causes pressure to rise in the pulmonary circulation. If untreated, chronic mitral stenosis develops into pulmonary hypertension, pulmonary edema, and right ventricular failure.

Blood flow through the stenotic valve results in a rumbling decrescendo diastolic murmur heard best over the cardiac apex and radiating to the left axilla. If the mitral valve is forced open during diastole, it may make a sharp noise called an opening snap. The first heart sound ($S_1$) is often accentuated and somewhat delayed because of increased left atrial pressure. Other signs and symptoms are generally those of pulmonary congestion and right heart failure. Atrial enlargement and valvular obstruction are demonstrated by chest x-ray films, electrocardiography, and echocardiography. Management includes use of anticoagulation therapy and control of heart rate. Mitral stenosis can often be repaired with percutaneous balloon commissurotomy, but may require valve replacement in advanced cases.  

Regurgitation
Aortic regurgitation.

**Aortic regurgitation** results from an inability of the aortic valve leaflets to close properly during diastole because of abnormalities of the leaflets, the aortic root and annulus, or both. It can be primary, caused by congenital bicuspid valve or degeneration in the elderly; or secondary, resulting from chronic hypertension, rheumatic heart disease, bacterial endocarditis, syphilis, connective tissue disorders (e.g., Marfan syndrome and ankylosing spondylitis), appetite-suppressing medications, trauma, or atherosclerosis. During systole, blood is ejected from the left ventricle into the aorta. During diastole, some of the ejected blood flows back into the left ventricle through the leaking valve. Volume overload occurs in the ventricle because it receives blood both from the left atrium and from the aorta during diastole. The hemodynamic abnormalities depend on the amount of regurgitation. As the end-diastolic volume of the left ventricle increases, myocardial fibers stretch to accommodate the extra fluid. Compensatory dilation permits the left ventricle to increase its stroke volume and maintain cardiac output. Ventricular hypertrophy also occurs as an adaptation to the increased volume and because of increased afterload created by the high stroke volume and resultant systolic hypertension. Over time, ventricular dilation and hypertrophy eventually cannot compensate for aortic incompetence, and heart failure develops.

Clinical manifestations include widened pulse pressure resulting from increased stroke volume and diastolic backflow. Turbulence across the aortic valve during diastole produces a decrescendo murmur in the second, third, or fourth intercostal spaces parasternally and may radiate to the neck. Large stroke volume and rapid runoff of blood from the aorta cause prominent carotid pulsations and bounding peripheral pulses (Corrigan pulse). Other symptoms are usually associated with heart failure that occurs when the ventricle can no longer pump adequately. Dysrhythmias are a common complication of aortic regurgitation. The severity of regurgitation can be estimated by echocardiography, and valve replacement surgery may be delayed for many years through careful use of vasodilators and inotropic agents.

Mitral regurgitation.

**Mitral regurgitation** can be primary because of mitral valve prolapse, rheumatic heart disease, infective endocarditis, MI, connective tissue diseases (Marfan syndrome), and dilated cardiomyopathy. It can also be secondary because of ischemic or nonischemic myocardial disease, which damages the chordae tendineae or the mitral annulus. Mitral regurgitation permits backflow of blood from the left ventricle into the left atrium during ventricular systole, producing a holosystolic (throughout systole) murmur heard best at the apex, which radiates into
the back and axilla. Because of increased volume from the left atrium, the left ventricle becomes dilated and hypertrophied to maintain adequate cardiac output. The volume of backflow reentering the left atrium gradually increases, causing atrial dilation and associated atrial fibrillation. As the left atrium enlarges, the valve structures stretch and become deformed, leading to further backflow. As mitral valve regurgitation progresses, left ventricular function may become impaired to the point of failure. Eventually, increased atrial pressure leads to pulmonary hypertension and failure of the right ventricle. Mitral incompetence is usually well tolerated—often for years—until ventricular failure occurs. Most clinical manifestations are caused by heart failure. The severity of regurgitation can be estimated by echocardiography, and transcatheter or surgical repair or valve replacement may become necessary. In acute mitral regurgitation caused by MI, surgical repair must be done emergently.

**Tricuspid regurgitation.**

**Tricuspid regurgitation** is more common than tricuspid stenosis. Primary tricuspid regurgitation is caused by congenital defects, rheumatic heart disease, endocarditis, or trauma. However, 80% of the cases of tricuspid regurgitation are functional because of annular dilatation and leaflet tethering abnormalities related to dilation of the right ventricle secondary to pulmonary hypertension (see p. 707). Tricuspid valve incompetence leads to volume overload in the right atrium and ventricle, increased systemic venous blood pressure, and right heart failure. Pulmonic valve dysfunction can have the same consequences as tricuspid valve dysfunction.

**Mitral Valve Prolapse Syndrome**

In mitral valve prolapse syndrome (MVPS), one or both of the cusps of the mitral valve billow upward (prolapse) into the left atrium during systole (Figure 24-30). The most common cause of mitral valve prolapse is myxomatous degeneration of the leaflets in which the cusps are redundant, thickened, and scalloped because of changes in tissue proteoglycans, increased levels of proteinases, and infiltration by myofibroblasts. Mitral regurgitation occurs if the ballooning valve permits blood to leak into the atrium.
Mitral valve prolapse is the most common valve disorder in the United States, with a prevalence of nearly 3% of adults. \(^{108}\) Because mitral valve prolapse can be
associated with other inherited connective tissue disorders (Marfan syndrome, Ehlers-Danlos syndrome, osteogenesis imperfecta), it has been suggested that it results from a genetic or environmental disruption of valvular development during the fifth or sixth week of gestation. There also may be a relationship between symptomatic mitral valve prolapse and hyperthyroidism.

Many cases of mitral valve prolapse are completely asymptomatic. Cardiac auscultation on routine physical examination may disclose a regurgitant murmur or midsystolic click in an otherwise healthy individual, or echocardiography may demonstrate the condition in the absence of auscultatory findings. Symptomatic mitral valve prolapse can cause palpitations related to dysrhythmias, tachycardia, lightheadedness, syncope, fatigue (especially in the morning), lethargy, weakness, dyspnea, chest tightness, hyperventilation, anxiety, depression, panic attacks, and atypical chest pain. Many symptoms are vague and puzzling and are unrelated to the degree of prolapse. Most individuals with mitral valve prolapse have an excellent prognosis, do not develop symptoms, and do not require any restriction in activity or medical management. Occasionally, beta-blockers are needed to alleviate syncope, severe chest pain, or palpitations.

**Acute Rheumatic Fever and Rheumatic Heart Disease**

*Rheumatic fever* is a systemic, inflammatory disease caused by a delayed exaggerated immune response to infection by the group A β-hemolytic streptococcus in genetically predisposed individuals. In its acute form, rheumatic fever is a febrile illness characterized by inflammation of the joints, skin, nervous system, and heart.\(^{111}\) If untreated, rheumatic fever can cause scarring and deformity of cardiac structures, resulting in *rheumatic heart disease (RHD).*

The incidence of acute rheumatic fever declined in the United States during the 1960s, 1970s, and early 1980s because of medical and socioeconomic improvements. The acute disease occurs most often in children between the ages of 5 and 15 years. Appropriate antibiotic therapy given within the first 9 days of group A β-hemolytic streptococcus infection usually prevents rheumatic fever.\(^{112}\)

**Pathophysiology**

Acute rheumatic fever can develop only as a sequel to pharyngeal infection by group A β-hemolytic streptococcus. Streptococcal skin infections do not progress to acute rheumatic fever, although both skin and pharyngeal infections can cause acute glomerulonephritis. This is because the strains of the microorganism that affect the skin do not have the same antigenic molecules in their cell membranes as those that cause pharyngitis and, therefore, do not elicit the same kind of immune response.
Acute rheumatic fever is the result of an abnormal humoral and cell-mediated immune response to group A streptococcal cell membrane antigens called M proteins (Figure 24-31).\textsuperscript{113,114} This immune response cross-reacts with molecularly similar self-antigens in heart, muscle, brain, and joints, causing an autoimmune response that results in diffuse, proliferative, and exudative inflammatory lesions in these tissues. The inflammation may subside before treatment, leaving behind damage to the heart valves. Repeated attacks of acute rheumatic fever cause chronic proliferative changes in the previously mentioned organs with resultant tissue scarring, granuloma formation, and thrombosis.

FIGURE 24-31 Pathogenesis and Structural Alterations of Acute Rheumatic Heart Disease. Beginning usually with a sore throat, rheumatic fever can develop only as a sequel to pharyngeal infection by group A β-hemolytic streptococcus. Suspected as a hypersensitivity reaction, it is proposed that antibodies directed against the M proteins of certain strains of streptococci cross-react with tissue glycoproteins in the heart, joints, and other tissues. The exact nature of cross-reacting antigens has been difficult to define, but it appears that the streptococcal infection causes an autoimmune response against self-antigens. Inflammatory lesions are found in various sites; the most distinctive within the heart are called Aschoff bodies. The chronic sequelae result from progressive fibrosis because of healing of the inflammatory lesions and the changes induced by valvular deformities. (From Damjanov I: Pathology for the health professions, ed 4, Philadelphia, 2012, Saunders.)

Approximately 10% of individuals with rheumatic fever develop rheumatic heart disease (RHD). In developed countries, the peak incidence of the development of RHD occurs in adults between the ages of 25 and 34. Although rheumatic fever can cause carditis in all three layers of the heart wall, the primary lesion usually involves the endocardium. Endocardial inflammation causes swelling of the valve leaflets, with secondary erosion along the lines of leaflet contact. Small, beadlike clumps of vegetation containing platelets and fibrin are deposited on eroded valvular tissue and on the chordae tendineae cordis. These lesions can become progressively adherent. Scarring and shortening of the involved structures occur over time. The valves lose their elasticity, and the leaflets may adhere to each other.

If inflammation penetrates the myocardium, called myocarditis, localized fibrin deposits develop that are surrounded by areas of necrosis. These fibrinoid necrotic deposits are called Aschoff bodies. Pericardial inflammation is usually characterized by serofibrinous effusion within the pericardial cavity. Cardiomegaly and left heart failure may occur during episodes of untreated acute or recurrent rheumatic fever. Conduction defects and atrial fibrillation often are associated with rheumatic heart disease.

Clinical manifestations

The common symptoms of acute rheumatic fever are fever, lymphadenopathy, arthralgia, nausea, vomiting, epistaxis (nosebleed), abdominal pain, and tachycardia. The major clinical manifestations of acute rheumatic fever usually occur singly or in combination 1 to 5 weeks after streptococcal infection of the pharynx. They are carditis, acute migratory polyarthritis, chorea, erythema marginatum, and subcutaneous nodules. Criteria for the diagnosis of rheumatic fever (Table 24-7) have not changed since 1992.111

Evaluation and treatment

As described in Table 24-7, supportive evidence for group A β-hemolytic streptococci includes positive throat cultures and measurement of serum antibodies against the hemolytic factor streptolysin O. Cultures may be negative when the rheumatic attack begins, however. Several other antibody tests are sensitive prognosticators of streptococcal infection, including antideoxyribonuclease B (anti-DNase B), antihyaluronidase, and antistreptozyme (ASTZ). Elevated measurements of white blood cell count, erythrocyte sedimentation rate, and C-reactive protein indicate inflammation. All three are usually increased at the time cardiac or joint symptoms begin to appear. Echocardiographic screening for rheumatic heart disease in children with a history of rheumatic fever is controversial because not all detectable abnormalities are clinically relevant.115

Therapy for acute rheumatic fever is aimed at eradicating the streptococcal infection and involves a 10-day regimen of oral penicillin or erythromycin administration. Nonsteroidal anti-inflammatory drugs are used as anti-inflammatory agents for both rheumatic carditis and arthritis. Serious carditis may require corticosteroids and diuretics. Because recurrent rheumatic fever occurs in more than half of affected children, continuous prophylactic antibiotic therapy may be necessary for as long as 5 years. Several potential group A streptococcus vaccines are being developed. RHD may require surgical repair of damaged valves.
Quick Check 24-8

1. Compare the effect of aortic stenosis with mitral stenosis on the left ventricle and atrium.

2. Describe aortic regurgitation, mitral regurgitation, and tricuspid regurgitation.

3. What are the common symptoms of mitral prolapse?

4. What is the cause of rheumatic heart disease?

Infective Endocarditis

Infective endocarditis is a general term used to describe infection and inflammation of the endocardium—especially the cardiac valves. Bacteria are the most common cause of infective endocarditis, especially streptococci, staphylococci, and enterococci, which account for more than 80% of cases. Other causes include viruses, fungi, rickettsia, and parasites. Infective endocarditis was once a lethal disease, but morbidity and mortality diminished significantly with the advent of antibiotics and improved diagnostic techniques (see Risk Factors: Infective Endocarditis).

Risk Factors

Infective Endocarditis

• Acquired valvular heart disease

• Implantation of prosthetic heart valves

• Congenital lesions associated with highly turbulent flow (e.g., ventricular septal defect)

• Previous attack of infective endocarditis

• Intravenous drug use

• Long-term indwelling intravenous catheterization (e.g., for pressure monitoring, feeding, hemodialysis)
Pathophysiology

The pathogenesis of infective endocarditis requires at least three critical elements (Figure 24-32):

1. **Endocardial damage.** Trauma, congenital heart disease, valvular heart disease, and the presence of prosthetic valves are the most common risk factors for endocardial damage that leads to infective endocarditis. Turbulent blood flow caused by these abnormalities usually affects the atrial surface of atrioventricular valves or the ventricular surface of semilunar valves. Endocardial damage exposes the endothelial basement membrane, which contains a type of collagen that attracts platelets and thereby stimulates sterile thrombus formation on the membrane. This causes an inflammatory reaction (nonbacterial thrombotic endocarditis).

2. **Adherence of blood-borne microorganisms to the damaged endocardial surface.** Bacteria may enter the bloodstream during injection drug use, trauma, dental procedures that involve manipulation of the gingiva, cardiac surgery, genitourinary procedures and indwelling catheters in the presence of infection, or gastrointestinal instrumentation, or they may spread from uncomplicated upper respiratory tract or skin infections. Bacteria adhere to the damaged endocardium using adhesins.  

3. **Formation of infective endocardial vegetations** (Figure 24-33). Bacteria infiltrate the sterile thrombi and accelerate fibrin formation by activating the clotting cascade. These vegetative lesions can form anywhere on the endocardium but usually occur on heart valves and surrounding structures. Although endocardial tissue is constantly bathed in antibody-containing blood and is surrounded by scavenging monocytes and polymorphonuclear leukocytes, bacterial colonies are inaccessible to host defenses because they are embedded in the protective fibrin clots. Embolization from these vegetations can lead to abscesses and characteristic skin changes, such as petechiae, splinter hemorrhages, Osler nodes, and Janeway lesions.
FIGURE 24-32  Pathogenesis of Infective Endocarditis.
Clinical manifestations

Fever occurs in 80% of cases. Infective endocarditis causes varying degrees of valvular dysfunction and may be associated with manifestations involving several organ systems (respiratory [lungs], sensory [eyes], genitourinary [kidneys], musculoskeletal [bones, joints], and central nervous systems), making diagnosis exceedingly difficult. Signs and symptoms of infective endocarditis are caused by infection and inflammation, systemic spread of microemboli, and immune complex deposition. The “classic” findings are fever; new or changed cardiac murmur; and petechial lesions of the skin, conjunctiva, and oral mucosa. Characteristic physical findings include Osler nodes (painful erythematous nodules on the pads of the fingers and toes) and Janeway lesions (nonpainful hemorrhagic lesions on the palms and soles). Central nervous system complications are the most frequent and the most severe extracardiac complications and include stroke, abscess, and meningitis. Other manifestations include weight loss, back pain, night sweats, and heart failure. Splenic, renal, pulmonary, peripheral arterial, coronary, and ocular emboli may lead to a wide variety of signs and symptoms.

Evaluation and treatment

The criteria for the diagnosis of infective endocarditis are called the Duke criteria and include repetitive blood cultures positive for bacteria and evidence for
endocardial involvement (murmurs or documented regurgitation) along with recognized risk factors, fever, and vascular complications. Serum measures, such as C-reactive protein, also are elevated. Echocardiography should be performed immediately. Antimicrobial therapy is generally given for several weeks, beginning with intravenous and ending with oral administration. In some cases, two different antibiotics are given simultaneously to eliminate the offending microorganism and prevent the development of drug resistance. Other drugs may be necessary to treat left heart failure secondary to valvular dysfunction. Surgery that involves excision of infected tissue with or without valve replacement improves outcomes in many persons with infective endocarditis, especially those with severe heart failure or persistent bacteremia despite antibiotic therapy.

Antibiotic prophylaxis to prevent infective endocarditis is indicated for those with prosthetic valves, a history of infective endocarditis, unrepaired cyanotic congenital heart disease, and heart transplant with valvular defect in the setting of gingival procedures or in the presence of documented acute gastrointestinal or genitourinary infection.

Antibiotic prophylaxis to prevent infective endocarditis is indicated for those with prosthetic valves, a history of infective endocarditis, unrepaired cyanotic congenital heart disease, and heart transplant with valvular defect in the setting of gingival procedures or in the presence of documented acute gastrointestinal or genitourinary infection.

Cardiac Complications in Acquired Immunodeficiency Syndrome (AIDS)

Individuals with HIV infection and AIDS are at risk for cardiac complications including dilated cardiomyopathy, myocarditis, pericardial effusion, endocarditis, pulmonary hypertension, and non-antiretroviral drug–related cardiotoxicity. In addition, cardiac involvement may be induced by various bacterial, viral, protozoal, mycobacterial, and fungal pathogens that complicate AIDS. Malignancies, such as lymphoma and Kaposi sarcoma, are seen often in individuals with AIDS and can affect the heart. HIV has been found to cause immune activation that increases the risk for coronary atherosclerosis. Furthermore, treatment with antiretroviral therapy can cause hyperlipidemia and atherosclerotic disease.

Left heart failure is the most common complication of HIV infection and is related to left ventricular dilation and dysfunction and sudden death. Pericardial effusion, ventricular dysrhythmias, electrocardiographic changes, and right ventricular dilation and hypertrophy are other less common findings.

Quick Check 24-9

1. What three critical elements are required for the pathogenesis of infective endocarditis?
2. Why does infective endocarditis involve several organ systems?

3. What effect does AIDS have on the heart?
Heart Failure

Heart failure is when the heart is unable to generate an adequate cardiac output, causing inadequate perfusion of tissues or increased diastolic filling pressure of the left ventricle, or both, so that pulmonary capillary pressures are increased. It affects nearly 10% of individuals older than age 65 and is the most common reason for admission to the hospital in that age group. Ischemic heart disease and hypertension are the most important predisposing risk factors. Other risk factors include age, obesity, diabetes, renal failure, valvular heart disease, cardiomyopathies, myocarditis, congenital heart disease, and excessive alcohol use. Numerous genetic polymorphisms have been linked to an increased risk for heart failure, including genes for cardiomyopathies, myocyte contractility, and neurohumoral receptors. Most causes of heart failure result from dysfunction of the left ventricle (heart failure with reduced ejection fraction and heart failure with preserved ejection fraction). The right ventricle also may be dysfunctional, especially in pulmonary disease (right ventricular failure). Finally, some conditions cause inadequate perfusion despite normal or elevated cardiac output (high-output failure).

Left Heart Failure (Congestive Heart Failure)

Left heart failure, commonly called congestive heart failure, is further categorized as heart failure with reduced ejection fraction or heart failure with preserved ejection fraction. It is possible for these two types of heart failure to occur simultaneously in one individual.

Heart failure with reduced ejection fraction (HFrEF), or systolic heart failure, is defined as an ejection fraction of <40% and an inability of the heart to generate an adequate cardiac output to perfuse vital tissues. Cardiac output depends on the heart rate and stroke volume. Stroke volume is influenced by three major determinants: contractility, preload, and afterload (see Chapter 23).

Contractility is reduced by diseases that disrupt myocyte activity. Myocardial infarction is the most common primary cause of decreased contractility. Other primary causes include myocarditis and cardiomyopathies. Secondary causes of decreased contractility, such as recurrent myocardial ischemia and increased myocardial workload, contribute to inflammatory, immune, and neurohumoral changes (activation of the SNS and RAAS) that mediate a process called ventricular remodeling. Ventricular remodeling results in disruption of the normal myocardial extracellular structure with resultant dilation of the myocardium and causes progressive myocyte contractile dysfunction over time (Figure 24-34). When
contractility is decreased, stroke volume falls and left ventricular end-diastolic volume (LVEDV) increases. This causes dilation of the heart and an increase in preload.
Preload, or LVEDV, increases with decreased contractility or an excess of plasma volume (intravenous fluid administration, renal failure, mitral valvular disease). Increases in LVEDV can actually improve cardiac output up to a certain point, but as
preload continues to rise, it causes a stretching of the myocardium that eventually can lead to dysfunction of the sarcomeres and decreased contractility. This relationship is described by the Frank-Starling law of the heart (see Figure 23-16). Decreased contractility leads to further increases in preload (Figure 24-35).

![Figure 24-35](Effect of Elevated Preload on Myocardial Oxygen Supply and Demand. LVEDV, Left ventricular end-diastolic volume.)

Increased afterload is most commonly a result of increased peripheral vascular resistance (PVR), such as that seen with hypertension. Nearly 75% of cases of heart failure have antecedent hypertension. Although much less common, it also can be the result of aortic valvular disease. With increased afterload, there is resistance to ventricular emptying and more workload for the ventricle; and the ventricle responds with hypertrophy, which is a form of myocardial remodeling. This process differs from the physiologic myocyte response to increased workload (exercise) in which the workload is intermittent rather than sustained, resulting in an increase in muscle mass but no distortion of the cardiac architecture. Sustained afterload leads to pathologic hypertrophy mediated by angiotensin II and catecholamines and results in an increase in oxygen demand by the thickened myocardium. A state of relative ischemia develops that further contributes to changes in the myocytes themselves and ventricular remodeling (Figure 24-36). In addition, hypertrophic remodeling results in alteration of the cardiac extracellular matrix and deposition of collagen between the myocytes, which can disrupt the integrity of the muscle, decrease contractility, and increase the likelihood that the
ventricle will dilate and fail. These changes in ventricular structure and function are referred to as hypertensive hypertrophic cardiomyopathy (see p. 624).

As cardiac output falls, renal perfusion diminishes with activation of the RAAS, which acts to increase PVR and plasma volume, thus further increasing afterload and preload. In addition, baroreceptors in the central circulation detect the decrease in perfusion and stimulate the SNS to cause yet more vasoconstriction and the hypothalamus to produce antidiuretic hormone. This vicious cycle of decreasing contractility, increasing preload, and increasing afterload causes progressive worsening of left heart failure.
In addition to these hemodynamic interactions, HFrEF is characterized by a complex constellation of neurohumoral, inflammatory, and metabolic processes. Ang II and aldosterone have direct toxicity to the myocardium, contributing to remodeling, myocyte death, and fibrosis. Catecholamines released by the SNS also are toxic to the myocardium and contribute to remodeling. \(^{121}\) Natriuretic peptides are released in an effort to improve renal salt and water excretion but are inadequate to compensate for these neurohumoral perturbations. \(^{124}\) Insulin resistance and diabetes not only contribute to heart failure but also are a complication of heart failure with changes in myocyte metabolism. Inflammatory cytokines, such as TNF-α, are released in heart failure, contributing to myocardial damage as well as systemic weight loss (cardiac cachexia). Finally, changes in the metabolic processes within the myocardium also are affected with a decreased ability of the heart to produce energy and an increase in release of toxic metabolites. \(^{125}\) (see Health Alert: Metabolic Changes in Heart Failure). These neurohumoral, inflammatory, and metabolic aspects of left HFrEF have led to the routine use of combinations of medications that inhibit angiotensin, aldosterone, and catecholamines and increase salt excretion in an effort to prevent long-term damage to the myocardium, as well as the exploration of new treatment modalities focused on reducing inflammation and improving myocardial metabolic function. \(^{125, 126}\)

**Health Alert**

**Metabolic Changes in Heart Failure**

Although the use of medications that block the renin-angiotensin-aldosterone and sympathetic nervous systems reduces remodeling and improves outcomes in heart failure, morbidity and mortality from this condition are still high. The heart is the largest consumer of energy in the body and relies on the efficient production of adenosine triphosphate (ATP), yet it has very little capacity for energy storage. In the failing heart, increased demand for oxygen and energy is coupled with a decreased ability to utilize fatty acids as an energy source. As a result, several genes are activated that alter the ability of myocytes to use lipids and glucose as fuel sources, the most studied of which are the peroxisome proliferator–activated receptor (PPAR) family of genes. These genes control fatty acid oxidation and are of particular importance in heart failure associated with insulin resistance and diabetes. Energy starvation and high levels of catecholamines associated with heart failure lead to altered fatty acid oxidation and decreased effective ATP generation and utilization. This results in decreased myocardial contractility and structural...
changes in the myocardium (remodeling). Increasing knowledge of these mechanisms has led to the exploration of potential new therapies for heart failure. For example, although currently available PPAR-γ agonists (thiazolidinediones) are contraindicated in worsening heart failure because of increased fluid retention at the renal tubule, new insulin sensitizers are being explored that may improve myocardial metabolic function. In addition, inhibitors of fatty acid oxidation (e.g., trimetazidine) have been tried in several small studies with some improvement in cardiac function. Other metabolic abnormalities in the failing heart are being discovered, including changes in the pentose phosphate pathway, ketone bodies, uncoupled electron transfer, and lipotoxins. Many new potential drugs are under investigation and mechanical support devices, such as left ventricular assist devices, are promising in reversing these metabolic changes. In the meantime, most researchers agree that exercise and a healthy diet are the most effective approaches to improving myocardial metabolic function.

The interaction of these hemodynamic, neurohumoral, inflammatory, and metabolic processes results in a steady decline in myocardial function. Pathologically, the heart muscle exhibits gradual changes in myocyte structure and function, with apoptosis of cells, deposition of fibrin, and remodeling of the myocardium such that contractility and cardiac output decline. A vicious cycle of decreasing contractility, increasing preload, and increasing afterload develops, causing the progressive worsening of symptoms associated with left heart failure (Figure 24-37).
The clinical manifestations of left heart failure are the result of pulmonary vascular congestion and inadequate perfusion of the systemic circulation. Individuals experience dyspnea, orthopnea, cough of frothy sputum, fatigue, decreased urine output, and edema. Physical examination often reveals pulmonary edema (cyanosis, inspiratory crackles, pleural effusions), hypotension or hypertension, an S₃ gallop, and evidence of underlying CAD or hypertension. The diagnosis can be further confirmed with echocardiography showing decreased cardiac output and cardiomegaly. The level of serum B-type natriuretic peptide (BNP) can also help make the diagnosis of heart failure and give some insight into its severity.¹²⁷

Management of HFrEF is aimed at interrupting the worsening cycle of decreasing contractility, increasing preload, and increasing afterload. The acute onset of left heart failure is most often the result of acute myocardial ischemia and must be managed in conjunction with management of the underlying coronary disease (see p. 614). Oxygen, nitrate, and morphine administration improves myocardial oxygenation and helps relieve coronary spasm while lowering preload through systemic venodilation. Inotropic drugs, such as dopamine, dobutamine, and milrinone, increase contractility and can help raise the blood pressure in hypotensive individuals but must be monitored carefully.¹²⁸ Diuretics reduce preload. ACE inhibitors, ARBs, and aldosterone blockers reduce both preload and afterload by decreasing aldosterone levels and reducing PVR. Finally, individuals with severe HFrEF failure may benefit from acute coronary bypass or percutaneous
coronary intervention (PCI). These people often are supported with the intra-aortic balloon pump (IABP) or left ventricular assist devices (LVADs) until surgery can be performed.

Management of chronic left heart failure is based on current clinical guidelines and clinical severity. The overall goals are to reduce preload and afterload. Salt restriction and diuretics (loop diuretics) are effective in reducing preload. ACE inhibitors (or Ang II receptor blockers) reduce preload and afterload and have been shown to significantly reduce mortality in individuals with chronic left heart failure. Aldosterone blockers, such as spironolactone, also are associated with improved outcomes. Beta-blockers improve symptoms and increase survival but must be used carefully to avoid hypotension. The inotropic drug digoxin may be considered in selected individuals, especially those with refractory heart failure or atrial fibrillation. Although many individuals with left heart failure die suddenly from dysrhythmias, prophylactic administration of antidysrhythmics has not been shown to improve survival. In individuals with sustained ventricular tachycardia, implantable cardioverter-defibrillators should be considered. Cardiac resynchronization therapy is proving to be an important modality in selected individuals. For those individuals with coronary artery disease, coronary bypass surgery or PCI may improve perfusion to ischemic myocardium (hibernating myocardium) and improve cardiac output. Surgical interventions may be performed (including improving ventricular geometry, implanting assist devices) or heart transplantation may need to be considered. Experimental therapies, including natriuretic peptide analogs, gene transfer, and stem cell therapies, are being explored. Gene therapy offers some exciting new hope for severe heart failure (see Health Alert: Gene Therapy for Heart Failure).

**Health Alert**

**Gene Therapy for Heart Failure**

The effectiveness and safety of recent gene therapy trials for heart failure have led to an explosion of interest in innovative methods for restoring cardiac function. Multiple components of cardiac contractility have been identified as targets for gene therapy, including calcium channel cycling, β-adrenergic functioning, and cellular proliferation. The most studied of the potential gene targets include sarcoendoplasmic reticulum calcium ATPase (SERCA2a) and S100A1, which affect intracellular myocyte calcium handling. Another exciting target is adenylyl cyclase 6 (AC6), the enzyme catalyzing cAMP formation and β-adrenergic receptor
function. Other targets include SDF1/CXCR4 complex, which promotes homing of stem cells to infarcted myocardium; microRNAs; and genes that code for critical neurohumoral factors, including insulin-like growth factor-1 (IGF-1), growth hormone, and B-type natriuretic peptide. Gene delivery vectors fall into one of two categories: nonviral or viral. Nonviral gene delivery vectors are safe and have minimal immunogenicity but do not appear to be efficient at delivering the genes to the tissues. Viral vectors are more efficient at delivering genes to cells but safety concerns persist. Today the viruses most widely used for cardiovascular gene transfer are adenovirus, Sendai virus, and adeno-associated virus (AAV). These viruses exhibit fairly good cardioprotic effect and various methods are being explored for delivering these gene vectors most efficiently to the myocardium, including antegrade or retrograde coronary infusion, intravenous infusion, direct myocardial injection, and pericardial injection. One recent report documented that intracoronary infusion of AAV with SERCA2a for individuals with severe heart failure significantly improved mortality and heart failure outcomes with positive effects and no reported safety concerns reported at 3 years. It is clear that the future will reveal many new and potentially lifesaving gene therapies for those with intractable heart failure.

Heart failure with preserved ejection function (HFpEF), or diastolic heart failure, can occur singly or along with HFrEF. Isolated HFpEF is defined as pulmonary congestion despite a normal stroke volume and cardiac output. It is estimated that HFpHF affects more than 25% of adults in the United States. HFpEF is preceded by a condition called preclinical diastolic dysfunction (PDD) in which affected individuals do not have symptoms, but have early changes in ventricular relaxation and a high untreated risk for developing heart failure. HFpHF results from decreased compliance of the left ventricle and abnormal diastolic relaxation such that a normal left ventricular end-diastolic volume (LVEDV) results in an increased left ventricular end-diastolic pressure (LVEDP). This pressure is reflected back into the pulmonary circulation and results in pulmonary edema, pulmonary hypertension, and right ventricular hypertrophy. The amount of LV stiffness and RV hypertrophy are the strongest pathophysiologic predictors of complications from HFpEF. The major causes of diastolic dysfunction include hypertension-induced myocardial hypertrophy and myocardial ischemia–induced ventricular remodeling. Hypertrophy and ischemia cause a decreased ability of the myocytes to
actively pump calcium from the cytosol, resulting in impaired relaxation. Other causes include aortic valvular disease, mitral valve disease, pericardial diseases, and cardiomyopathies. Diabetes also increases the risk for diastolic dysfunction. Like HFrEF, HFpEF is characterized by sustained activation of the RAAS and the SNS.

Individuals with diastolic dysfunction present with dyspnea on exertion and fatigue. Evidence of pulmonary edema (inspiratory crackles on auscultation, pleural effusions) is usually not present in resting individuals without tachycardia. Late in diastole, atrial contraction with rapid ejection of blood into the noncompliant ventricle may give rise to an $S_4$ gallop. Electrocardiography often reveals evidence of left ventricular hypertrophy, and chest x-ray may show pulmonary congestion without cardiomegaly (Table 24-8). There also may be evidence of underlying coronary disease, hypertension, or valvular disease. Diagnosis is based upon three factors: signs and symptoms of heart failure, normal left ventricular (LV) ejection fraction, and evidence of diastolic dysfunction. The diagnosis is confirmed by clinical Doppler echocardiography, which demonstrates poor ventricular filling with normal ejection fractions.136

Management is aimed at improving ventricular relaxation and prolonging diastolic filling times to reduce diastolic pressure. No therapy has been shown to improve survival, and calcium channel blockers, beta-blockers, ACE inhibitors, and ARBs have been used with only varying success.137 Treatment with the 3-hydroxy-3-methyl-glutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) has consistently resulted in improvements in LV diastolic function.137,138 Inotropic drugs are not indicated in isolated HFpEF because contractility and ejection fraction are not affected; however, digoxin may be used to slow the heart rate in individuals with atrial fibrillation. Outcomes for individuals with HFpEF are as poor as those with HFrEF, and there has been no improvement in prognosis despite numerous new treatment trials.139
**Right Heart Failure**

*Right heart failure* is defined as the inability of the right ventricle to provide adequate blood flow into the pulmonary circulation at a normal central venous pressure. It can result from left heart failure when an increase in left ventricular filling pressure is reflected back into the pulmonary circulation. As pressure in the pulmonary circulation rises, the resistance to right ventricular emptying increases ([Figure 24-38](#)). The right ventricle is poorly prepared to compensate for this increased afterload and will dilate and fail. When this happens, pressure will rise in the systemic venous circulation, resulting in peripheral edema and hepatosplenomegaly. Treatment relies on management of the left ventricular dysfunction as just outlined. When right heart failure occurs in the absence of left heart failure, it is typically attributable to diffuse hypoxic pulmonary disease such as chronic obstructive pulmonary disease (COPD), cystic fibrosis, and acute respiratory distress syndrome (ARDS). These disorders result in an increase in right ventricular afterload. The mechanisms for this type of right ventricular failure (cor pulmonale) are discussed in Chapter 27. Finally, myocardial infarction, cardiomyopathies, and pulmonic valvular disease interfere with right ventricular contractility and can lead to right heart failure.
High-Output Failure

High-output failure is the inability of the heart to adequately supply the body with blood-borne nutrients, despite adequate blood volume and normal or elevated myocardial contractility. In high-output failure, the heart increases its output but the body's metabolic needs are still not met. Common causes of high-output failure are anemia, septicemia, hyperthyroidism, and beriberi (Figure 24-39).
Anemia decreases the oxygen-carrying capacity of the blood. Metabolic acidosis occurs as the body's cells switch to anaerobic metabolism (see Chapter 5). In response to metabolic acidosis, heart rate and stroke volume increase in an attempt to improve tissue perfusion. If anemia is severe, however, even maximum cardiac output does not supply the cells with enough oxygen for metabolism.

In septicemia, disturbed metabolism, bacterial toxins, and the inflammatory process cause systemic vasodilation and fever. Faced with a lowered systemic vascular resistance (SVR) and an elevated metabolic rate, cardiac output increases to maintain blood pressure and prevent metabolic acidosis. In overwhelming septicemia, however, the heart may not be able to raise its output enough to compensate for vasodilation. Body tissues show signs of inadequate blood supply despite a high cardiac output.

Hyperthyroidism accelerates cellular metabolism through the actions of elevated levels of thyroxine from the thyroid gland. This may occur chronically (thyrotoxicosis) or acutely (thyroid storm). Because the body's increased demand for oxygen threatens to cause metabolic acidosis, cardiac output increases. If blood levels of thyroxine are high and the metabolic response to thyroxine is vigorous, even an abnormally elevated cardiac output may be inadequate.

In the United States, beriberi (thiamine deficiency) usually is caused by
malnutrition secondary to chronic alcoholism. Beriberi actually causes a mixed type of heart failure. Thiamine deficiency impairs cellular metabolism in all tissues, including the myocardium. In the heart, impaired cardiac metabolism leads to insufficient contractile strength. In blood vessels, thiamine deficiency leads to peripheral vasodilation, which decreases SVR. Heart failure ensues as decreased SVR triggers increased cardiac output, which the impaired myocardium is unable to deliver. The strain of demands for increased output in the face of impaired metabolism may deplete cardiac reserves until low-output failure begins.

**Dysrhythmias**

A dysrhythmia, or arrhythmia, is a disturbance of heart rhythm. Normal heart rhythms are generated by the sinoatrial (SA) node and travel through the heart's conduction system, causing the atrial and ventricular myocardium to contract and relax at a regular rate that is appropriate to maintain circulation at various levels of physical activity (see Chapter 23). Dysrhythmias range in severity from occasional “missed” or rapid beats to serious disturbances that impair the pumping ability of the heart, contributing to heart failure and death. Dysrhythmias can be caused either by an abnormal rate of impulse generation (Table 24-9) from the SA node or other pacemaker or by the abnormal conduction of impulses (Table 24-10) through the heart's conduction system, including the myocardial cells themselves.

**Quick Check 24-10**

1. Why are changes in LVEDV important for left heart failure?
2. What is ventricular remodeling?
3. What is the vicious cycle of heart failure with preserved ejection fraction?

Shock

In shock the cardiovascular system fails to perfuse the tissues adequately, resulting in widespread impairment of cellular metabolism. Because tissue perfusion can be disrupted by any factor that alters heart function, blood volume, or blood pressure, shock has many causes and various clinical manifestations. Ultimately, however, shock progresses to organ failure and death, unless compensatory mechanisms reverse the process or clinical intervention succeeds. Untreated severe shock overwhelms the body's compensatory mechanisms through positive feedback loops that initiate and maintain a downward physiologic spiral.

The term multiple organ dysfunction syndrome (MODS) describes the failure of two or more organ systems after severe illness and injury and is a frequent complication of severe shock. The disease process is initiated and perpetuated by uncontrolled inflammatory and stress responses. It is progressive and is associated with significant mortality.

Impairment of Cellular Metabolism

The final common pathway in shock of any type is impairment of cellular metabolism. Figure 24-40 illustrates the pathophysiology of shock at the cellular level.
Impairment of Oxygen Use

In all types of shock, the cell either is not receiving an adequate amount of oxygen or is unable to use oxygen. Without oxygen, the cell shifts from aerobic to anaerobic metabolism. Anaerobic metabolism is a less efficient method of extracting energy from carbon bonds, and the cell begins to use its stores of adenosine triphosphate (ATP) faster than stores can be replaced. Without ATP, the cell cannot maintain an electrochemical gradient across its selectively permeable membrane. Specifically, the cell cannot operate the sodium-potassium pump. Sodium and chloride accumulate inside the cell, and potassium exits the cell. Cells of the nervous system and myocardium are profoundly and immediately affected. The resting potentials of these cells are reduced, and action potentials decrease in amplitude. Various clinical manifestations of impaired central nervous system and myocardial function result.

As sodium moves into the cell, water follows. Throughout the body, the water drawn from the interstitium into the cells is “replaced” by water that is, in turn, drawn out of the vascular space. This decreases circulatory volume. Within the cells, water causes cellular edema that disrupts cellular membranes, releasing lysosomal enzymes that injure the cells internally and then leak into the interstitium.
Compensatory mechanisms, including inflammation and activation of the clotting cascade, further impair oxygen use and contribute to the complications of shock, such as acute tubular necrosis (ATN), acute respiratory distress syndrome (ARDS), and disseminated intravascular coagulation (DIC).

In addition to decreasing ATP stores, anaerobic metabolism affects the pH of the cell, and metabolic acidosis develops. A compensatory mechanism enables cardiac and skeletal muscles to use lactic acid as a fuel source, but only for a limited time. The decreasing pH of the cell that is functioning anaerobically has serious consequences. Enzymes necessary for cellular function dissociate under acid conditions. Enzyme dissociation stops cell function, repair, and division. As lactic acid is released systemically, blood pH drops, reducing the oxygen-carrying capacity of the blood (see Chapter 4). Therefore less oxygen is delivered to the cells. Further acidosis triggers the release of more lysosomal enzymes because the low pH disrupts lysosomal membrane integrity.

**Impairment of Glucose Use**

Impaired glucose use can be caused by either impaired glucose delivery or impaired glucose uptake by the cells (see Figure 24-40). The reasons for inadequate glucose delivery are the same as those enumerated for inadequate oxygen delivery. In addition, in septic and anaphylactic shock, glucose metabolism may be increased or disrupted because of fever or bacteria, and glucose uptake can be prevented by the presence of vasoactive toxins, endotoxins, histamine, and kinins.

Some compensatory mechanisms activated by shock contribute to decreased glucose uptake by the cells. High serum levels of cortisol, thyroid hormone, and catecholamines account for hyperglycemia and insulin resistance, tachycardia, increased SVR, and increased cardiac contractility. Cells shift to glycogenolysis, gluconeogenesis, and lipolysis to generate fuel for survival (see Chapter 1). Except in the liver, kidneys, and muscles, the body's cells have extremely limited stores of glycogen. In fact, total body stores can fuel the metabolism for only about 10 hours. The depletion of fat and glycogen stores is not itself a cause of organ failure, but the energy costs of glycogenolysis and lipolysis are considerable and contribute to cell failure.

The depletion of protein also is a cause of organ failure. When gluconeogenesis causes proteins to be used for fuel, these proteins are no longer available to maintain cellular structure, function, repair, and replication. The breakdown of protein occurs in starvation states, hyperdynamic metabolic states, and septic shock. During anaerobic metabolism, protein metabolism liberates alanine, which is converted to pyruvate. In sepsis, pyruvic acid is changed into lactic acid, and a
positive feedback loop is formed. As proteins are broken down anaerobically, ammonia and urea are produced. Ammonia is toxic to living cells. Uremia develops, and uric acid further disrupts cellular metabolism. Serum albumin and other plasma proteins are consumed for fuel first. Serum protein consumption decreases capillary osmotic pressure and contributes to the development of interstitial edema, creating another positive feedback loop that decreases circulatory volume. In septic shock, plasma protein breakdown includes metabolism of immunoglobulins, thereby impairing immune system function when it is most needed.

Muscle wasting caused by protein breakdown weakens skeletal and cardiac muscle. Skeletal muscle wasting impairs the muscles that facilitate breathing. Muscle wasting therefore alters the actions of both the heart and the lungs. The delivery of oxygen and glucose to the cells is directly reduced, as is the removal of waste products, forming another positive feedback loop.

A final outcome of impaired cellular metabolism is the buildup of metabolic end products in the cell and interstitial spaces. Waste products are toxic to the cells and further disrupt cellular function and membrane integrity. Once a sufficiently large number of cells from vital organs have damage to cellular membranes, leakage of lysosomal enzymes, and depletion of ATP, shock can be irreversible.

**Clinical Manifestations of Shock**

The clinical manifestations of shock are variable depending on the type of shock, and observable and measurable signs and symptoms are often conflicting in nature. Subjective complaints in shock are usually nonspecific. The individual may report feeling sick, weak, cold, hot, nauseated, dizzy, confused, afraid, thirsty, and short of breath. Hypotension, characterized by a mean arterial pressure below 60 mm Hg, is common to almost all shock states; however, it is a late sign of decreased tissue perfusion. Cardiac output and urinary output are usually variable early in shock states but generally become decreased as the shock syndrome progresses. Respiratory rate is usually increased, and respiratory alkalosis may be an important early indicator of impending shock. Other variable indicators of shock include alterations of heart rate, core body temperature, skin temperature, systemic vascular resistance (SVR), and skin color. Altered sensorium may be another indicator of poor tissue perfusion. Decreased mixed venous oxygen saturation indicates poor tissue oxygenation and an alteration in cellular oxygen extraction and can be used to monitor response to therapy.
Treatment for Shock

The first treatment for shock is to discover and correct or remove the underlying cause. Simultaneously, management should begin directed at improvement in microcirculatory tissue perfusion. General supportive treatment includes administration of intravenous fluids to expand intravascular volume, use of vasopressors and supplemental oxygen, and control of glucose levels. Further treatment depends on the cause and severity of the shock syndrome, which is discussed with each type of shock. Once positive feedback loops are established, intervention in shock is difficult. Prevention and very early treatment offer the best prognosis.

Types of Shock

Shock is classified by cause as cardiogenic (caused by heart failure), hypovolemic (caused by insufficient intravascular fluid volume), neurogenic (caused by neural alterations of vascular smooth muscle tone), anaphylactic (caused by immunologic processes), or septic (caused by infection). As described previously, each of these share similar effects on tissues and cells but can vary in their clinical manifestations and severity.

Cardiogenic Shock

Cardiogenic shock is defined as decreased cardiac output and evidence of tissue hypoxia in the presence of adequate intravascular volume. Most cases of cardiogenic shock follow myocardial infarction, but shock also can follow left heart failure, dysrhythmias, acute valvular dysfunction, ventricular or septal rupture, myocardial or pericardial infections, massive pulmonary embolism, cardiac tamponade, and drug toxicity. Microcirculation changes within the myocardium contribute to decreased contractility and worsening cardiac output. Compensatory neurohumoral responses contribute to the overall pathophysiology (Figure 24-41).
The clinical manifestations of cardiogenic shock are caused by widespread impairment of cellular metabolism. They include impaired mentation, dyspnea and tachypnea, systemic venous and pulmonary edema, dusky skin color, marked hypotension, oliguria, and ileus. Management of cardiogenic shock includes careful fluid and vasopressor administration followed by early angiography, intra-aortic balloon pump counterpulsation, ventricular assist devices, extracorporeal membrane oxygenation, and early revascularization (PCI or bypass surgery). Cardiogenic shock is often unresponsive to treatment, with a mortality of more than
70% reported. New therapies being explored include anti-inflammatory drugs and nitric oxide synthase inhibitors.

**Hypovolemic Shock**

**Hypovolemic shock** is caused by loss of whole blood (hemorrhage), plasma (burns), or interstitial fluid (diaphoresis, diabetes mellitus, diabetes insipidus, emesis, diarrhea, or diuresis) in large amounts. Hypovolemic shock begins to develop when intravascular volume has decreased by about 15%.

Hypovolemia is offset initially by compensatory mechanisms (Figure 24-42). Heart rate and SVR increase, boosting both cardiac output and tissue perfusion pressures. Interstitial fluid moves into the vascular compartment. The liver and spleen add to blood volume by disgorging stored red blood cells and plasma. In the kidneys, renin stimulates aldosterone release and the retention of sodium (and hence water), whereas antidiuretic hormone (ADH) from the posterior pituitary gland increases water retention. However, if the initial fluid or blood loss is great or if loss continues, compensation fails, resulting in decreased tissue perfusion. As in cardiogenic shock, oxygen and nutrient delivery to the cells is impaired and cellular metabolism fails. Anaerobic metabolism and lactate production result in lactic acidosis and serum and cellular electrolyte abnormalities.
The clinical manifestations of hypovolemic shock include high SVR, poor skin turgor, thirst, oliguria, low systemic and pulmonary preloads, rapid heart rate, thready pulse, and mental status deterioration. The differences between the signs and symptoms of hypovolemic shock and those of cardiogenic shock are mainly caused by differences in fluid volume and cardiac muscle health. Management begins with rapid fluid replacement with crystalloids and blood products. For hemorrhagic hypovolemic shock, the administration of pharmacologic doses of ADH can improve blood pressure. Hypothermia and coagulopathies frequently complicate treatment. If adequate tissue perfusion cannot be restored promptly, systemic inflammation and multiple organ dysfunction are likely.

**Neurogenic Shock**
Neurogenic shock (sometimes called vasogenic shock) is the result of widespread and massive vasodilation that results from parasympathetic overstimulation and sympathetic understimulation (Figure 24-43) (see Chapter 23). This type of shock can be caused by any factor that stimulates parasympathetic or inhibits sympathetic stimulation of vascular smooth muscle. Trauma to the spinal cord or medulla and conditions that interrupt the supply of oxygen or glucose to the medulla can cause neurogenic shock by interrupting sympathetic activity. Depressive drugs, anesthetic agents, and severe emotional stress and pain are other causes. The loss of vascular tone results in “relative hypovolemia,” in which blood volume has not changed but SVR decreases drastically so that the amount of space containing the blood has increased. The pressure in the vessels falls below that which is needed to drive nutrients across capillary membranes to the cells. In addition, neurologic insult may cause bradycardia, which decreases cardiac output and further contributes to hypotension and underperfusion of tissues. As with other types of shock, this leads to impaired cellular metabolism. Management includes the careful use of fluids and vasopressors until blood pressure stabilizes.
**Anaphylactic Shock**

Anaphylactic shock results from a widespread hypersensitivity reaction known as **anaphylaxis**. The lifetime prevalence of anaphylaxis is 0.5% to 2%. The basic physiologic alteration is the same as that of neurogenic shock: vasodilation and relative hypovolemia, leading to decreased tissue perfusion and impaired cellular metabolism (Figure 24-44). Anaphylactic shock is characterized by other effects that rapidly involve the entire body.
Anaphylactic shock begins with exposure of a sensitized individual to an allergen. Common allergens known to cause these reactions are insect venoms, shellfish, peanuts, latex, and medications such as penicillin. In genetically predisposed individuals, these allergens initiate a vigorous humoral immune response (type I hypersensitivity reaction) that results in the production of large quantities of
immunoglobulin E (IgE) antibody (see Chapter 6). Allergen bound to IgE causes degranulation of mast cells. Mast cells release a large number of vasoactive and inflammatory cytokines. This provokes an extensive immune and inflammatory response, including vasodilation and increased vascular permeability, resulting in peripheral pooling and tissue edema. Extravascular effects include constriction of extravascular smooth muscle, often causing laryngospasm and bronchospasm (see Chapter 27) and cramping abdominal pain with diarrhea.

The onset of anaphylactic shock is usually sudden, and progression to death can occur within minutes unless emergency treatment is given. The primary clinical manifestations of anaphylaxis include anxiety, dizziness, difficulty breathing, stridor, wheezing, pruritus with hives (urticaria), swollen lips and tongue, and abdominal cramping. A precipitous fall in blood pressure occurs, followed by impaired mentation. Other signs include decreased SVR, with high or normal cardiac output, and oliguria. The diagnosis can be confirmed by a number of serum markers, such as plasma histamine and tryptase. Treatment begins with removal of the antigen (if possible). Epinephrine is administered intramuscularly to cause vasoconstriction and reverse airway constriction. Fluids are given intravenously to reverse the relative hypovolemia, and antihistamines and corticosteroids are administered to stop the inflammatory reaction. Vaspressors and inhaled β-adrenergic agonist bronchodilators may also be necessary.

</table>

In the United States, severe sepsis and septic shock occur in 2% of persons admitted to the hospital, of which half are treated in the intensive care unit (ICU), accounting for 10% of ICU admissions. Although death rates from septic shock have been declining, it remains a highly lethal condition. Septic shock can be caused by community-acquired or healthcare-associated infections, especially pneumonia, intra-abdominal, and urinary tract infections. Indwelling arterial and central venous catheters also are an important source of infection (see Health Alert: Central Line–Associated Bloodstream Infection). Bacteria cause most sepsis, with Staphylococcus aureus and Streptococcus pneumoniae as the most common gram-positive causes; and Escherichia coli, Klebsiella species, and Pseudomonas aeruginosa as the most common gram-negative causes. Septic shock also can be caused by fungi and viruses, and in almost one third of cases, the infectious organism is never identified. The source and virulence of the infectious microorganism, as well as the underlying health of the affected individual, significantly affect prognosis. Risk factors for septic shock include the individual's genetic composition, underlying chronic diseases, immune deficiency states, and timeliness of therapeutic interventions for infection.

Health Alert

Central Line–Associated Bloodstream Infection

Central line–associated bloodstream infection (CLABSI) is an important cause of
Sepsis and septic shock begins when bacteria enter the bloodstream to produce bacteremia. These bacteria and their associated toxins initiate an innate immune response. Gram-negative microorganisms release endotoxins, and gram-positive microorganisms release exotoxins, lipoteichoic acids, and peptidoglycans. These pathogen-associated molecular patterns (PAMPs), as well as molecules released from injured cells (damage-associated molecular patters), trigger the septic syndrome by interacting with pattern-associated receptors on macrophages, such as Toll-like receptor 2 (TLR-2) for gram-positive PAMPs and Toll-like receptor 4 (TLR-4) for gram-negative PAMPs (Figure 24-45)\(^ {148,151}\). These microbial molecules also activate complement, coagulation, kinins, and inflammatory cells.
The release of inflammatory mediators triggers intense cellular responses and the subsequent release of secondary mediators, including cytokines, complement fragments, prostaglandins, platelet-activating factor, oxygen free radicals, nitric oxide, and proteolytic enzymes. (see *Risk Factors: Proinflammatory Mediators Contributing to Septic Shock*). Chemotaxis, activation of granulocytes, and
reactivation of the phagocytic cells and inflammatory cascades result. This systemic inflammation, especially through the action of nitric oxide, leads to widespread vasodilation with compensatory tachycardia and increased cardiac output in the early stages of septic shock (hyperdynamic phase).\textsuperscript{151} Later in the course of disease, inflammatory mediators, such as complement and interleukins, depress myocardial contractility such that cardiac output falls and tissue perfusion decreases. Tissue perfusion and cellular oxygen extraction also are affected by activation of the clotting cascade through the action of platelet-activating factor and depletion of the endogenous anticoagulant protein C.\textsuperscript{148,151} Furthermore, unresponsiveness to or depletion of vasoactive factors such as vasopressin contributes to hypotension and tissue hypoperfusion. The inflammatory response can become overwhelming, leading to the systemic inflammatory response syndrome (SIRS).\textsuperscript{152} SIRS can progress to widespread tissue hypoxia, necrosis, and apoptosis, leading to septic shock and MODS. It has been determined that there is a parallel release of anti-inflammatory mediators and impairment of phagocytic and adaptive immune cell function that accompanies SIRS, causing a depression in the immune response to infection that contributes to the overall shock syndrome.\textsuperscript{148,152}

## Risk Factors

### Proinflammatory Mediators Contributing to Septic Shock

More than 100 inflammatory mediators have been implicated in the pathogenesis of septic shock. The following are some of the most important contributors:

**Tumor Necrosis Factor-alpha (TNF-α)**

Produced from macrophages, natural killer cells, and mast cells in response to endotoxin and interleukins

*Net effect:* generates same symptoms of septic shock as those seen with interleukins; thus is redundant

**Interleukin-1β (IL-1β)**

Released by macrophages and lymphocytes in septic shock in response to bacterial toxins

*Net effect:* produces fever, vasodilation and hypotension, edema, myocardial depression, and elevated white blood count
**Interleukin-6 (IL-6)**

Released by macrophages and lymphocytes during infection

*Net effect:* fever, elevated white blood count

**Nitric Oxide (NO)**

Released by activated macrophages and neutrophils

*Net effect:* damages tissues and causes systemic vasodilation and hypotension

**Platelet-Activating Factor (PAF)**

Released from mononuclear phagocytes, platelets, and some endothelial cells in response to endotoxin

*Net effect:* contributes to widespread clotting, generates same symptoms of shock as those seen with interleukins and tumor necrosis factor-alpha, and may initiate multiple organ failure

**Complement**

Activated by bacterial products and antigen/antibody complexes

*Net effect:* damages tissues and amplifies the inflammatory process by cellular chemotaxis and promotion of phagocytosis

Clinical manifestations of septic shock are the result of inflammation, decreased perfusion of vital tissues, and an alteration in oxygen extraction by all cells. In early shock, tachycardia causes cardiac output to remain normal or become elevated, although myocardial contractility is reduced. Temperature instability is present, ranging from hyperthermia to hypothermia. Effects on other organ systems may result in deranged renal function, jaundice, clotting abnormalities with disseminated intravascular coagulation (DIC), deterioration of mental status, and ARDS. Gastrointestinal mucosa changes cause the translocation of bacteria from the gut into the bloodstream. Increased permeability of the gut also can lead to increased inflammation and immune reactions attributable to toxins carried by the intestinal lymphatics.

The diagnosis of septic shock rests on the recognition of the systemic
manifestations of overwhelming inflammation (SIRS) in individuals with suspected or documented infection. Determining the cause and severity of septic shock can be aided by measurement of levels of serum lactate, troponin, C-reactive protein, and procalcitonin. The management of septic shock has improved outcomes by following the Surviving Sepsis Guidelines (see Health Alert: The Surviving Sepsis Guidelines). These guidelines include rapid goal-directed resuscitation with fluids and vasopressors, antibiotic administration, and respiratory support. Control of hyperglycemia with insulin, treatment of complications associated with MODS, careful nutritional support, and prevention of stress ulcers and deep venous thrombosis are also essential. Despite improvements in septic shock–related mortality in recent years, mortality remains high and new treatments are being explored.

---

**Health Alert**

**The Surviving Sepsis Guidelines**

Mortality rates for severe sepsis and septic shock have declined because of more rapid recognition of systemic infection and more effective management. Current Surviving Sepsis Guidelines for the management of sepsis were developed based on an in-depth analysis of the pathophysiology, clinical manifestations, and management outcomes reported over the past decade of sepsis care. The Guidelines provide a prioritized list of interventions that seek to quickly restore tissue perfusion, control infection, and support adequate oxygenation and ventilation. Intravenous infusion of fluids along with vasopressors, such as norepinephrine and vasopressin, is implemented quickly. Blood cultures, imaging modalities to determine the source of infection, and administration of appropriate antimicrobials are essential components of care. Respiratory support often includes mechanical ventilation, proper patient positioning, and careful monitoring of outcomes. Sedation is implemented as needed and general supportive care includes glucose management with insulin, stress ulcer prevention, and nutrition. These Surviving Sepsis Guidelines have improved morbidity and mortality outcomes for individuals with septic shock.

✅Quick Check 24-12
1. What are some of the important causes of septic shock?

2. What is the systemic inflammatory response syndrome?

3. Why is correction of the underlying problem the most important treatment for all kinds of shock?

**Multiple Organ Dysfunction Syndrome**

*Multiple organ dysfunction syndrome (MODS)* is the progressive dysfunction of two or more organ systems resulting from an uncontrolled inflammatory response to a severe illness or injury. The organ dysfunction can progress to organ failure and death (*Figure 24-46*). Although sepsis and septic shock are the most common causes, any severe injury or disease process that activates a massive systemic inflammatory response in the host can initiate MODS. These triggers include severe trauma, burns, acute pancreatitis, obstetric complications, major surgery, circulatory shock, some drugs, and gangrenous or necrotic tissue.

Multiple organ
dysfunction syndrome
(MODS)
MODS is a common cause of mortality in intensive care units. Mortality for individuals ranges from 36% to 100% if there is failure of five or more organs, with liver and kidney failure being the most common. People at greatest risk for developing MODS are elderly individuals and persons with significant tissue injury or preexisting disease (Box 24-3).

**Box 24-3**

**Other Common Triggers of MODS**

- Severe trauma
- Major surgery
- Burns
- Circulatory shock
- Acute pancreatitis
- Acute renal failure
- Acute respiratory distress syndrome
- Blood transfusion
- Heat stroke
- Liver failure
- Mesenteric ischemia
- Propofol infusion syndrome
- Persistent inflammatory foci
- Necrotic tissue
- Disseminated intravascular coagulation
Pathophysiology

As a result of the initiating insult (sepsis, injury, or disease), the neuroendocrine system is activated with the release of the stress hormones cortisol, epinephrine, and norepinephrine into the bloodstream (see Chapter 8). Vascular endothelial damage occurs as a direct result of injury or from damage by bacterial toxins and inflammatory mediators, such as nitric oxide, TNF, and IL-1, which are released into the circulation. The vascular endothelium becomes permeable, allowing fluid and protein to leak into the interstitial spaces, contributing to hypotension and hypoperfusion. Leakage of fluid into the lungs causes a condition called acute respiratory distress syndrome (ARDS). When the endothelium is damaged, platelets and tissue thromboplastin are activated, resulting in systemic microvascular coagulation that may lead to DIC (see Chapter 20).158

Because of the release of inflammatory mediators, four major plasma enzyme cascades are activated: complement, coagulation, fibrinolytic, and kallikrein/kinin. The overall effect of the activation of these cascades is a hyperinflammatory and hypercoagulant state that maintains the interstitial edema formation, cardiovascular instability, endothelial damage, and clotting abnormalities characteristic of MODS.159 A massive systemic immune/inflammatory response then develops involving neutrophils, macrophages, and mast cells (Table 24-12). The inflammatory process initiated is the same as that described in septic shock and SIRS (see p. 644) and sets the stage for MODS.

</table>
The numerous inflammatory and clotting processes operating in MODS cause maldistribution of blood flow and hypermetabolism. Oxygen delivery to the tissues decreases despite the supranormal systemic blood flow for several reasons:

1. Shunting of blood past selected regional capillary beds is caused when inflammatory mediators override the normal vascular tone.

2. Interstitial edema, resulting from microvascular changes in permeability, contributes to decreased oxygen delivery by creating a relative hypovolemia and by increasing the distance oxygen must travel to reach the cells.

3. Capillary obstruction occurs because of formation of microvascular thrombi and the aggregation of white blood cells.

Hypermetabolism in MODS with accompanying alterations in carbohydrate, fat, and lipid metabolism is initially a compensatory measure to meet the body's increased demands for energy. The alterations in metabolism affect all aspects of substrate utilization. The net result of hypermetabolism is depletion of oxygen and fuel supplies.

Myocardial depression also accompanies MODS. The cause is unclear but inflammatory cytokines, bacterial products, and ischemia have been implicated. Decreased cardiac output contributes to poor perfusion of tissues and exacerbation of MODS.

Maldistribution of blood flow, coagulation, myocardial depression, ARDS, and the hypermetabolic state combine to create an imbalance in oxygen supply and demand. This imbalance is critical in the pathogenesis of MODS because it results in a pathologic condition known as supply-dependent oxygen consumption. Ordinarily, the amount of oxygen consumed by the cells depends only on the demands of the cells, because there is an adequate reserve of oxygen that can be delivered if needed. The reserve, however, has been exhausted in MODS, and the amount of oxygen consumed becomes dependent on the amount the circulation is able to deliver; this amount is inadequate in MODS. Therefore tissue hypoxia with cellular acidosis and impaired cellular function ensue and result in multiple organ failure.

Clinical manifestations
There may be a lag time between the inciting event and the onset of symptoms that may last for as long as 24 hours. The individual develops a low-grade fever, tachycardia, dyspnea, altered mental status, and hyperdynamic and hypermetabolic
states. ARDS is often an early manifestation of MODS (see Chapter 27) and is characterized by tachypnea, pulmonary edema with crackles and diminished breath sounds, use of accessory muscles, and hypoxemia.

As the syndrome continues, hypermetabolic and hyperdynamic states intensify and signs of liver and kidney failure appear. Liver failure presents with jaundice, abdominal distention, liver tenderness, muscle wasting, and hepatic encephalopathy. All facets of metabolism, substance detoxification, and immune response are impaired; albumin and clotting factor synthesis decreases; protein wastes accumulate; and liver tissue macrophages (Kupffer cells) no longer function effectively. Progressive oliguria, azotemia, and edema mark the development of renal failure. Anuria, hyperkalemia, and metabolic acidosis may occur if renal shutdown is severe.

The gastrointestinal system also shows evidence of dysfunction. The gastrointestinal system is sensitive to ischemic and inflammatory injury. Clinical manifestations of bowel involvement are hemorrhage, ileus, malabsorption, diarrhea or constipation, vomiting, anorexia, and abdominal pain. Stress ulceration of the stomach lining is a common complication of shock and MODS and, although usually painless, can result in massive blood loss and death. Compounding the damage caused by injury to the bowel is the phenomenon of bacterial translocation. When mediators and severe ischemia injure the mucosal epithelium, bacteria and toxins pass from the gut into the portal circulation. The overwhelmed liver is unable to clear these products and they move into the systemic circulation. Thus, whether infection or some other injury was the precipitating cause of MODS, sepsis occurs once the gut barrier is damaged.

Hematologic failure and myocardial failure are usually later manifestations. The signs and symptoms of cardiac failure in the hypermetabolic, hyperdynamic phase of MODS are similar to those of septic shock: tachycardia, bounding pulse, increased cardiac output, decreased systemic vascular resistance, and hypotension. In the terminal stages, hypodynamic circulation with bradycardia, profound hypotension, and ventricular dysrhythmias may develop. Encephalopathy, characterized by mental status changes ranging from confusion to deep coma, may occur at any time. Ischemia and inflammation are responsible for the central nervous system manifestations, which include apprehension, confusion, disorientation, restlessness, agitation, headache, decreased cognitive ability and memory, and decreased level of consciousness. When ischemia is severe, seizures and coma can occur. Death may occur as early as 14 days or after a period of several weeks.

**Evaluation and treatment**
Early detection of organ failure is extremely important so that supportive measures can be initiated immediately. Frequent assessment of the clinical status of individuals at known risk is essential. The Acute Physiology and Chronic Health Evaluation (APACHE) II and III systems assess for severity and progression of MODS. Once organ failure develops, monitoring of laboratory values and hemodynamic parameters also can be used to assess the degree of impairment.

There is no specific treatment for MODS and therapeutic management consists of prevention and support. Prevention consists of controlling the initial insult, treating infections quickly, and supporting healing. Management goals include controlling infection, restoring oxygenation and perfusion, and supporting organ function. Sources of infection are removed and antimicrobials are administered. Ventilatory support is initiated to maintain adequate oxygen saturation and fluids are administered to maintain vascular volume. Nutritional support must be provided to meet metabolic demand. Dialysis also may be required.

Quick Check 24-13

1. Why can MODS be initiated by either a septic or a nonseptic insult?

2. Why are inflammation and clotting triggered when the vascular endothelium is injured?

3. Describe the mechanisms that result in decreased oxygen delivery to the tissues in MODS.
Did You Understand?

Diseases of the Veins and Arteries

1. Varicosities are areas of veins in which blood has pooled, usually in the saphenous veins. Varicosities may be caused by damaged valves as a result of trauma to the valve or by chronic venous distention involving gravity and venous constriction.

2. Chronic venous insufficiency is inadequate venous return over a long period of time that causes pathologic ischemic changes in the vasculature, skin, and supporting tissues.

3. Venous stasis ulcers follow the development of chronic venous insufficiency and probably develop as a result of the borderline metabolic state of the cells in the affected extremities.

4. Deep venous thrombosis results from stasis of blood flow, endothelial damage, or hypercoagulability. The most serious complication of deep venous thrombosis is pulmonary embolism.

5. Superior vena cava syndrome is a progressive occlusion of the superior vena cava that leads to venous distention in the upper extremities and head. Because this syndrome is usually caused by bronchogenic cancer, it is generally considered an oncologic emergency rather than a vascular emergency.

6. Hypertension is the elevation of systemic arterial blood pressure resulting from increases in cardiac output (blood volume), total peripheral resistance, or both.

7. Hypertension can be primary, without a known cause, or secondary, caused by an underlying disease.

8. The risk factors for hypertension include a positive family history; male gender; advancing age; black race; obesity; high sodium intake; low magnesium, potassium, or calcium intake; diabetes mellitus; cigarette smoking; and heavy alcohol consumption.

9. The exact cause of primary hypertension is unknown, although several hypotheses are proposed, including overactivity of the sympathetic nervous system; overactivity of the renin-angiotensin-aldosterone system; sodium and water
retention by the kidneys; hormonal inhibition of sodium-potassium transport across cell walls; and complex interactions involving insulin resistance, inflammation, and endothelial function.

10. Clinical manifestations of hypertension result from damage of organs and tissues outside the vascular system. These include retinal changes, heart disease, renal disease, and central nervous system disorders, such as stroke and dementia.

11. Hypertension is managed with both pharmacologic and nonpharmacologic methods that lower the blood volume and the total peripheral resistance.

12. Orthostatic hypotension is a drop in blood pressure that occurs on standing. The compensatory vasoconstriction response to standing is replaced by a marked vasodilation and blood pooling in the muscle vasculature.

13. The clinical manifestations of orthostatic hypotension include fainting and may involve cardiovascular symptoms, as well as impotence and bowel and bladder dysfunction.

14. An aneurysm is a localized dilation of a vessel wall; the aorta is particularly susceptible.

15. A thrombus is a clot that remains attached to a vascular wall. An embolus is a mobile aggregate of a variety of substances that occludes the vasculature. Sources of emboli include clots, air, amniotic fluid, bacteria, fat, and foreign matter. These emboli cause ischemia and necrosis when a vessel is totally blocked.

16. The most common source of arterial thrombotic emboli is the heart as a result of mitral and aortic valvular disease and atrial fibrillation, followed by myxomas. Tissues affected include the lower extremities, the brain, and the heart.

17. Emboli to the central organs cause tissue death in lungs, kidneys, and mesentery.

18. Peripheral vascular diseases include Buerger disease and Raynaud phenomenon, involving arterioles of the extremities.

19. Atherosclerosis is a form of arteriosclerosis and is the leading contributor to coronary artery disease (CAD) and cerebrovascular disease (CVD).

20. Atherosclerosis is an inflammatory disease that begins with endothelial injury.
21. Important steps in atherogenesis include vasoconstriction, adherence of macrophages, release of inflammatory mediators, oxidation of LDL, formation of foam cells and fatty streaks, and development of fibrous plaque.

22. Once a plaque has formed, it can rupture, resulting in clot formation and instability and vasoconstriction, which lead to obstruction of the lumen and inadequate oxygen delivery to tissues.

23. Peripheral artery disease is the result of atherosclerotic plaque formation in the arteries that supply the extremities, and it causes pain and ischemic changes in the nerves, muscles, and skin of the affected limb.

24. Coronary artery disease (CAD) is the result of an atherosclerotic plaque that gradually narrows the coronary arteries or that ruptures and causes sudden thrombus formation.

25. Many risk factors contribute to the onset and escalation of CAD, including traditional risk factors such as dyslipidemia, smoking, hypertension, diabetes mellitus (insulin resistance), and obesity/sedentary lifestyle and nontraditional risk factors such as elevated C-reactive protein levels, hyperhomocysteinemia, and changes in adipokines.

26. Ischemic heart disease is most commonly the result of coronary artery disease and the ensuing decrease in myocardial blood supply.

27. Atherosclerotic plaque progression can be gradual and cause stable angina pectoris, which is predictable chest pain caused by myocardial ischemia in response to increased demand (e.g., exercise) without infarction.

28. Prinzmetal angina results from coronary artery vasospasm.

29. Myocardial ischemia may be asymptomatic, which is called silent ischemia, and is a risk factor for the development of the acute coronary syndromes.

30. Sudden coronary obstruction because of thrombus formation causes the acute coronary syndromes. These include unstable angina, non-ST elevation myocardial infarction (non-STEMI), and ST elevation myocardial infarction (STEMI).

31. Unstable angina results in reversible myocardial ischemia.

32. Myocardial infarction is caused by prolonged, unrelieved ischemia that
interrupts blood supply to the myocardium. After about 20 minutes of myocardial ischemia, irreversible hypoxic injury causes cellular death and tissue necrosis.

33. Myocardial infarction is clinically classified as non-STEMI or STEMI based on electrocardiographic findings that suggest the extent of myocardial damage (subendocardial versus transmural).

34. An increase in plasma enzyme levels is used to diagnose the occurrence of myocardial infarction as well as indicate its severity. Elevations of the isoenzymes creatine kinase-myocardial bound (CK-MB), troponins, and lactate dehydrogenase 1 (LDH-1) are most predictive of a myocardial infarction.

35. Treatment of a myocardial infarction includes revascularization (thrombolytics or PCI) and administration of antithrombotics, ACE inhibitors, and beta-blockers. Pain relief and fluid management also are key components of care. Dysrhythmias and cardiac failure are the most common complications of acute myocardial infarction.

**Disorders of the Heart Wall**

1. Inflammation of the pericardium, or pericarditis, may result from several sources (infection, drug therapy, tumors). Pericarditis presents with symptoms that are physically troublesome, but in and of themselves they are not life-threatening.

2. Fluid may collect within the pericardial sac (pericardial effusion). Cardiac function may be severely impaired if the accumulation of fluid occurs rapidly and involves a large volume.

3. Cardiomyopathies are a diverse group of primary myocardial disorders that are usually the result of remodeling, neurohumoral responses, and hypertension. The cardiomyopathies are categorized as dilated (congestive), restrictive (rigid and noncompliant), and hypertrophic (asymmetric). The size of the cardiac muscle walls and chambers may increase or decrease depending on the type of cardiomyopathy, thereby altering contractile activity.

4. The hemodynamic integrity of the cardiovascular system depends to a great extent on properly functioning cardiac valves. Congenital or acquired disorders that result in stenosis, regurgitation, or both can structurally alter the valves.

5. Characteristic heart sounds, cardiac murmurs, and systemic complaints assist in
identification of an abnormal valve. If severely compromised function exists, a prosthetic heart valve may be surgically implanted to replace the faulty one.

6. Mitral valve prolapse (MVP) describes the condition in which the mitral valve leaflets do not position themselves properly during systole. Mitral valve prolapse may be a completely asymptomatic condition or can result in unpredictable symptoms.

7. Rheumatic fever is an inflammatory disease that results from a delayed immune response to a streptococcal infection in genetically predisposed individuals. The disorder usually resolves without sequelae if treated early.

8. Severe or untreated cases of rheumatic fever may progress to rheumatic heart disease, a potentially disabling cardiovascular disorder.

9. Infective endocarditis is a general term for infection and inflammation of the endocardium, especially the cardiac valves. In the mildest cases, valvular function may be slightly impaired by vegetations that collect on the valve leaflets. If left unchecked, severe valve abnormalities, chronic bacteremia, and systemic emboli may occur as vegetations detach from the valve surface and travel through the bloodstream. Antibiotic therapy can limit the extension of this disease.

10. Human immunodeficiency virus (HIV) infection and AIDS are associated with cardiac abnormalities, including myocarditis, endocarditis, pericarditis, and cardiomyopathy.

**Manifestations of Heart Disease**

1. A dysrhythmia (arrhythmia) is a disturbance of heart rhythm. Dysrhythmias range in severity from occasional missed beats or rapid beats to disturbances that impair myocardial contractility and are life-threatening.

2. Dysrhythmias can occur because of an abnormal rate of impulse generation or an abnormal conduction of impulses.

3. Heart failure (HF) can be divided into heart failure with reduced ejection fraction (systolic) and heart failure with preserved ejection fraction (diastolic).

4. The most common causes of left ventricular failure are myocardial infarction and hypertension.
5. Heart failure with reduced ejection fraction (systolic) is caused by increased preload, decreased contractility, or increased afterload. These processes result in an increased left ventricular end-diastolic volume and an increased left ventricular end-diastolic pressure that cause increased pulmonary venous pressures and pulmonary edema.

6. In addition to the hemodynamic changes of left ventricular failure, there is a neuroendocrine response that tends to exacerbate and perpetuate the condition.

7. The neuroendocrine mediators of heart failure include the sympathetic nervous system and the renin-angiotensin-aldosterone system; thus diuretics, beta-blockers, and angiotensin-converting enzyme (ACE) inhibitors are important components of the pharmacologic therapy.

8. Heart failure with preserved ejection fraction (diastolic heart failure) is a clinical syndrome characterized by the symptoms and signs of heart failure, a preserved ejection fraction, and abnormal diastolic function.

9. Diastolic dysfunction means that the left ventricular end-diastolic pressure is increased, even if volume and cardiac output are normal.

10. Right heart failure can result from left heart failure or pulmonary disease.

**Shock**

1. Shock is a widespread impairment of cellular metabolism involving positive feedback loops that places the individual on a downward physiologic spiral leading to multiple organ dysfunction syndrome.

2. Types of shock are cardiogenic, hypovolemic, neurogenic, anaphylactic, and septic. Multiple organ dysfunction syndrome can develop from all types of shock.

3. The final common pathway in all types of shock is impaired cellular metabolism — cells switch from aerobic to anaerobic metabolism. Energy stores drop, and cellular mechanisms relative to membrane permeability, action potentials, and lysozyme release fail.

4. Anaerobic metabolism results in activation of the inflammatory response, decreased circulatory volume, and decreasing pH.
5. Impaired cellular metabolism results in cellular inability to use glucose because of impaired glucose delivery or impaired glucose intake, resulting in a shift to glycogenolysis, gluconeogenesis, and lipolysis for fuel generation.

6. Glycogenolysis is effective for about 10 hours. Gluconeogenesis results in the use of proteins necessary for structure, function, repair, and replication that leads to more impaired cellular metabolism.

7. Gluconeogenesis contributes to lactic acid, uric acid, and ammonia buildup, interstitial edema, and impairment of the immune system, as well as general muscle weakness, leading to decreased respiratory function and cardiac output.

8. Cardiogenic shock is decreased cardiac output, tissue hypoxia, and the presence of adequate intravascular volume.

9. Hypovolemic shock is caused by loss of blood or fluid in large amounts. The use of compensatory mechanisms may be vigorous, but tissue perfusion ultimately decreases and results in impaired cellular metabolism.

10. Neurogenic shock results from massive vasodilation, causing a relative hypovolemia even though cardiac output may be high, and leads to impaired cellular metabolism.

11. Anaphylactic shock is caused by physiologic recognition of a foreign substance. The inflammatory response is triggered, and a massive vasodilation with fluid shift into the interstitium follows. The relative hypovolemia leads to impaired cellular metabolism.

12. Septic shock begins with impaired cellular metabolism caused by uncontrolled sepsis. The infecting agent triggers the inflammatory and immune responses. This inflammatory response is accompanied by widespread changes in tissue and cellular function.

13. Multiple organ dysfunction syndrome (MODS) is the progressive failure of two or more organ systems after a severe illness or injury. It can be triggered by chronic inflammation, necrotic tissue, severe trauma, burns, adult respiratory distress syndrome, acute pancreatitis, and other severe injuries.

14. MODS involves the stress response; changes in the vascular endothelium resulting in microvascular coagulation; release of complement, coagulation, and
kinin proteins; and numerous inflammatory processes. Consequences of all these mediators are a maldistribution of blood flow, hypermetabolism, hypoxic injury, and myocardial depression.

15. Clinical manifestations of MODS include inflammation, tissue hypoxia, and hypermetabolism. All organs can be affected including the kidney, lung, liver, gastrointestinal tract, and central nervous system.

Cardiovascular disorders in children are classified as congenital or acquired. Congenital heart disease is the most common. The diagnosis and management of congenital heart disease continues to improve with the use of fetal echocardiography and early interventional catheterization or surgical repair. Acquired heart disease in children continues to present challenges to the practitioner. Although guidelines for diagnosing acquired diseases are available, work is still needed in developing standards of treatment and long-term follow-up protocols.
Congenital Heart Disease

The incidence of congenital heart disease (CHD) varies from 4 to 8 per 1000 live births and is the major cause of death in the first year of life other than prematurity. Several environmental and genetic risk factors are associated with the incidence of different types of CHD. Among the environmental factors are (1) maternal conditions, such as intrauterine viral infections (especially rubella), diabetes mellitus, phenylketonuria, alcoholism, hypercalcemia, drugs (e.g., thalidomide, phenytoin), and complications of increased age; (2) antepartal bleeding; and (3) prematurity (Table 25-1).

Genetic factors also have been implicated in the incidence of CHD, although the mechanism of causation is often unknown (Table 25-2). The incidence of CHD is three to four times higher in siblings of affected children, and chromosomal defects account for about 6% of all cases of CHD. Down syndrome, trisomies 13 and 18, Turner syndrome, and cri du chat syndrome (chromosome 5p deletion syndrome) have been associated with a relatively high incidence of heart defects. Only a small percentage of cases of CHD are clearly linked solely to genetic or environmental factors. There also are multiple hereditary and nonhereditary syndromes that are associated with cardiovascular abnormalities in children. However, the cause of most defects is multifactorial.

From Park MK: *Pediatric cardiology for practitioners*, ed 6, St Louis, 2014, Mosby.

Congenital heart defects can be categorized according to (1) whether the defect causes cyanosis, (2) whether the defect causes increased or decreased blood flow into the pulmonary circulation, and (3) whether the defect causes obstruction of blood flow from the ventricles (Figure 25-1). The normal movement of blood through the right side of the heart and into the pulmonary system is separate from the blood flow through the left side of the heart into the systemic circulation (Figure 25-2, A). Abnormal movement from one side of the heart to the other is termed a shunt. Shunting of blood flow from the left heart into the right heart is called a **left-to-right shunt** and occurs in conditions such as atrial septal defect and ventricular septal defect (see Figure 25-2, B). This increases blood flow into the pulmonary circulation. Because blood continues to flow through the lungs before passing into the systemic circulation, there is no decrease in tissue oxygenation or cyanosis. Thus defects that cause left-to-right shunt are termed **acyanotic heart defects**. Other types of acyanotic heart defects obstruct blood flow from the ventricles but do not cause shunting. **Cyanotic heart defects** frequently cause shunting of blood from the right side of the heart directly into the left side of the heart (**right-to-left shunt**). This type of shunt decreases blood flow through the pulmonary system, causing less than normal oxygen delivery to the tissues and resultant cyanosis (see Chapter 27). Tetralogy of Fallot (TOF) occurs in 5% to 10% of all CHD and is the most common cyanotic heart defect. In this condition, narrowing of the pulmonary outflow tract increases right heart pressures, thus forcing blood through a defect in the ventricular septum into the left heart (see Figure 25-2, C). **Cyanosis**, a bluish discoloration of the skin indicating that tissues are not receiving normal amounts of oxygen, also can be caused by other types of heart defects that result in the mixing of venous and arterial blood that enter the systemic circulation.
Most congenital heart defects are named to describe the underlying defect (for example, valvular abnormalities; abnormal openings in the septa, including persistence of the foramen ovale; continued patency of the ductus arteriosus; and malformation or abnormal placement of the great vessels). Descriptions of the most common defects follow.

**Obstructive Defects**

**Coarctation of the Aorta**

**Pathophysiology**
Coarctation of the aorta (COA) is an abnormal localized narrowing of the aorta just proximal to the insertion of the ductus arteriosus. Before birth, the ductus arteriosus bypasses this obstruction and allows for blood to flow from the pulmonary artery into the distal aorta. However, once the ductus functionally closes within 15 hours after birth, blood flow to the lower extremities is then restricted by the coarctation. Clinically, there is increased blood pressure proximal to the defect (head and upper extremities, right greater than left) and decreased blood pressure distal to the obstruction (torso and lower extremities) (Figure 25-3).
**FIGURE 25-3** Postductal and Preductal Coarctation of the Aorta. A, Postductal coarctation occurs distal to (“after”) the insertion of the closed ductus arteriosus into the aortic arch. Preductal coarctation occurs proximal to (“before”) the insertion of the patent ductus arteriosus. The coarctation consists of a flap of tissue that protrudes from the tunica media of the aortic wall. B, Coarctation of the aorta with typical indentation of the aortic wall (arrow) opposite the ductal arterial ligament (asterisk). Ao, Aorta. (A from Hockenberry M.J, Wilson D: Wong’s essentials of pediatric nursing, ed 9, St Louis, 2013, Mosby; B from Damjanov I, Linder J, editors: Anderson’s pathology, ed 10, St Louis, 1996, Mosby.)
Clinical manifestations

The location and severity of the COA determine whether an infant will become symptomatic after the ductus arteriosus closes. If the COA is severe, infants will present with low cardiac output, poor tissue perfusion, acidosis, and hypotension. Physical examination of the infant will reveal weak or absent femoral pulses. Some infants with COA will remain asymptomatic after the closure of the ductus arteriosus. As they age, children with undiagnosed COA will present with unexplained upper extremity hypertension. Children may complain of leg pain or cramping with exercise. Although rare, they also may experience dizziness, headaches, fainting, or epistaxis from hypertension.\(^1,2\)

Evaluation and treatment

Physical examination and measurement of upper and lower extremity blood pressures will often suggest the diagnosis. Echocardiography, magnetic resonance imaging (MRI), and cardiac catheterization may be needed to confirm the diagnosis. Initial treatment in the symptomatic newborn consists of continuous intravenous infusion of prostaglandin E\(_1\) to maintain the patency of the ductus arteriosus. Once the symptomatic newborn is stabilized, surgical correction is indicated.\(^3\)

Surgical correction consists of either resection of the narrowed portion of the aorta with an end-to-end anastomosis or enlargement of the constricted section using a graft taken from a portion of the left subclavian artery. Because this defect is outside the heart and pericardium, cardiopulmonary bypass usually is not required and a thoracotomy incision is used. However, coarctation repair may be part of a more complex operation, which might require a sternotomy incision and cardiopulmonary bypass. Postoperative hypertension is treated with intravenous medication, often a short-acting beta-blocker, followed by oral medications, such as an angiotensin-converting enzyme inhibitor. Residual hypertension after repair of COA seems to be related to age and time of repair.

Studies have shown percutaneous balloon angioplasty with or without the use of a stent to be an effective, less invasive option for treating native COA or for reducing residual postoperative coarctation in most children.\(^1,2,4\) Balloon angioplasty of COA as an initial intervention can also be considered. However, in infants younger than 6 months of age, most will experience recoarctation in only a short period of time after primary angioplasty. Other complications include aneurysm formation and blood vessel injury from arterial access. Data exist that support balloon angioplasty as an effective therapy in selected infants older than 6 months of age with a decreased risk of aneurysm formation as compared to younger infants.\(^4\)
Aortic Stenosis

Pathophysiology

Aortic stenosis (AS) is a narrowing or stricture of the left ventricular outlet, causing resistance of blood flow from the left ventricle into the aorta (Figure 25-4). The physiologic consequence of severe AS is hypertrophy of the left ventricular wall, which eventually leads to increased end-diastolic pressure, resulting in pulmonary venous and pulmonary arterial hypertension. If severe, there may be decreased cardiac output and pulmonary vascular congestion. Left ventricular hypertrophy impedes coronary artery perfusion and may result in subendocardial ischemia and associated papillary muscle dysfunction that cause mitral insufficiency.

There are three types of AS. Valvular AS occurs as a consequence of malformed or fused cusps, resulting in a unicuspid or bicuspid valve. Valvular AS is a serious defect because (1) the obstruction tends to be progressive; (2) there may be sudden episodes of myocardial ischemia or low cardiac output that, on rare occasions, can result in sudden death in late childhood or adolescence; and (3) surgical repair will not result in a normal valve. This is one of the rare forms of congenital heart disease in which strenuous physical activity may be curtailed because of the cardiac condition.\(^1\,\text{2}\)
**Subvalvular AS** is a stricture caused by a fibrous ring below a normal valve. It can also be caused by a narrowed left ventricular outflow tract in combination with a small aortic valve annulus. **Supravalvular AS**, a narrowing of the aorta just above the valve, occurs infrequently. It can occur as a single defect (familial supravalvular stenosis syndrome) or as a part of Williams syndrome, which also is characterized by unusual elfin-like facial appearance and mental disability.²

**Clinical manifestations**

Infants with significant AS demonstrate signs of decreased cardiac output with faint pulses, hypotension, tachycardia, and poor feeding. A loud, harsh systolic ejection murmur is expected. Older children also may have complaints of exercise intolerance and, rarely, chest pain. Children are at risk for bacterial endocarditis, although prophylaxis with antibiotics is no longer routinely recommended (see **Health Alert**: Endocarditis Risk). Aortic stenosis, when severe, also can be complicated by coronary insufficiency, ventricular dysfunction, and, rarely, sudden death.

**Health Alert**

**Endocarditis Risk**

Children with CHD are at risk for developing endocarditis. Although the risk is low, a transient bacteremia has been noted to follow dental and surgical procedures and instrumentation involving mucosal surfaces. A blood-borne pathogen can inhabit areas of the heart where there is high turbulence (such as an abnormal valve or vessel) or reside on artificial material (such as a valve or homograft). *Streptococcus viridans* (α-hemolytic streptococci) is the most commonly found pathogen following dental or oral procedures. *Enterococcus faecalis* (enterococci) is the most common bacterium found following genitourinary and gastrointestinal tract surgery or instrumentation. The American Heart Association has provided updated guidelines for the prevention of bacterial endocarditis. The type and dose of antibiotic prophylaxis recommended depend on the procedure and the cardiac classification of risk for endocarditis. Good dental hygiene with daily brushing and flossing is critically important along with regular dental check-ups.

Data from the American Heart Association: available at www.americanheart.org.

**Evaluation and treatment**

Valvular aortic stenosis (AS) diagnosis is confirmed by echocardiography. Mild to
moderate valvular AS does not usually require intervention or restriction of activity. Treatment of severe valvular AS varies, with nonsurgical palliation the initial treatment of choice by many interventional cardiologists. Dilation of the stenotic valve with balloon angioplasty, which is performed in the cardiac catheterization laboratory, still carries a high morbidity and mortality in the critically ill neonate; however, in older infants and children it compares favorably with surgical valvotomy. Balloon angioplasty is, however, associated with the risk of aortic regurgitation (insufficiency). Children undergoing this procedure almost always require surgical intervention at some time to relieve recurrent narrowing or worsening regurgitation.

Surgical treatment for valvular AS depends on the severity of the stenosis, previous interventions, and age of the child. Aortic valve commissurotomy or valvotomy may be used as an early intervention. Aortic valve replacement may be required if the valve is severely dysplastic. The Ross procedure, which involves moving the native pulmonary valve (autograft) into the aortic position and replacing the pulmonary valve with an allograft (cadaver), and coronary artery reimplantation have become an option. The advantage of the Ross procedure over mechanical valve replacement, especially in a young child, is that there is no requirement for long-term anticoagulation therapy; however, the valve may fail with time. Mechanical valve replacement is usually deferred as long as possible to minimize the number of valve replacements related to growth. Aortic stenosis requires lifelong evaluation and treatment. Multiple surgical or catheterization interventions are expected. Mortality for sick infants and young children is higher than that for older children.

Subvalvular Aortic Stenosis. Surgical correction for subvalvular as involves incising the constricting fibromuscular ring, if the obstruction results from a narrow left ventricular outflow tract and a small aortic valve annulus, a patch may be required to enlarge the entire left ventricular outflow tract and annulus and replace the aortic valve, an approach known as the Konno procedure. An aortic homograft with a valve also may be used (extended aortic root replacement).

Supravalvular Aortic Stenosis. Surgery is usually required for management of moderate-to-severe supravalvular AS. Balloon angioplasty and stent insertion have been successful but carry a higher risk of rupture. An extended graft with coronary reimplantation may be needed if narrowing is severe.

**Pulmonic Stenosis**

**Pathophysiology**

**Pulmonic stenosis (PS)** is a narrowing or stricture of the pulmonary valve that
causes resistance to blood flow from the right ventricle to the pulmonary artery (Figure 25-5). Generally moderate to severe stenosis causes right ventricular hypertrophy. **Pulmonary atresia** is an extreme form of PS with total fusion of the valve leaflets (blood cannot flow to the lungs); the right ventricle may be hypoplastic. In some cases of right ventricular outflow obstruction, the narrowing is below the valve (infundibular or subvalve PS).

**Clinical manifestations**

Most infants are asymptomatic if the PS is mild to moderate. Newborns with severe PS or pulmonary atresia will be cyanotic (from a right-to-left shunt through an atrial septal defect [ASD]) and may have signs of decreased cardiac output. A harsh systolic murmur is expected with PS. Pulmonary atresia produces a continuous murmur.

**Evaluation and treatment**

Echocardiography confirms the diagnosis and determines the severity of the PS. The treatment of choice for infants with moderate to severe pulmonary stenosis is balloon angioplasty (see Figure 25-5, B). A catheter with a special balloon device is used to dilate the area of narrowing. Multiple studies have proven the effectiveness and safety of balloon angioplasty in reducing the pressure gradient across the
In rare cases, surgical valvotomy may be required. Pulmonary blood flood is supported with prostaglandin E₁ infusion to maintain the patency of the ductus arteriosus in cases of pulmonary atresia with right ventricle–dependent coronary circulation in the neonatal period until surgery is performed to supply pulmonary blood flow.⁴

Both balloon dilation and surgical valvotomy leave the pulmonary valve incompetent (insufficient); however, most children are usually able to tolerate pulmonary valve incompetence and are asymptomatic. Long-term problems with restenosis are rare for uncomplicated PS.¹,²,⁴ However, clinically significant valve incompetence that results in right ventricle dilation and dysfunction may occur, requiring surgical intervention.¹,²,⁴

Defects with Increased Pulmonary Blood Flow

Patent Ductus Arteriosus

Pathophysiology

Patent ductus arteriosus (PDA) is failure of the fetal ductus arteriosus (artery connecting the aorta and pulmonary artery) to functionally close within the first 15 hours after birth. However, several weeks after birth (Figure 25-6) may be needed for attainment of true anatomic closure, in which the ductus loses the ability to reopen. The continued patency of this vessel allows blood to flow from the higher pressure aorta to the lower pressure pulmonary artery, causing a left-to-right shunt.
Clinical manifestations

Infants may be asymptomatic or show signs of pulmonary overcirculation, such as dyspnea, fatigue, and poor feeding. There is a characteristic machinery-like murmur in both systole and diastole. Aortic flow (run-off) into the lower pressure pulmonary circulation produces low diastolic blood pressure, widened pulse pressure, and bounding pulses. Children are at risk for bacterial endocarditis and may develop pulmonary hypertension in later life from chronic excessive pulmonary blood flow.
Evaluation and treatment

Diagnosis is confirmed with echocardiography. Administration of indomethacin (a prostaglandin inhibitor) has proved successful in closing a PDA in premature infants and some newborns. Surgical division of the PDA through a left thoracotomy also may be done; in some cases the procedure can be performed with thoracoscopy. Closure with an occlusion device during cardiac catheterization is performed in select children older than 6 months of age. Both surgical and nonsurgical procedures are considered low risk.²,⁴

Atrial Septal Defect

Pathophysiology

An atrial septal defect (ASD) is an opening in the septal wall between the two atria. This opening allows blood to shunt from the left atrium to the right atrium. There are three types of ASDs. An ostium primum ASD is an opening low in the atrial septum and may be associated with abnormalities of the mitral valve. An ostium secundum ASD is an opening in the middle of the atrial septum and is the most common type. A sinus venosus ASD is an opening usually high in the atrial wall near the junction of the superior vena cava and may be associated with partial anomalous pulmonary venous connection.⁶ Left-to-right shunting of blood can occur with a large ASD.

Another opening in the atrial septal wall that is part of normal fetal communication, which usually closes after birth, is the foramen ovale. When the lungs become functional at birth, the pulmonary pressure decreases and the left atrial pressure exceeds that of the right. The pressure change forces the septum to functionally close the foramen ovale. If it does not close, it is called a patent foramen ovale (PFO). About one out of four adults has a PFO without CHD; however, in children with CHD the foramen ovale often remains open.

Clinical manifestations

Children with an ASD are usually asymptomatic. Infants with a large ASD may, in rare cases, develop pulmonary overcirculation and slow growth. Some older children and adults will experience shortness of breath with activity as the right ventricle becomes less compliant with age. Pulmonary hypertension and stroke are associated rare complications. A systolic ejection murmur and a widely split second heart sound are the expected findings on physical examination.

Evaluation and treatment
Diagnosis is confirmed by echocardiography. The ASD may be closed surgically with primary repair (sutured closed) or with a patch (pericardium or Dacron). Surgical repair involves open-heart surgery with cardiopulmonary bypass. Catheterization device closure offers a less invasive alternative for children with an ASD that meets anatomic and size criteria. All options have low morbidity and mortality. Atrial dysrhythmias persist in about 5% to 10% of individuals in both groups after closure.

**Ventricular Septal Defect**

**Pathophysiology**

A ventricular septal defect (VSD) is an opening of the septal wall between the ventricles. VSDs are the most common type of congenital heart defect and account for 15% to 20% of all such defects. VSDs are classified by location. Perimembranous VSDs are located high in the ventricular septal wall underneath the atrioventricular valves, and VSDs located under the aortic valve are subarterial. Muscular VSDs are located low in the septal wall. VSDs also can be located in the inlet or outlet portion of the ventricle. VSDs are similar to ASDs in that blood will shunt from left to right. Left-to-right shunting of blood can occur with a large VSD. Depending on the size and location, many VSDs close spontaneously, most often within the first 2 years of life.

**Clinical manifestations**

Depending on the size, location, and degree of shunting and pulmonary vascular resistance, children may have no symptoms or have clinical effects from excessive pulmonary blood flow. In the infant, excessive pulmonary blood flow from left-to-right shunting causes dyspnea and tachypnea symptoms, commonly referred to as heart failure (HF), even though the heart muscle functions well with a VSD. A holosystolic (pansystolic) murmur is expected.

If the degree of shunting is significant and not corrected, the child is at risk for developing pulmonary hypertension. Irreversible pulmonary hypertension can result in **Eisenmenger syndrome**, a condition in which shunting of blood is reversed because of high pulmonary pressure and resistance (right-to-left shunt with cyanosis).

**Evaluation and treatment**

Diagnosis is confirmed by echocardiogram. Cardiac catheterization may be needed to calculate the degree of shunting and to directly measure the pressures in the heart. Smaller VSDs require minimal treatment and may close completely or become
small enough that surgical closure is not required. If the infant has severe HF or failure to thrive that is unmanageable with medical therapy, early surgical repair is performed. Surgical repair involves open-heart surgery with cardiopulmonary bypass. The opening is either sutured closed (primary) or covered with a patch (pericardium or Dacron). Nonsurgical device closure is available but only under restricted conditions. Endocarditis prophylaxis is only recommended for 6 months after surgical or device closure and indefinitely with a residual VSD after patch closure.

**Atrioventricular Canal Defect**

**Pathophysiology**

Atrioventricular canal (AVC) defect, also known as atrioventricular septal defect (AVSD) or by the traditional term endocardial cushion defect (ECD), is the result of incomplete fusion of endocardial cushions (Figure 25-7). AVC defect consists of an ostium primum ASD and inlet VSD with associated abnormalities of the atrioventricular valve tissue. These valve abnormalities range from a cleft in the mitral valve to a common mitral and tricuspid valve. The directions and pathways of flow are determined by pulmonary and systemic resistance, left and right ventricular pressures, and the compliance of each chamber. Flow is generally from left to right. AVC is a common cardiac defect in children with Down syndrome. However, children with this defect can have a normal karyotype.
Clinical manifestations

Infants with this defect often display moderate to severe heart failure attributable to left-to-right shunting and pulmonary overcirculation. Infants with pulmonary hypertension and high pulmonary resistance have less shunting and therefore minimal signs of HF. There may be mild cyanosis that increases with crying. Those with a large left-to-right shunt will have a murmur, and those with minimal shunt may not have a murmur. Children with AVC are at risk for developing irreversible pulmonary hypertension if left surgically untreated.

Evaluation and treatment

AVC is one of the most frequent diagnoses made with fetal echocardiography. Cardiac catheterization usually is not needed. Initial treatment goals include aggressive medical management of HF and nutritional supplementation. Infants are followed closely for signs or symptoms of failure to thrive. Pulmonary artery banding is occasionally performed in small infants with severe symptoms. However, complete surgical repair is most common and typically performed between 3 and 6 months of age to prevent irreversible pulmonary hypertension.
This procedure consists of patch closure of the septal defects and reconstruction of the AV valve tissue (either repair of the mitral valve cleft or fashioning of two AV valves). If the mitral valve defect is severe, valve replacement may be needed. A potential problem following repair is mitral regurgitation, which may later require valve replacement.

**Defects with Decreased Pulmonary Blood Flow**

**Tetralogy of Fallot**

**Pathophysiology**

The classic form of tetralogy of Fallot (TOF) includes four defects: (1) VSD, (2) PS, (3) overriding aorta, and (4) right ventricular hypertrophy (Figure 25-8). The pathophysiology varies widely, depending not only on the degree of PS but also on the pulmonary and systemic vascular resistance to flow. If total resistance to pulmonary flow is greater than systemic resistance, the shunt is from right to left. If systemic resistance is more than pulmonary resistance, the shunt is from left to right. PS decreases blood flow to the lungs and, consequently, the amount of oxygenated blood that returns to the left heart. Physiologic compensation to chronic, severe hypoxia includes production of more red blood cells (polycythemia), development of collateral bronchial vessels, and enlargement of the nail beds (clubbing).
Clinical manifestations

Some infants may be acutely cyanotic at birth. In others, progression of hypoxia and cyanosis may be more gradual over the first year of life as the pulmonary stenosis worsens. Acute episodes of cyanosis and hypoxia can occur, called hypercyanotic spells, blue spells, or “tet” spells. These spells (increased right-to-left shunt) may occur during crying or after feeding. Oxygen has little effect in improving hypoxemia but placing the infant in a knee-chest position (Figure 25-9) and administering morphine sulfate subcutaneously or intravenously is most commonly used to treat “tet” spells. If prolonged or frequent, these spells are an indication for emergent evaluation and surgical treatment.

Chronic cyanosis may cause clubbing of the fingers and poor growth in children. squatting or the knee-chest position can help with cyanosis in these children because it increases peripheral resistance in the systemic circulation, which causes an increase in pressures in the left heart and consequent reduction in right-to-left shunting and improvement in pulmonary perfusion. Children with unrepaired TOF are at risk for emboli, stroke, brain abscess, seizures, and loss of consciousness or
sudden death following a “tet” spell.

**Evaluation and treatment**

Diagnosis is confirmed with echocardiography. Elective surgical repair is usually performed in the first year of life. Indications for earlier repair include increasing cyanosis or the development of hypercyanotic spells. Complete repair involves closure of the VSD, resection of the infundibular stenosis, and application of a pericardial patch to enlarge the right ventricular outflow tract that can extend across the pulmonary valve annulus (transannular patch).

In very small infants who cannot undergo primary repair, a palliative procedure to increase pulmonary blood flow and increase oxygen saturation may be performed. This systemic artery to pulmonary artery anastomosis is the Blalock-Taussig or modified Blalock-Taussig shunt, which provides blood flow to the pulmonary arteries.

**Tricuspid Atresia**

**Pathophysiology**

*Tricuspid atresia* is failure of the tricuspid valve to develop; consequently, there is no communication from right atrium to right ventricle (Figure 25-10). Blood flows through an ASD or a patent foramen ovale (PFO) to the left atrium and through a VSD to the right ventricle. This condition is often associated with PS or transposition of the great arteries. There is complete mixing of unoxygenated and oxygenated blood in the left side of the heart, resulting in systemic desaturation and mild cyanosis. The physiologic process that causes lesion development is variable, depending on the great vessel anatomy and amount of pulmonary stenosis.
Clinical manifestations
A murmur is noted, and cyanosis is usually seen in the newborn period. Tachycardia, dyspnea, fatigue, and poor feeding may be noted with excessive pulmonary blood flow. Older children may have signs of chronic hypoxemia with clubbing. Children are at risk for bacterial endocarditis, brain abscess, and stroke.

Evaluation and treatment
After diagnosis is confirmed by echocardiography, the neonate with decreased pulmonary blood flow is treated with a continuous infusion of prostaglandin E₁ to
maintain the patency of the ductus arteriosus until surgical intervention. If the ASD is restrictive, an atrial septostomy is performed during cardiac catheterization or under echocardiographic guidance. Treatment is accomplished in staged procedures. Once the infant is stabilized, a Blalock-Taussig shunt (systemic to pulmonary artery anastomosis) is placed to increase blood flow to the lungs.

Further surgery is undertaken between 4 and 8 months of age, depending on the child's growth and degree of cyanosis. The second-stage procedure is the bidirectional Glenn shunt in which the superior vena cava is anastomosed to the pulmonary artery. At that time, the pulmonary artery may be ligated and the Blalock-Taussig shunt is removed. The final separation of the pulmonary circulation from the systemic circulation is the modified Fontan procedure. In this stage, the inferior vena cava blood flow is routed to the pulmonary artery using an intra- or extracardiac tube graft or baffle. The procedure is typically performed between 2 and 4 years of age. Surgical outcomes are best in the child with normal ventricular function and low pulmonary vascular resistance (PVR). For children with borderline PVR, a fenestration (opening) can be created in the baffle or graft to relieve high systemic pulmonary venous pressures if needed.

Postoperative complications that increase hospital stay include pleural and pericardial effusions, elevated PVR, and ventricular dysfunction. Exercise tolerance is limited in many children with the Fontan procedure, but general health is considered good.

**Mixing Defects**

**Transposition of the Great Arteries or Transposition of the Great Vessels**

**Pathophysiology**

In transposition of the great arteries (TGA) or transposition of the great vessels (TGV), the pulmonary artery leaves the left ventricle and the aorta exits the right ventricle (Figure 25-11). Associated defects, such as ASD, VSD, or PDA, permit mixing of saturated and desaturated blood, which maintains adequate tissue oxygenation for a limited time.
Clinical manifestations

Clinical manifestations depend on the type and size of the associated defects. Children with limited communication between cardiac chambers are severely cyanotic, acidotic, and ill at birth. Those with large septal defects or a PDA may be less severely cyanotic but may have symptoms of pulmonary overcirculation. Classically, no murmur is heard unless there is an associated VSD.

Evaluation and treatment

Diagnosis is suspected by physical examination and confirmed with echocardiography. Administration of intravenous prostaglandin E₁ to maintain the patency of the ductus arteriosus may be initiated to temporarily increase oxygen delivery. Enlargement of the PFO by balloon atrial septostomy may be performed during cardiac catheterization or under echocardiographic guidance to increase mixing and maintain cardiac output.⁴⁹

The most preferred type of surgical repair for TGA performed in the first weeks of life is the arterial switch procedure. It involves transecting the great arteries and anastomosing the main pulmonary artery to the native proximal aorta (just above the aortic valve) and anastomosing the ascending aorta to the native proximal pulmonary artery. The coronary arteries are moved with a “button” of tissue from the proximal aorta to the proximal pulmonary artery, creating a new aorta. Reimplantation of the coronary arteries is critical to the infant's survival, and the arteries must be reattached without torsion or kinking to provide the heart with its
supply of oxygen. The advantage of the arterial switch procedure is the reestablishment of normal circulation with the left ventricle acting as the systemic pump. Potential complications of the arterial switch include narrowing at the great artery anastomoses, neoaortic valve regurgitation, or coronary artery insufficiency. Long-term results for the arterial switch operation are usually good.

**Total Anomalous Pulmonary Venous Connection**

**Pathophysiology**

Total anomalous pulmonary venous connection (TAPVC) is a rare defect characterized by failure of the pulmonary veins to join the left atrium during cardiac development. TAPVC is also called total anomalous pulmonary venous return (TAPVR) or total anomalous pulmonary venous drainage (TAPVD) ([Figure 25-12](#)). The pulmonary venous return is connected to the right side of the circulation rather than to the left atrium. The type of TAPVC is classified according to the pulmonary venous point of attachment:

- **Supracardiac**: Attachment above the diaphragm, usually to the superior vena cava (most common form)
- **Cardiac**: Direct attachment to the heart, usually to the right atrium or coronary sinus
- **Infracardiac**: Attachment below the diaphragm, such as to the inferior vena cava (most severe and least common form)
FIGURE 25-12 Total Anomalous Pulmonary Venous Connection (TAPVC).

The right atrium receives all the blood that normally would flow into the left atrium. As a result, the right side of the heart is enlarged and the left side, especially the left atrium, is smaller than normal. An associated ASD or PFO allows systemic venous blood to shunt from the right atrium to the left side of the heart. As a result, the oxygen saturation of the blood in both sides of the heart (and, ultimately, in the systemic arterial circulation) is the same. If the pulmonary blood flow is increased, pulmonary venous return is also large, and the amount of saturated blood is relatively high. However, if there is obstruction to pulmonary venous drainage, the infant has severe cyanosis and low cardiac output. Infra-cardiac TAPVC often is associated with obstruction of pulmonary venous drainage and is a surgical emergency with higher mortality than the unobstructed types.

Clinical manifestations
Most infants develop cyanosis early in life. The degree of cyanosis is inversely related to the amount of pulmonary blood flow. Children with unobstructed TAPVC may be asymptomatic until PVR decreases during infancy, increasing pulmonary blood flow, with resulting signs of pulmonary overcirculation. Cyanosis becomes
worse with pulmonary vein obstruction; once obstruction occurs, the infant's condition usually deteriorates rapidly. Without intervention, cardiac failure will progress to death. Murmur is not a common feature of TAPVC.

**Evaluation and treatment**

Diagnosis is suspected with echocardiography but may require confirmative angiography. Corrective repair is usually required in early infancy. The surgical approach varies with the anatomic defect. In general, however, the common pulmonary vein (venous confluence) is sutured to the left atrium, the ASD is closed, and the anomalous pulmonary venous connection or vertical vein may be ligated.

**Truncus Arteriosus**

**Pathophysiology**

**Truncus arteriosus (TA)** is failure of normal septation and division of the embryonic outflow tract into a pulmonary artery and an aorta, resulting in a single vessel that exits the heart. There is always an associated VSD with mixing of the systemic and arterial circulations ([Figure 25-13](#)) causing some degree of cyanosis. Blood ejected from the heart flows preferentially to the lower pressure pulmonary arteries, causing increased pulmonary blood flow. The three types are as follows:

- **Type I**: A single pulmonary trunk arises near the base of the truncus and divides into the left and right pulmonary arteries.

- **Type II**: The left and right pulmonary arteries arise separately from the posterior aspect of the truncus.

- **Type III**: The pulmonary arteries arise independently and from the lateral aspect of the truncus.
Clinical manifestations
Most infants are symptomatic with moderate heart failure and variable cyanosis, poor growth, and activity intolerance. Children are at risk for brain abscess and bacterial endocarditis.

Evaluation and treatment
Diagnosis is made by echocardiography. Corrective repair is a modification of the Rastelli procedure and is performed in the first few weeks or months of life. It involves closing the VSD so that the truncus arteriosus receives the outflow from the left ventricle, and excising the pulmonary arteries from the aorta and attaching them to the right ventricle by means of a homograft (cadaver) conduit. These children require additional procedures to replace the conduit since its size becomes inadequate in relation to growth or narrows because of calcification over time.

Hypoplastic Left Heart Syndrome

Pathophysiology
Hypoplastic left heart syndrome (HLHS) is underdevelopment of the left side of the heart. Features include small left atrium, small or absent mitral valve, small or absent left ventricle, and small or absent aortic valve. Coarctation also is expected (Figure 25-14). Most blood from the left atrium flows across the PFO to the right
atrium, to the right ventricle, and out the pulmonary artery. The descending aorta receives blood from the PDA supplying systemic blood flow and filling the aorta and coronary arteries as well.

**FIGURE 25-14** Hypoplastic Left Heart Syndrome (HLHS). (From HockenberryMJ et al: Wong’s essentials of pediatric nursing, ed 8, St Louis, 2009, Mosby)

**Clinical manifestations**

HLHS presents in the early newborn period as mild cyanosis, tachypnea, and low cardiac output if not already detected by fetal echocardiogram. Support of the systemic circulation is accomplished with prostaglandin E$_1$ infusion. If HLHS is not suspected and the PDA closes, there is progressive deterioration with cyanosis and decreased cardiac output, leading to cardiovascular collapse. If untreated, HLHS is usually fatal in the first months of life.

**Evaluation and treatment**

Echocardiography shows all of the features of HLHS. Cardiac catheterization is rarely required. A multistage repair approach is used. The first stage is the Norwood procedure, which is anastomosis of the main pulmonary artery to the aorta to create a new aorta, construction of either a modified Blalock-Taussig (systemic to pulmonary artery) or Sano (right ventricle to pulmonary artery) shunt to provide
pulmonary blood flow, creation of a large ASD, and repair of the coarctation. The second stage is a bidirectional Glenn shunt performed at 3 to 6 months of age by connecting the superior vena cava to the pulmonary artery, which minimizes cyanosis and reduces the volume load on the right ventricle. The final stage is a modified Fontan procedure that relieves cyanosis by connecting the inferior vena cava blood to the pulmonary artery using an intra- or extracardiac tube graft or baffle. Few centers perform heart transplantation in the newborn period rather than the staged procedure (Norwood, Glenn, Fontan) because of the scarcity of newborn donor hearts. Disadvantages of neonatal transplantation include shortage of newborn organ donors, risk of rejection, long-term problems with chronic immunosuppression, and infection. For infants who are not candidates for staged procedures or transplantation, the family is then offered palliative care.

Infants successfully treated for HLHS have improved survival rates related to advances in surgical and medical technology. Long-term (10 to 15 years) health problems after the Fontan procedure related to reduced right ventricular function and high central venous pressures have been reported to impact quality of life.  

Quick Check 25-1

1. What are the three principal classifications of CHD?

2. Describe the different characteristics that determine whether the defects are cyanotic or acyanotic.

3. What is the most common type of congenital heart defect?

Heart Failure

Heart failure (HF) is a common complication of many congenital heart defects. HF occurs when the heart is unable to maintain sufficient cardiac output to meet the metabolic demands of the body. The most common congenital causes of HF in infancy and childhood are listed in Table 25-3. Classic HF in children also can be acquired, usually resulting from cardiomyopathies, dysrhythmias, or electrolyte disturbances. Pulmonary overcirculation from a large left-to-right shunt is often called congestive heart failure but is not usually associated with decreased ventricular function and failure to meet metabolic demands. However, the clinical manifestations are similar, such as failure to thrive, tachypnea, tachycardia, and exercise intolerance.²

Modified from Park MK: *Pediatric cardiology for practitioners*, ed 6, St Louis, 2014, Mosby.

In general, the pathophysiologic mechanisms of HF in infants and children are similar to those in adults. It is most often a result of decreased left ventricular systolic function and the associated left atrial and pulmonary venous hypertension and pulmonary venous congestion. The same compensatory mechanisms are activated in the face of inadequate cardiac output. Right ventricular failure is rare in childhood.

Left heart failure in infants is manifested as poor feeding and sucking, often leading to failure to thrive. In left heart failure, dyspnea, tachypnea, and diaphoresis may be accompanied by retractions, grunting, and nasal flaring. Wheezing, coughing, and rales are rare in childhood HF.\(^1,2,12\) Common skin changes, such as pallor or mottling, are often present (Box 25-1). Signs of systemic venous congestion, such as hepatomegaly, weight gain, ascites, and peripheral edema, can be present but could be suggestive of other medical conditions such as renal or nutritional deficiencies.

**Systemic Venous Congestion**

Weight gain
Hepatomegaly
Peripheral edema, especially periorbital
Ascites
Neck vein distention

A thorough physical examination with emphasis on cardiac and pulmonary findings will often reveal the degree of HF. Plotting a child's growth (height, weight, head circumference) is an important method of assessing a child's health. Infants with HF or pulmonary overcirculation usually have low weight with normal length and head circumference measurements. The failure to thrive is usually the result of increased metabolic expenditure relative to caloric intake. An electrocardiogram (ECG) also should be performed to determine the presence of dysrhythmia or hypertrophy. A chest x-ray is useful in assessing the presence of cardiomegaly and signs of increased pulmonary circulation or pulmonary edema with echocardiogram to assess impaired function and possible etiology. B-type natriuretic peptide (BNP) has emerged as another diagnostic test of HF in children to confirm or exclude a cardiac cause for the symptoms.1,13

Treatment is aimed at decreasing cardiac workload and increasing the efficiency of heart function. Severe CHD is typically managed with surgical repair if applicable. Medical management initially consists of diuretics, such as furosemide. Depending on the degree of HF, other diuretics can be used in combination with furosemide to counteract potassium losses. Agents that reduce afterload, such as captopril or enalapril and beta-blockers, are employed to further manage severe HF.1,2,12 Children with end-stage HF on maximal medical therapy can be supported on a ventricular assist device (VAD) while awaiting cardiac transplantation in severe
cases that meet eligibility.¹²
Acquired Cardiovascular Disorders

Acquired heart diseases refer to disease processes or abnormalities that occur after birth. They result from various causes, such as infection, genetic disorders, autoimmune processes in response to infection, environmental factors, or autoimmune diseases. Examples of acquired heart diseases include Kawasaki disease, myocarditis, rheumatic heart disease, cardiomyopathy, and systemic hypertension. This chapter discusses Kawasaki disease and systemic hypertension. Myocarditis, rheumatic heart disease, and cardiomyopathy are discussed in Chapter 24.

Kawasaki Disease

Kawasaki disease (KD), formerly known as mucocutaneous lymph node syndrome, is an acute, usually self-limiting systemic vasculitis that may result in cardiac sequelae without treatment. Although KD occurs throughout the world, the greatest number of cases are seen in Japan. This reflects the genetic component of KD, with the case rate being highest among Asians and less among white and black children.

Kawasaki disease is primarily a condition of young children. Eighty percent of cases are seen in children younger than 5 years of age, with the incidence peaking in the toddler age group. Males are affected slightly more than females. The peak incidence is in the winter and spring.

The etiology of KD remains unknown. Current etiologic theories center on an immunologic response to an infectious, toxic, or antigenic substance.

Pathophysiology

Kawasaki disease progresses pathologically and clinically in the following stages. In the early or acute phase, small capillaries, arterioles, and venules become inflamed, as does the heart itself. In the subacute state, inflammation spreads to larger vessels and aneurysms of the coronary arteries may develop. In the convalescent stage, medium-sized arteries begin the granulation process and may cause coronary artery thickening with increased risk for thrombosis. After the convalescent stage, inflammation wanes with potential scarring of the affected vessels, calcification, and stenosis.

Clinical manifestations

The clinical course of KD progresses in three stages: acute, subacute, and convalescent. In the acute phase, the child with classic or typical KD has fever,
conjunctivitis, oral changes (“strawberry” tongue), rash, erythema of the palms and soles, and lymphadenopathy, and is often irritable. During this phase, myocarditis may develop. The subacute phase begins when the fever ends and continues until the clinical signs have resolved. It is at this time that the child is most at risk for coronary artery aneurysm development. Desquamation of the palms and soles occurs at this time, as well as marked thrombocytosis. The convalescent phase is marked by the elevation of the erythrocyte sedimentation rate and C-reactive protein level, as well as by an increased platelet count. Arthritis or arthralgia of the joints may be present. This phase continues until all laboratory values return to normal—usually about 6 to 8 weeks after onset.\(^1,2\) Atypical or “incomplete” KD can be seen in infants and children who lack the diagnostic criteria (have fewer than four signs) or “classic” physical findings. Recognition can be difficult and often results in delay of treatment with possible cardiovascular sequelae.\(^2,13\)

**Evaluation and treatment**

The diagnostic criteria for KD is based on clinical features, which state that the child must exhibit fever for more than 5 days along with four of five criteria (**Box 25-2**). These children usually have leukocytosis, increased erythrocyte sedimentation rates, thrombocytosis, and elevated liver enzymes. An echocardiogram is obtained at the time of diagnosis as a baseline measurement to assess for coronary aneurysms or inflammation. Serial echocardiograms are obtained after treatment to assess for development of coronary aneurysms or regression of those present early in the course of the disease. Treatment includes oral administration of aspirin and intravenous infusion of gamma globulin (most often only one dose). Aspirin is continued until the manifestations of inflammation are resolved but may be used indefinitely in children with residual coronary artery abnormalities.

**Box 25-2**

**Diagnostic Criteria for Kawasaki Disease**

The child must exhibit five of the following six criteria, including fever:

1. Fever for 5 or more days (often diagnosed with shorter duration of fever if other symptoms are present)

2. Bilateral conjunctival infection without exudation

3. Changes in the oral mucous membranes, such as erythema, dryness, and fissuring of the lips; oropharyngeal reddening; or “strawberry tongue”
4. Changes in the extremities, such as peripheral edema, peripheral erythema, and desquamation of palms and soles, particularly periungual peeling

5. Polymorphous rash, often accentuated in the perineal area

6. Cervical lymphadenopathy (one lymph node >1.5 cm)

Treatment with aspirin and intravenous immunoglobulin during the acute phase has decreased the morbidity of KD and has reduced the incidence of coronary abnormalities from approximately 20% to less than 10% at 6 to 8 weeks after initiation of therapy. Most children recover completely from KD, including regression of aneurysms. The most common cardiovascular sequela is coronary thrombosis.\(^{13}\)

**Systemic Hypertension**

**Systemic hypertension** in children is defined as systolic and diastolic blood pressure levels greater than the 95th percentile for age and gender on at least three occasions (*Tables 25-4 and 25-5*). The Fourth Task Force on Blood Pressure Control in Children uses height as an additional criterion to the blood pressure guidelines.\(^{1,14}\)

BP, Blood pressure; K5, Korotkoff phase 5.

From Park MK: *Pediatric cardiology for practitioners*, ed 6, St Louis, 2014, Mosby.

Hypertension is classified into two categories: primary, or essential, hypertension, in which a specific cause cannot be identified; and secondary hypertension, in which a cause can be identified (Box 25-3). Hypertension (HTN) in children differs from adult hypertension in etiology and presentation. Young children, when diagnosed with HTN, are often found to have secondary hypertension caused by some underlying disease, such as renal disease or COA (see Box 25-3). An increased prevalence of primary HTN in older children has been noted. Researchers are now focusing on primary HTN in older children in relation to morbidity and the presence of early atherosclerotic disease. Certain factors influence blood pressure in children. Children who are overweight are often hypertensive (see Health Alert: U.S. Childhood Obesity and Its Association with Cardiovascular Disease). Smoking also is associated with an increased risk for HTN.  

---

**Health Alert**

**U.S. Childhood Obesity and Its Association with Cardiovascular Disease**

Childhood obesity prevalence remains high in the United States. Approximately
17% (or 12.7 million) of children and adolescents ages 2 to 19 years are obese. This number has not changed significantly since 2003. However, the number of obese children between 2 and 5 years of age has decreased significantly from 13.9% between 2003 and 2004 to 8.4% between 2011 and 2012. Obesity continues to be a major health concern in children and is linked to insulin resistance and diabetes and increased cardiovascular risk, especially atherosclerosis, hypertension, and lipid abnormalities. The mechanisms by which insulin resistance and diabetes cause cardiovascular diseases include endothelial dysfunction, structural changes in arterial walls, abnormal vasoconstriction, and changes in renal function and salt transport. Research into genetics and insulin-regulated transcription factors suggests that obesity, insulin resistance, diabetes, and cardiovascular disease share important molecular etiologies and processes. These findings may lead investigators to important new treatments. For now, helping children develop good exercise and dietary habits has been shown to significantly improve arterial function and reduce cardiovascular risk. Content and updated references and statistics can be found at www.cdc.gov/obesity/childhood/index.html.

**Box 25-3**

**Conditions Associated with Secondary Hypertension in Children**

**Renal**

Renal parenchymal disease

Glomerulonephritis, acute and chronic

Pyelonephritis, acute and chronic

Congenital anomalies (polycystic or dysplastic kidneys)

Obstructive uropathies (hydronephrosis)

Hemolytic-uremic syndrome
Collagen disease (periarteritis, lupus)

Renal damage from nephrotoxic medications, trauma, or radiation

Renovascular disease

Renal artery disorders (e.g., stenosis, polyarteritis, thrombosis)

Renal vein thrombosis

**Cardiovascular**

Coarctation of the aorta

Conditions with large stroke volume (patent ductus arteriosus, aortic insufficiency, systemic arteriovenous fistula, complete heart block) (these conditions cause only systolic hypertension)

**Endocrine**

Hyperthyroidism (systolic hypertension)

Excessive catecholamine levels

**Pheochromocytoma**

**Neuroblastoma**

Adrenal dysfunction

**Congenital adrenal hyperplasia**
11-β-Hydroxylase deficiency
17-Hydroxylase deficiency
Cushing's syndrome
Hyperaldosteronism
Primary
Conn's syndrome
Idiopathic nodular hyperplasia
Dexamethasone-suppressible hyperaldosteronism
Secondary
Renovascular hypertension
Renin-producing tumor (juxtaglomerular cell tumor)
Hyperparathyroidism (and hypercalcemia)

**Neurogenic**
Increased intracranial pressure (any cause, especially tumors, infections, trauma)
Poliomyelitis
Guillain-Barré syndrome
Dysautonomia (Riley-Day syndrome)
### Drugs and chemicals

Sympathomimetic drugs (nose drops, cough medications, cold preparations, theophylline)

Amphetamines

Corticosteroids

Nonsteroidal anti-inflammatory drugs

Oral contraceptives

Heavy-metal poisoning (mercury, lead)

Cocaine, acute or chronic use

Cyclosporine

Thyroxine

Tacrolimus

### Miscellaneous

Hypervolemia and hypernatremia

Stevens-Johnson syndrome

Bronchopulmonary dysplasia (newborns)

---

From Park MK: *Pediatric cardiology for practitioners*, ed 6, St Louis, 2014, Mosby.

### Pathophysiology

In infants and children, a cause of HTN is almost always found. In general, the younger the child with significant hypertension, the more likely a correctable cause can be determined. Therefore a thorough evaluation needs to be performed.\(^2,15\)

The pathophysiology of primary HTN in children is not clearly understood but may result from a complex interaction of a strong predisposing genetic component with disturbances in sympathetic vascular smooth muscle tone, humoral agents (angiotensin, catecholamines), renal sodium excretion, and cardiac output. New
studies have shown an increased level of leptin, a hormone produced by adipose tissue, to be associated with hypertension in obese children. Ultimately, these factors impair the ability of the peripheral vascular bed to relax.

**Clinical manifestations**

Most children with systemic HTN are asymptomatic. It is necessary that a thorough history and physical examination be obtained. The examination should include an accurate blood pressure measurement obtained in the right arm with the arm supported at the level of the heart; three separate measurements using an appropriate-size cuff also are needed for an accurate blood pressure reading.

**Evaluation and treatment**

In children, the history and physical examination should be directed at determining the etiology of HTN, such as COA or renal disease (Table 25-6). A complete blood count, serum chemistry levels (including blood urea nitrogen and creatinine), uric acid level, urinalysis, urine culture, lipid profile, and renal ultrasound are part of the routine evaluation for renal disease (Table 25-7). Blood pressure differential between upper and lower extremities and echocardiogram can be used to identify COA. If COA is found, surgical correction or balloon angioplasty with or without a stent is initiated depending on age and severity of the coarctation. If HTN is determined to be essential, or primary, in nature, nonpharmacologic therapy is used initially. Moderate weight loss and exercise can decrease systolic and diastolic pressures in many children. Appropriate diet, regular physical activity, and avoidance of smoking have been shown to be effective in reducing blood pressure. Ambulatory blood pressure monitoring (ABPM) has the potential to become an important tool in the evaluation and management of childhood hypertension.

From Park MK: *Pediatric cardiology for practitioners*, ed 6, St Louis, 2014, Mosby.

Medication therapy is controversial in children with primary hypertension; however, when nonpharmacologic therapy fails, the approach is similar to the treatment of hypertension in adults with the use of angiotensin-converting enzyme inhibitors or angiotensin receptor blocker medications. The current emphasis on preventive cardiology, especially for children, is significant because many investigators believe signs of atherosclerosis are present during childhood.

**Quick Check 25-2**

1. Why are the infant's height and weight important in the assessment of HF?
2. Why is it critical to recognize and treat children during the acute phase of KD?
3. Discuss the causes of obesity in children and the cardiovascular effects.
Did You Understand?

Congenital Heart Disease

1. Most congenital heart defects have begun to develop by the eighth week of gestation, and some have associated causes, both environmental and genetic.

2. Environmental risk factors associated with the incidence of congenital heart defects typically are maternal conditions. Maternal conditions include viral infections, diabetes, drug intake, and advanced maternal age.

3. Genetic factors associated with congenital heart defects include, but are not limited to, Down syndrome, trisomy 13, trisomy 18, cri du chat syndrome, and Turner syndrome.

4. Classification of congenital heart defects is based on (1) whether they cause blood flow to the lungs to increase, decrease, or remain normal; (2) whether they cause cyanosis; and (3) whether they cause obstruction to flow.

5. Cyanosis, a bluish discoloration of the skin, indicates that the tissues are not receiving normal amounts of oxygenated blood. Cyanosis can be caused by defects that (1) restrict blood flow into the pulmonary circulation; (2) overload the pulmonary circulation, causing pulmonary overcirculation, pulmonary edema, and respiratory difficulty; or (3) cause large amounts of unoxygenated blood to shunt from the pulmonary to the systemic circulation.

6. Congenital defects that maintain or create direct communication between the pulmonary and systemic circulatory systems cause blood to shunt from one system to another, mixing oxygenated and unoxygenated blood and increasing blood volume and, occasionally, pressure on the receiving side of the shunt.

7. The direction of shunting through an abnormal communication depends on differences in pressure and resistance between the two systems. Flow is always from an area of high pressure to an area of low pressure.

8. Obstruction of ventricular outflow is commonly caused by PS (right ventricle) or AS (left ventricle).

9. In less severe obstruction, ventricular outflow remains normal because of compensatory ventricular hypertrophy stimulated by increased afterload and, in
postductal COA, development of collateral circulation around the coarctation.

10. Acyanotic congenital defects that increase pulmonary blood flow consist of abnormal openings (ASD, VSD, PDA, or AVC) that permit blood to shunt from left (systemic circulation) to right (pulmonary circulation). Cyanosis does not occur because the left-to-right shunt does not interfere with the flow of oxygenated blood through the systemic circulation.

11. If the abnormal communication between the left and right circuits is large, volume and pressure overload in the pulmonary circulation can lead to left-sided HF.

12. Cyanotic congenital defects in which saturated and desaturated blood mix within the heart or great arteries include TA, TOF, TGA, TAPVC, and HLHS.

13. In cyanotic heart defects that decrease pulmonary blood flow (TOF), myocardial hypertrophy cannot compensate for restricted right ventricular outflow. Flow to the lungs decreases, and cyanosis is caused by an insufficient volume of oxygenated blood and right-to-left shunt.

14. Initial treatment for CHD, depending on the defect, is aimed at controlling the level of HF symptoms or cyanosis. Interventional procedures in the cardiac catheterization laboratory and surgical palliation or repair are performed to establish a source of pulmonary blood flow or restore normal circulation.

15. Heart failure is usually the result of congenital heart defects that increase blood volume in the pulmonary circulation. A clinical manifestation of HF unique to children is failure to thrive.

**Acquired Cardiovascular Disorders in Children**

1. Two examples of acquired heart disease in children are Kawasaki disease and systemic hypertension.

2. Kawasaki disease is an acute systemic vasculitis that also may result in the development of coronary artery aneurysms and thrombosis if untreated.

3. Systemic hypertension in children differs from HTN in adults in etiology and presentation. When significant hypertension is found in a young child, the examiner should evaluate for the presence of secondary hypertension, most commonly renal
disease or COA.

- Gas Transport, 680

*GERIATRIC CONSIDERATIONS: Aging & the Pulmonary System, 684*
The primary function of the pulmonary system is the exchange of gases between the environmental air and the blood. The three steps in this process are (1) ventilation, the movement of air into and out of the lungs; (2) diffusion, the movement of gases between air spaces in the lungs and the bloodstream; and (3) perfusion, the movement of blood into and out of the capillary beds of the lungs to body organs and tissues. The first two functions are carried out by the pulmonary system and the third by the cardiovascular system (see Chapter 23). Normally the pulmonary system functions efficiently under a variety of conditions and with little energy expenditure.
Structures of the Pulmonary System

The pulmonary system includes two lungs, the upper and lower airways, the blood vessels that serve these structures (Figure 26-1), the diaphragm, and the chest wall or thoracic cage. The lungs are divided into lobes: three in the right lung (upper, middle, lower) and two in the left lung (upper, lower). Each lobe is further divided into segments and lobules. The **mediastinum** is the space between the lungs and contains the heart, great vessels, and esophagus. A set of conducting airways, or bronchi, delivers air to each section of the lung. The lung tissue that surrounds the airways supports them, preventing distortion or collapse of the airways as gas moves in and out during ventilation. The diaphragm is a dome-shaped muscle that separates the thoracic and abdominal cavities and is involved in ventilation.
The lungs are protected from exogenous contaminants by a series of mechanical barriers (Table 26-1). These defense mechanisms are so effective that, in the healthy individual, contamination of the lung tissue itself, particularly by infectious agents, is rare.

Conducting Airways

The conducting airways allow air into and out of the gas-exchange structures of the lung. The **nasopharynx, oropharynx**, and related structures are often called the **upper airway** (Figure 26-2). These structures are lined with a ciliated mucosa that warms and humidifies inspired air and removes foreign particles from it. The mouth and oropharynx are used for ventilation when the nose is obstructed or when increased flow is required (e.g., during exercise). Filtering and humidifying are not as efficient with mouth breathing.
The larynx connects the upper and lower airways and consists of the endolarynx and its surrounding triangular-shaped bony and cartilaginous structures. The endolarynx encompasses two pairs of folds: the false vocal cords (supraglottis) and the true vocal cords. The slit-shaped space between the true cords forms the glottis (see Figure 26-2). The vestibule is the space above the false vocal cords. The laryngeal box is formed of three large cartilages (epiglottis, thyroid, cricoid) and three smaller cartilages (arytenoid, corniculate, cuneiform) connected by ligaments. The supporting cartilages prevent collapse of the larynx during inspiration and swallowing. The internal laryngeal muscles control vocal cord length and tension, and the external laryngeal muscles move the larynx as a whole. Both sets of muscles are important to swallowing, ventilation, and vocalization. The internal muscles contract during swallowing to prevent aspiration into the trachea. These muscles also contribute to voice pitch.

The trachea, which is supported by U-shaped cartilage, connects the larynx to the
bronchi, the conducting airways of the lungs. The trachea branches into two main airways, or bronchi (sing., bronchus), at the carina (see Figure 26-1). The right and left main bronchi enter the lungs at the hila (sing., hilum), or “roots” of the lungs, along with the pulmonary blood and lymphatic vessels. From the hila the main bronchi branch farther, as shown in Figure 26-3.

The bronchial walls have three layers: an epithelial lining, a smooth muscle layer, and a connective tissue layer. The epithelial lining of the bronchi contains single-celled exocrine glands—the mucus-secreting goblet cells—and ciliated cells. The goblet cells produce a mucous blanket that protects the airway epithelium, and the
ciliated epithelial cells rhythmically beat this mucous blanket toward the trachea and pharynx where it can be swallowed or expectorated by coughing. The layers of epithelium that line the bronchi become thinner with each successive branching (see Figure 26-3).

**Gas-Exchange Airways**

The conducting airways terminate in the *respiratory bronchioles, alveolar ducts, and alveoli* (sing., *alveolus*). These thin-walled structures together are sometimes called the *acinus* (see Figures 26-1 and 26-3), and all of them participate in gas exchange.²

The alveoli are the primary gas-exchange units of the lung, where oxygen enters the blood and carbon dioxide is removed (Figure 26-4). Tiny passages called *pores of Kohn* permit some air to pass through the septa from alveolus to alveolus, promoting collateral ventilation and even distribution of air among the alveoli. The lungs contain approximately 25 million alveoli at birth and 300 million by adulthood.

*FIGURE 26-4  Alveoli. Bronchioles subdivide to form tiny tubes called alveolar ducts, which end in clusters of alveoli called alveolar sacs.* (From Patton KT, Thibodeau GA: *The human body in health & disease*, ed 6, St Louis, 2014, Mosby)
Lung epithelial cells provide a protective interface with the environment and are essential for adequate gas exchange, preventing entry of foreign agents, regulating ion and water transport, and maintaining mechanical stability of the alveoli. Two major types of epithelial cells appear in the alveolus. Type I alveolar cells provide structure, and type II alveolar cells secrete surfactant, a lipoprotein that coats the inner surface of the alveolus and lowers alveolar surface tension at end-expiration, thereby preventing lung collapse. Like the bronchi, alveoli contain cellular components of immunity and inflammation, particularly the mononuclear phagocytes (called alveolar macrophages). These cells ingest foreign material that reaches the alveolus and prepare it for removal through the lymphatics. (Phagocytosis and the mononuclear phagocyte system are described in Chapters 6 and 7.)

Quick Check 26-1

1. List the major components of the pulmonary system.
2. What are conducting airways?
3. Describe an alveolus.
4. Which components of the pulmonary system contribute to the body's defense?

Pulmonary and Bronchial Circulation

The pulmonary circulation facilitates gas exchange, delivers nutrients to lung tissues, acts as a reservoir for the left ventricle, and serves as a filtering system that removes clots, air, and other debris from the circulation. Although the entire cardiac output from the right ventricle goes into the lungs, the pulmonary circulation has a lower pressure and resistance than the systemic circulation. Pulmonary arteries are exposed to about one fifth the pressure of the systemic circulation. Usually about one third of the pulmonary vessels are filled with blood (perfused) at any given time. More vessels become perfused when right ventricular cardiac output increases. Therefore increased delivery of blood to the lungs does not normally increase mean pulmonary artery pressure.

The pulmonary artery divides and enters the lung at the hila, branching with each main bronchus and with all bronchi at every division. Thus, every bronchus and bronchiole has an accompanying artery or arteriole. The arterioles divide at the terminal bronchioles to form a network of pulmonary capillaries around the acinus.
Capillary walls consist of an endothelial layer and a thin basement membrane, which often fuses with the basement membrane of the alveolar septum. Consequently, there is very little separation between blood in the capillary and gas in the alveolus.

The shared alveolar and capillary walls compose the alveolocapillary membrane (respiratory membrane) (Figure 26-5). Gas exchange occurs across this membrane. With normal perfusion, approximately 100 ml of blood in the pulmonary capillary bed is spread very thinly over 70 to 100 m² of alveolar surface area. Any disorder that thickens the membrane impairs gas exchange.

Each pulmonary vein drains several pulmonary capillaries. Unlike the pulmonary arteries, pulmonary veins are dispersed randomly throughout the lung and then leave the lung at the hila and enter the left atrium. They have no valves.

The bronchial circulation is part of the systemic circulation, and it both moistens inspired air and supplies nutrients to the conducting airways, large pulmonary vessels, and membranes (pleurae) that surround the lungs. Not all of its capillaries drain into its own venous system. Some empty into the pulmonary vein and
contribute to the normal venous mixture of oxygenated and deoxygenated blood or right-to-left shunt (right-to-left shunts are described in Chapter 27). The bronchial circulation does not participate in gas exchange.\(^6\)

Lung vasculature also includes deep and superficial pulmonary lymphatic capillaries. Fluid and alveolar macrophages migrate from the alveoli to the terminal bronchioles, where they enter the lymphatic system. Both deep and superficial lymphatic vessels leave the lung at the hilum through a series of mediastinal lymph nodes. The lymphatic system plays an important role in both providing immune defense and keeping the lung free of fluid. (The lymphatic system is described in Chapter 23.)

**Control of the Pulmonary Circulation**

The caliber of pulmonary artery lumina decreases as smooth muscle in the arterial walls contracts. Contraction increases pulmonary artery pressure. Caliber increases as these muscles relax, decreasing blood pressure. Contraction (vasoconstriction) and relaxation (vasodilation) primarily occur in response to local humoral conditions, even though the pulmonary circulation is innervated by the autonomic nervous system (ANS), as is the systemic circulation.

The most important cause of pulmonary artery constriction is a low alveolar \(P_{O_2}\) (\(P_{A\ O_2}\)). Vasoconstriction is caused by alveolar and pulmonary venous hypoxia, often termed **hypoxic pulmonary vasoconstriction**, and results from an increase in intracellular calcium levels in vascular smooth muscle cells in response to low oxygen concentration and the presence of charged oxygen molecules called oxygen radicals.\(^7\) It can affect only one portion of the lung (i.e., one lobe that is obstructed, decreasing its \(P_{A\ O_2}\)) or the entire lung. If only one segment of the lung is involved, the arterioles to that segment constrict, shunting blood to other, well-ventilated portions of the lung. This reflex improves the lung's efficiency by better matching ventilation and perfusion. If all segments of the lung are affected, however, vasoconstriction occurs throughout the pulmonary vasculature and pulmonary hypertension (elevated pulmonary artery pressure) can result. The pulmonary vasoconstriction caused by low alveolar \(P_{O_2}\) is reversible if the alveolar \(P_{O_2}\) is corrected. Chronic alveolar hypoxia can result in structural changes in pulmonary arterioles causing permanent pulmonary artery hypertension, which eventually leads to right heart failure (cor pulmonale).\(^7\)

Acidemia also causes pulmonary artery constriction. If the acidemia is corrected, the vasoconstriction is reversed. (Respiratory acidosis and metabolic acidosis are described in Chapter 5.) An elevated \(P_{a\ CO_2}\) value without a drop in pH does not
cause pulmonary artery constriction. Other biochemical factors that affect the caliber of vessels in pulmonary circulation are histamine, prostaglandins, serotonin, nitric oxide, and bradykinin (see *Geriatric Considerations: Aging & the Pulmonary System*, p. 684).

**Chest Wall and Pleura**

The chest wall (skin, ribs, intercostal muscles) protects the lungs from injury. The intercostal muscles of the chest wall, along with the diaphragm, accessory muscles, and abdominal muscles, perform the muscular work of breathing. The *thoracic cavity* is contained by the chest wall and encases the lungs (*Figure 26-6*). A serous membrane called the *pleura* adheres firmly to the lungs and then folds over itself and attaches firmly to the chest wall. The membrane covering the lungs is the *visceral pleura*; that lining the thoracic cavity is the *parietal pleura*. The area between the two pleurae is called the *pleural space*, or *pleural cavity*. Normally, only a thin layer of fluid secreted by the pleura (pleural fluid) fills the pleural space, lubricating the pleural surfaces and allowing the two layers to slide over each other without separating. Pressure in the pleural space is usually negative or subatmospheric (−4 to −10 mm Hg).

Function of the Pulmonary System

The pulmonary system (1) ventilates the alveoli, (2) diffuses gases into and out of the blood, and (3) perfuses the lungs so that the organs and tissues of the body receive blood that is rich in oxygen and deficient in carbon dioxide. Each component of the pulmonary system contributes to one or more of these functions (Figure 26-7).

**Ventilation**

Ventilation is the mechanical movement of gas or air into and out of the lungs. It is often misnamed respiration, which is actually the exchange of oxygen and carbon dioxide during cellular metabolism. “Respiratory rate” is actually the ventilatory rate, or the number of times gas is inspired and expired per minute. The amount of effective ventilation is calculated by multiplying the ventilatory rate (breaths per minute) by the volume or amount of air per breath (liters per breath or tidal volume). This is called the minute volume (or minute ventilation) and is expressed
in liters per minute.

Carbon dioxide (CO$_2$), the gaseous form of carbonic acid (H$_2$CO$_3$), is produced by cellular metabolism. The lung eliminates about 10,000 milliequivalents (mEq) of carbonic acid per day in the form of CO$_2$, which is produced at the rate of approximately 200 ml/min. Carbon dioxide is eliminated to maintain a normal arterial CO$_2$ pressure ($\text{Paco}_2$) of 40 mm Hg and normal acid-base balance (see Chapter 5 for a discussion of acid-base regulation). Adequate ventilation is necessary to maintain normal Paco$_2$ levels. Diseases that limit ventilation result in CO$_2$ retention. The adequacy of alveolar ventilation cannot be accurately determined by observation of ventilatory rate, pattern, or effort. If a healthcare professional needs to determine the adequacy of ventilation, an arterial blood gas analysis must be performed to measure Paco$_2$.

**Neurochemical Control of Ventilation**

Breathing is usually involuntary, because homeostatic changes in ventilatory rate and volume are adjusted automatically by the nervous system to maintain normal gas exchange. Voluntary breathing is necessary for talking, singing, laughing, and deliberately holding one's breath. The mechanisms that control respiration are complex (Figure 26-8).
The respiratory center in the brainstem controls respiration by transmitting impulses to the respiratory muscles, causing them to contract and relax. The respiratory center is composed of several groups of neurons: the dorsal respiratory group (DRG), the ventral respiratory group (VRG), the pneumotaxic center, and the apneustic center.\(^1,2,4\)

The basic automatic rhythm of respiration is set by the DRG, which receives afferent input from peripheral chemoreceptors in the carotid and aortic bodies;
from mechanical, neural, and chemical stimuli; and from receptors in the lungs. The VRG contains both inspiratory and expiratory neurons and is almost inactive during normal, quiet respiration, becoming active when increased ventilatory effort is required. The pneumotaxic center and apneustic center, situated in the pons, do not generate primary rhythm but, rather, act as modifiers of the rhythm established by the medullary centers. The pattern of breathing can be influenced by emotion, pain, and disease.

**Lung Receptors**

Three types of lung receptors send impulses from the lungs to the DRG:

1. **Irritant receptors** (C fibers) are found in the epithelium of all conducting airways. They are sensitive to noxious aerosols (vapors), gases, and particulate matter (e.g., inhaled dusts), which cause them to initiate the cough reflex. When stimulated, irritant receptors also cause bronchoconstriction and increased ventilatory rate.

2. **Stretch receptors** are located in the smooth muscles of airways and are sensitive to increases in the size or volume of the lungs. They decrease ventilatory rate and volume when stimulated, an occurrence sometimes referred to as the Hering-Breuer expiratory reflex. This reflex is active in newborns and assists with ventilation. In adults, this reflex is active only at high tidal volumes (such as with exercise) and may protect against excess lung inflation. Bronchopulmonary C fibers and a subset of stretch-sensitive, acid-sensitive myelinated sensory nerves mediate the cough reflex.

3. **J-receptors** (juxtapulmonary capillary receptors) are located near the capillaries in the alveolar septa. They are sensitive to increased pulmonary capillary pressure, which stimulates them to initiate rapid, shallow breathing; hypotension; and bradycardia.

The lung is innervated by the autonomic nervous system (ANS). Fibers of the sympathetic division in the lung branch from the upper thoracic and cervical ganglia of the spinal cord. Fibers of the parasympathetic division of the ANS travel in the vagus nerve to the lung. (Structures and function of the ANS are discussed in detail in Chapter 13.) The parasympathetic and sympathetic divisions control airway caliber (interior diameter of the airway lumen) by stimulating bronchial smooth muscle to contract or relax. The parasympathetic receptors cause smooth muscle to contract, whereas sympathetic receptors cause it to relax. Bronchial smooth muscle
tone depends on equilibrium—that is, equal stimulation of contraction and relaxation. The parasympathetic division of the ANS is the main controller of airway caliber under normal conditions. Constriction occurs if the irritant receptors in the airway epithelium are stimulated by irritants in inspired air, by inflammatory mediators (e.g., histamine, serotonin, prostaglandins, leukotrienes), by many drugs, and by humoral substances.

**Chemoreceptors**

Chemoreceptors monitor the pH, PaCO$_2$, and PaO$_2$ (arterial pressure of oxygen) of arterial blood. **Central chemoreceptors** monitor arterial blood indirectly by sensing changes in the pH of cerebrospinal fluid (CSF) (see Figure 26-8). They are located near the respiratory center and are sensitive to hydrogen ion concentration in the CSF. (Chapter 5 describes the relationship between ions and the pH, or acid-base status, of body fluids.) The pH of the CSF reflects arterial pH because carbon dioxide in arterial blood can diffuse across the blood-brain barrier (the capillary wall separating blood from cells of the central nervous system) into the CSF until the partial pressure of carbon dioxide (P$_{CO_2}$) is equal on both sides. Carbon dioxide that has entered the CSF combines with H$_2$O to form carbonic acid, which subsequently dissociates into hydrogen ions that are capable of stimulating the central chemoreceptors. In this way, PaCO$_2$ regulates ventilation through its impact on the pH (hydrogen ion content) of the CSF.$^{1,2,4,11}$

If alveolar ventilation is inadequate, PaCO$_2$ increases. Carbon dioxide diffuses across the blood-brain barrier until P$_{CO_2}$ values in the blood and the CSF reach equilibrium. As the central chemoreceptors sense the resulting decrease in pH (increase in hydrogen ion concentration), they stimulate the respiratory center to increase the depth and rate of ventilation. Increased ventilation causes the P$_{CO_2}$ of arterial blood to decrease below that of the CSF, and carbon dioxide diffuses out of the CSF, returning its pH to normal.

The central chemoreceptors are sensitive to very small changes in the pH of CSF (equivalent to a 1 to 2 mm Hg change in P$_{CO_2}$) and can maintain a normal P$_{CO_2}$ under many different conditions, including strenuous exercise.$^{11}$ If inadequate ventilation, or hypoventilation, is long term (e.g., in chronic obstructive pulmonary disease), these receptors become insensitive to small changes in P$_{CO_2}$ (“reset”) and regulate ventilation poorly (see **Health Alert: Changes in the Chemical Control of Breathing During Sleep**).$^{12}$

**Health Alert**
Changes in the Chemical Control of Breathing During Sleep

There are multiple sites of central carbon dioxide chemosensitivity in the brainstem, and there are specialized chemosensory sites that function only during certain sleep states. Chemical control of ventilation, related to both hypercapnia and hypoxia, appears to be blunted during sleep. The orexins are neurohormones that control feeding, vigilance, and sleep. It is postulated that changes in orexin activity contribute to the blunting of chemoreceptor sensitivity seen in many states, including obesity and sleep apnea. Congestive heart failure, chronic obstructive pulmonary disease, and hypertension also are associated with abnormal breathing responses during sleep. Changes in the chemical control of breathing during sleep may contribute to morbidity and mortality seen in individuals with these disorders.

The peripheral chemoreceptors are somewhat sensitive to changes in $\text{PaCO}_2$ and pH but are sensitive primarily to oxygen levels in arterial blood ($\text{PaO}_2$). As $\text{PaO}_2$ and pH decrease, peripheral chemoreceptors, particularly in the carotid bodies, send signals to the respiratory center to increase ventilation. However, the $\text{PaO}_2$ must drop well below normal (to approximately 60 mm Hg) before the peripheral chemoreceptors have much influence on ventilation. If $\text{Paco}_2$ is elevated as well, ventilation increases much more than it would in response to either abnormality alone. The peripheral chemoreceptors become the major stimulus to ventilation when the central chemoreceptors are reset by chronic hypoventilation.\(^\text{13}\)

Quick Check 26-3

1. What are the functions of the pulmonary system?

2. How do ventilation and respiration differ?

3. Describe three functions of the respiratory center in the brainstem.

4. What are the three types of lung receptors?

5. How do the functions of central and peripheral chemoreceptors differ?
Mechanics of Breathing

The mechanical aspects of inspiration and expiration are known collectively as the mechanics of breathing and involve (1) major and accessory muscles of inspiration and expiration, (2) elastic properties of the lungs and chest wall, and (3) resistance to airflow through the conducting airways. Alterations in any of these properties increase the work of breathing or the metabolic energy needed to achieve adequate ventilation and oxygenation of the blood.

Major and Accessory Muscles

The major muscles of inspiration are the diaphragm and the external intercostal muscles (muscles between the ribs) (Figure 26-9). The diaphragm is a dome-shaped muscle that separates the abdominal and thoracic cavities. When it contracts and flattens downward, it increases the volume of the thoracic cavity, creating a negative pressure that draws gas into the lungs through the upper airways and trachea. Contraction of the external intercostal muscles elevates the anterior portion of the ribs and increases the volume of the thoracic cavity by increasing its front-to-back (anterior-posterior [AP]) diameter. Although the external intercostals may contract during quiet breathing, inspiration at rest is usually assisted by the diaphragm only.
The accessory muscles of inspiration are the sternocleidomastoid and scalene
muscles. Like the external intercostals, these muscles enlarge the thorax by increasing its AP diameter. The accessory muscles assist inspiration when the minute volume (volume of air inspired and expired per minute) is high, as during strenuous exercise, or when the work of breathing is increased because of disease. The accessory muscles do not increase the volume of the thorax as efficiently as the diaphragm does.

There are no major muscles of expiration because normal, relaxed expiration is passive and requires no muscular effort. The accessory muscles of expiration, the abdominal and internal intercostal muscles, assist expiration when minute volume is high, during coughing, or when airway obstruction is present. When the abdominal muscles contract, intra-abdominal pressure increases, pushing up the diaphragm and decreasing the volume of the thorax. The internal intercostal muscles pull down the anterior ribs, decreasing the AP diameter of the thorax.

**Alveolar Surface Tension**

**Surface tension** occurs at any gas-liquid interface and refers to the tendency for liquid molecules that are exposed to air to adhere to one another. This phenomenon can be seen in the way liquids “bead” when splashed on a waterproof surface.

Within a sphere, such as an alveolus, surface tension tends to make expansion difficult. According to the law of Laplace, the pressure ($P$) required to inflate a sphere is equal to two times the surface tension ($2T$) divided by the radius ($r$) of the sphere, or $P = 2T/r$. As the radius of the sphere (or alveolus) decreases, more and more pressure is required to inflate it. If the alveoli were lined only with a water-like fluid, taking breaths would be extremely difficult.

Alveolar ventilation, or distention, is made possible by surfactant, which lowers surface tension by coating the air-liquid interface in the alveoli. Surfactant, a lipoprotein (90% lipids and 10% protein) produced by type II alveolar cells, includes two groups of surfactant proteins. One group consists of small hydrophobic molecules that have a detergent-like effect that separates the liquid molecules, thereby decreasing alveolar surface tension. The second group of surfactant proteins consists of large hydrophilic molecules called collectins that are capable of inhibiting foreign pathogens (see Chapter 6).

As the radius of an alveolus shrinks, the surface tension of the surfactant-lined sphere decreases, and as the radius expands, the surface tension increases. Thus, normal alveoli are much easier to inflate at low lung volumes (i.e., after expiration) than at high volumes (i.e., after inspiration). The decrease in surface tension caused by surfactant also is responsible for keeping the alveoli free of fluid. If surfactant is not produced in adequate quantities, alveolar surface tension increases, causing
alveolar collapse, decreased lung expansion, increased work of breathing, and severe gas-exchange abnormalities.

**Elastic Properties of the Lung and Chest Wall**

The lung and chest wall have elastic properties that permit expansion during inspiration and return to resting volume during expiration. The elasticity of the lung is caused both by elastin fibers in the alveolar walls and surrounding the small airways and pulmonary capillaries, and by surface tension at the alveolar air-liquid interface. The elasticity of the chest wall is the result of the configuration of its bones and musculature.

Elastic recoil is the tendency of the lungs to return to the resting state after inspiration. Normal elastic recoil permits passive expiration, eliminating the need for major muscles of expiration. Passive elastic recoil may be insufficient during labored breathing (high minute volume), when the accessory muscles of expiration may be needed. The accessory muscles are used also if disease compromises elastic recoil (e.g., in emphysema) or blocks the conducting airways.

Normal elastic recoil depends on an equilibrium between opposing forces of recoil in the lungs and chest wall. Under normal conditions, the chest wall tends to recoil by expanding outward. The tendency of the chest wall to recoil by expanding is balanced by the tendency of the lungs to recoil or inward collapse around the hila. The opposing forces of the chest wall and lungs create the small negative intrapleural pressure.

Balance between the outward recoil of the chest wall and inward recoil of the lungs occurs at the resting level, the end of expiration, where the functional residual capacity (FRC) is reached. However, muscular effort is needed to overcome lung resistance to expansion. During inspiration, the diaphragm and intercostal muscles contract, air flows into the lungs, and the chest wall expands. During expiration, the muscles relax and the elastic recoil of the lungs causes the thorax to decrease in volume until, once again, balance between the chest wall and lung recoil forces is reached (Figure 26-10).
Compliance is the measure of lung and chest wall distensibility and is defined as volume change per unit of pressure change. It represents the relative ease with which these structures can be stretched and is, therefore, the opposite of elasticity. Compliance is determined by the alveolar surface tension and the elastic recoil of the lung and chest wall.

Increased compliance indicates that the lungs or chest wall is abnormally easy to inflate and has lost some elastic recoil. A decrease in compliance indicates that the lungs or chest wall is abnormally stiff or difficult to inflate. Compliance increases with normal aging and with disorders such as emphysema; it decreases in individuals with acute respiratory distress syndrome, pneumonia, pulmonary
edema, and fibrosis. (These disorders are described in Chapter 27.)

**Airway Resistance**

Airway resistance, which is similar to resistance to blood flow (described in Chapter 23), is determined by the length, radius, and cross-sectional area of the airways and by the density, viscosity, and velocity of the gas (Poiseuille law). Resistance ($R$) is computed by dividing change in pressure ($P$) by rate of flow ($F$), or $R = P/F$ (Ohm law). Airway resistance is normally very low. One half to two thirds of total airway resistance occurs in the nose. The next highest resistance is in the oropharynx and larynx. There is very little resistance in the conducting airways of the lungs because of their large cross-sectional area. Airway resistance is affected by the diameter of the airways. Bronchodilation, which decreases resistance to airflow, is caused by $\beta_2$-adrenergic receptor stimulation. Bronchoconstriction, which increases airway resistance, can be caused by stimulation of parasympathetic receptors in the bronchial smooth muscle and by numerous irritants and inflammatory mediators. Airway resistance can also be increased by edema of the bronchial mucosa and by airway obstructions such as mucus, tumors, or foreign bodies. Pulmonary function tests (PFTs) measure lung volumes and flow rates and can be used to diagnose lung disease.

**Work of Breathing**

The work of breathing is determined by the muscular effort (and therefore oxygen and energy) required for ventilation. Normally very low, the work of breathing may increase considerably in diseases that disrupt the equilibrium between forces exerted by the lung and chest wall. More muscular effort is required when lung compliance decreases (e.g., in pulmonary edema), chest wall compliance decreases (e.g., in spinal deformity or obesity), or airways are obstructed by bronchospasm or mucous plugging (e.g., in asthma or bronchitis). An increase in the work of breathing can result in a marked increase in oxygen consumption and an inability to maintain adequate ventilation (Figure 26-11).

**Quick Check 26-4**

1. Describe the work of the diaphragm in ventilation.

2. What is surfactant? What is its function?

3. How is elastic recoil related to compliance?
4. What causes changes in airway resistance?
Gas Transport

Gas transport is the delivery of oxygen to the cells of the body and the removal of carbon dioxide. It has four steps: (1) ventilation of the lungs, (2) diffusion of oxygen from the alveoli into the capillary blood, (3) perfusion of systemic capillaries with oxygenated blood, and (4) diffusion of oxygen from systemic capillaries into the cells. Steps in the transport of carbon dioxide occur in reverse order: (1) diffusion of carbon dioxide from the cells into the systemic capillaries, (2) perfusion of the pulmonary capillary bed by venous blood, (3) diffusion of carbon dioxide into the alveoli, and (4) removal of carbon dioxide from the lung by ventilation. If any step in gas transport is impaired by a respiratory or cardiovascular disorder, gas exchange at the cellular level is compromised.

Measurement of Gas Pressure

A gas is composed of millions of molecules moving randomly and colliding with each other and with the wall of the space in which they are contained. These collisions exert pressure. If the same number of gas molecules is contained in a small and a large container, the pressure is greater in the small container because more collisions occur in the smaller space (Figure 26-12). Heat increases the speed of the molecules, which also increases the number of collisions and therefore the pressure.
Barometric pressure ($P_B$) (atmospheric pressure) is the pressure exerted by gas molecules in air at specific altitudes. At sea level, barometric pressure is 760 mm Hg and is the sum of the pressures exerted by each gas in the air at sea level. The portion of the total pressure exerted by any individual gas is its partial pressure (see Figure 26-12). At sea level the air consists of oxygen ($20.9\%$), nitrogen ($78.1\%$), and a few other trace gases. The partial pressure of oxygen is equal to the percentage of oxygen in the air ($20.9\%$) times the total barometric pressure (760 mm Hg at sea level), or 159 mm Hg ($760 \times 0.209 = 158.84$ mm Hg). (Symbols used in the measurement of gas pressures and pulmonary ventilation are defined in Table 26-2.)

*An overhead dot means measurement over time, usually 1 minute.

The amount of water vapor contained in a gas mixture is determined by the temperature of the gas and is unrelated to barometric pressure. Gas that enters the lungs becomes saturated with water vapor (humidified) as it passes through the upper airway. At body temperature (37°C [98.6°F]), water vapor exerts a pressure of 47 mm Hg regardless of total barometric pressure. The partial pressure of water vapor must be subtracted from the barometric pressure before the partial pressures of other gases in the mixture can be determined. In saturated air at sea level, the partial pressure of oxygen is therefore \((760 – 47) \times 0.209 = 149\) mm Hg. All pressure and volume measurements made in pulmonary function laboratories specify the temperature and humidity of a gas at the time of measurement.

Many pressure measurements are stated as variations from barometric pressure, rather than percentages of it. On such scales, barometric pressure is considered zero, and pressure varies up or down from zero. Physiologic pressure measurements that involve fluids, rather than gases, are measured as variations from barometric pressure. For example, a systolic blood pressure of 120 mm Hg indicates that the systolic pressure is 120 mm Hg higher than the barometric pressure.

**Distribution of Ventilation and Perfusion**
Effective gas exchange depends on an approximately even distribution of gas (ventilation) and blood (perfusion) in all portions of the lungs. The lungs are suspended from the hila in the thoracic cavity. When an individual is in an upright position (sitting or standing), gravity pulls the lungs down toward the diaphragm and compresses their lower portions or bases. The alveoli in the upper portions, or apices, of the lungs contain a greater residual volume of gas and are larger and less numerous than those in the lower portions. Because surface tension increases as the alveoli become larger, the larger alveoli in the upper portions of the lung are more difficult to inflate (less compliant) than the smaller alveoli in the lower portions of the lung. Therefore, during ventilation most of the tidal volume is distributed to the bases of the lungs, where compliance is greater.

The heart pumps against gravity to perfuse the pulmonary circulation. As blood is pumped into the lung apices of a sitting or standing individual, some blood pressure is dissipated in overcoming gravity. As a result, blood pressure at the apices is lower than that at the bases. Because greater pressure causes greater perfusion, the bases of the lungs are better perfused than the apices (Figure 26-13). Thus, ventilation and perfusion are greatest in the same lung portions—the lower lobes—and depend on body position. If a standing individual assumes a supine or side-lying position, the areas of the lungs that are then most dependent become the best ventilated and perfused.
The greatest volume of pulmonary blood flow normally will occur in the gravity-dependent areas of the lung. Body position has a significant effect on the distribution of pulmonary blood flow. Shaded areas represent gravity dependent pulmonary blood flow.

Distribution of perfusion in the pulmonary circulation also is affected by alveolar pressure (gas pressure in the alveoli). The pulmonary capillary bed differs from the systemic capillary bed in that it is surrounded by gas-containing alveoli. If the gas pressure in the alveoli exceeds the blood pressure in the capillary, the capillary collapses and flow ceases. This is most likely to occur in portions of the lung where blood pressure is lowest and alveolar gas pressure is greatest—that is, at the apex of the lung.
The lungs are divided into three zones on the basis of relationships among all the factors affecting pulmonary blood flow. Alveolar pressure and the forces of gravity, arterial blood pressure, and venous blood pressure affect the distribution of perfusion, as shown in Figure 26-14.

In zone I, alveolar pressure exceeds pulmonary arterial and venous pressures. The capillary bed collapses, and normal blood flow ceases. Normally zone I is a very small part of the lung at the apex. In zone II, alveolar pressure is greater than venous pressure but not arterial pressure. Blood flows through zone II, but it is impeded to a certain extent by alveolar pressure. Zone II is normally above the level of the left atrium. In zone III, both arterial and venous pressures are greater than alveolar pressure and blood flow is not affected by alveolar pressure. Zone III is in the base of the lung. Blood flow through the pulmonary capillary bed increases in regular increments from the apex to the base.

Although both blood flow and ventilation are greater at the base of the lungs than...
at the apices, they are not perfectly matched in any zone. Perfusion exceeds ventilation in the bases, and ventilation exceeds perfusion in the apices of the lung. The relationship between ventilation and perfusion is expressed as a ratio called the **ventilation-perfusion ratio** \((\dot{V}/\dot{Q})\).\(^1\) The normal \(\dot{V}/\dot{Q}\) is 0.8. This is the amount by which perfusion exceeds ventilation under normal conditions.

**Oxygen Transport**

Approximately 1000 ml (1 L) of oxygen is transported to the cells of the body each minute. Oxygen is transported in the blood in two forms: a small amount dissolves in plasma, and the remainder binds to hemoglobin molecules. Without hemoglobin, oxygen would not reach the cells in amounts sufficient to maintain normal metabolic function. (Hemoglobin is discussed in detail in [Chapter 20](#), and cellular metabolism is explored in [Chapter 1](#).)

**Diffusion across the alveolocapillary membrane.**

The alveolocapillary membrane is ideal for oxygen diffusion because it has a large total surface area (70 to 100 m\(^2\)) and is very thin (0.5 micrometer [µm]). In addition, the partial pressure of oxygen molecules in alveolar gas (\(P_{A}O_2\)) is much greater than that in capillary blood, a condition that promotes rapid diffusion down the concentration gradient from the alveolus into the capillary. The partial pressure of oxygen (oxygen tension) in mixed venous or pulmonary artery blood (\(P_{V}O_2\)) is approximately 40 mm Hg as it enters the capillary, and alveolar oxygen tension (\(P_{A}O_2\)) is approximately 100 mm Hg at sea level. Therefore a pressure gradient of 60 mm Hg facilitates the diffusion of oxygen from the alveolus into the capillary ([Figure 26-15](#)).
Blood remains in the pulmonary capillary for about 0.75 second, but only 0.25 second is required for oxygen concentration to equilibrate (equalize) across the alveolocapillary membrane. Therefore oxygen has ample time to diffuse into the blood, even during increased cardiac output, which speeds blood flow and shortens the time the blood remains in the capillary.

**Determinants of arterial oxygenation.**

As oxygen diffuses across the alveolocapillary membrane, it dissolves in the plasma, where it exerts pressure (the partial pressure of oxygen in arterial blood, or \( \text{Pao}_2 \)). As the \( \text{Pao}_2 \) increases, oxygen moves from the plasma into the red blood cells (erythrocytes) and binds with hemoglobin molecules. Oxygen continues to bind with
hemoglobin until the hemoglobin-binding sites are filled or saturated. Oxygen then continues to diffuse across the alveolo-capillary membrane until the $\text{P}_{\text{A}O_2}$ (oxygen dissolved in plasma) and $\text{P}_{\text{A}O_2}$ (oxygen in the alveolus) equilibrate, eliminating the pressure gradient across the alveolo-capillary membrane. At this point, diffusion ceases (see Figure 26-15).

The majority (97%) of the oxygen that enters the blood is bound to hemoglobin. The remaining 3% stays in the plasma and creates the partial pressure of oxygen ($\text{P}_{\text{A}O_2}$). The $\text{P}_{\text{A}O_2}$ can be measured in the blood by obtaining an arterial blood gas measurement. The oxygen saturation ($\text{S}_\text{a}O_2$) is the percentage of the available hemoglobin that is bound to oxygen and can be measured using a device called an oximeter.

Because hemoglobin transports all but a small fraction of the oxygen carried in arterial blood, changes in hemoglobin concentration affect the oxygen content of the blood. Decreases in hemoglobin concentration below the normal value of 15 g/dl of blood reduce oxygen content, and increases in hemoglobin concentration may increase oxygen content, minimizing the impact of impaired gas exchange. In fact, increased hemoglobin concentration is a major compensatory mechanism in pulmonary diseases that impair gas exchange. For this reason, measurement of hemoglobin concentration is important in assessing individuals with pulmonary disease. If cardiovascular function is normal, the body's initial response to low oxygen content is to accelerate cardiac output. In individuals who also have cardiovascular disease, this compensatory mechanism is ineffective, making increased hemoglobin concentration an even more important compensatory mechanism. (Hemoglobin structure and function are described in Chapter 20.)

**Oxyhemoglobin association and dissociation.**

When hemoglobin molecules bind with oxygen, oxyhemoglobin ($\text{HbO}_2$) forms. Binding occurs in the lungs and is called oxyhemoglobin association or hemoglobin saturation with oxygen ($\text{S}_\text{a}O_2$). The reverse process, where oxygen is released from hemoglobin, occurs in the body tissues at the cellular level and is called hemoglobin desaturation. When hemoglobin saturation and desaturation are plotted on a graph, the result is a distinctive S-shaped curve known as the oxyhemoglobin dissociation curve (Figure 26-16).
Several factors can change the relationship between $P_{\text{ao}_2}$ and $S_{\text{ao}_2}$, causing the oxyhemoglobin dissociation curve to shift to the right or left (see Figure 26-16). A shift to the right depicts hemoglobin's decreased affinity for oxygen or an increase in the ease with which oxyhemoglobin dissociates and oxygen moves into the cells. A shift to the left depicts hemoglobin's increased affinity for oxygen, which promotes association in the lungs and inhibits dissociation in the tissues.

The oxyhemoglobin dissociation curve is shifted to the right by acidosis (low pH) and hypercapnia (increased $P_{\text{aco}_2}$). In the tissues, the increased levels of carbon
dioxide and hydrogen ions produced by metabolic activity decrease the affinity of hemoglobin for oxygen. The curve is shifted to the left by alkalosis (high pH) and hypocapnia (decreased \( \text{Paco}_2 \)). In the lungs, as carbon dioxide diffuses from the blood into the alveoli, the blood carbon dioxide level is reduced and the affinity of hemoglobin for oxygen is increased. The shift in the oxyhemoglobin dissociation curve caused by changes in carbon dioxide and hydrogen ion concentrations in the blood is called the **Bohr effect**.

The oxyhemoglobin curve is also shifted by changes in body temperature and increased or decreased levels of 2,3-diphosphoglycerate (2,3-DPG), a substance normally present in erythrocytes. Hyperthermia and increased 2,3-DPG levels shift the curve to the right. Hypothermia and decreased 2,3-DPG levels shift the curve to the left.

**Carbon Dioxide Transport**

Carbon dioxide is carried in the blood in three ways: (1) dissolved in plasma (\( \text{PCO}_2 \)), (2) as bicarbonate (\( \text{HCO}_3^- \)), and (3) as carbamino compounds. As \( \text{CO}_2 \) diffuses out of the cells into the blood, it dissolves in the plasma. Approximately 10% of the total \( \text{CO}_2 \) in venous blood and 5% of the \( \text{CO}_2 \) in arterial blood are transported dissolved in the plasma (\( \text{PVCO}_2 \) and \( \text{PACO}_2 \), respectively). As \( \text{CO}_2 \) moves into the blood, it diffuses into the red blood cells. Within the red blood cells, \( \text{CO}_2 \), with the help of the enzyme carbonic anhydrase, combines with water to form carbonic acid and then quickly dissociates into \( \text{H}^+ \) and \( \text{HCO}_3^- \). As carbonic acid dissociates, the \( \text{H}^+ \) binds to hemoglobin, where it is buffered, and the \( \text{HCO}_3^- \) moves out of the red blood cell into the plasma. Approximately 60% of the \( \text{CO}_2 \) in venous blood and 90% of the \( \text{CO}_2 \) in arterial blood are carried in the form of bicarbonate. The remainder combines with blood proteins, hemoglobin in particular, to form carbamino compounds. Approximately 30% of the \( \text{CO}_2 \) in venous blood and 5% of the \( \text{CO}_2 \) in arterial blood are carried as carbamino compounds.

\( \text{CO}_2 \) is 20 times more soluble than \( \text{O}_2 \) and diffuses quickly from the tissue cells into the blood. The amount of \( \text{CO}_2 \) able to enter the blood is enhanced by diffusion of oxygen out of the blood and into the cells. Reduced hemoglobin (hemoglobin that is dissociated from oxygen) can carry more \( \text{CO}_2 \) than can hemoglobin saturated with \( \text{O}_2 \). Therefore the drop in \( \text{SO}_2 \) at the tissue level increases the ability of hemoglobin to carry \( \text{CO}_2 \) back to the lung.

The diffusion gradient for \( \text{CO}_2 \) in the lung is only approximately 6 mm Hg (venous \( \text{PCO}_2 = 46 \text{ mm Hg} \); alveolar \( \text{PCO}_2 = 40 \text{ mm Hg} \)) (see **Figure 26-15**). Yet \( \text{CO}_2 \)
is so soluble in the alveolocapillary membrane that the CO₂ in the blood quickly diffuses into the alveoli, where it is removed from the lung with each expiration. Diffusion of CO₂ in the lung is so efficient that diffusion defects that cause hypoxemia (low oxygen content of the blood) do not as readily cause hypercapnia (excessive carbon dioxide in the blood).

The diffusion of CO₂ out of the blood is also enhanced by oxygen binding with hemoglobin in the lung. As hemoglobin binds with O₂, the amount of CO₂ carried by the blood decreases. Thus, in the tissue capillaries, O₂ dissociation from hemoglobin facilitates the pickup of CO₂, and the binding of O₂ to hemoglobin in the lungs facilitates the release of CO₂ from the blood. This effect of oxygen on CO₂ transport is called the Haldane effect.

Quick Check 26-5

1. What are the eight steps of gas transport?

2. Describe the relationship between ventilation and pulmonary blood flow.

3. What is the alveolocapillary membrane? How does it function in ventilation and perfusion?

4. Describe the process of oxyhemoglobin association and dissociation.

5. What is barometric pressure? How is it related to physiologic pressure measurements?
Geriatric Considerations

Aging & the Pulmonary System

Elasticity/Chest Wall

Chest wall compliance decreases because ribs become ossified and joints are stiffer, which results in increased work of breathing.

Kyphoscoliosis may curve the vertebral column, decreasing lung volumes.

Intercostal muscle strength decreases.

Elastic recoil diminishes, possibly the result of loss of elastic fibers.

Result: Lung compliance increases and ventilatory capacity (VC) declines, residual volume (RV) increases, total lung capacity (TLC) is unchanged, ventilatory reserves decline, and ventilation-perfusion ratios fall.

Gas Exchange

Pulmonary capillary network decreases.

Alveoli dilate, and peripheral airways lose supporting tissues.

Surface area for gas exchange decreases.

pH and P\text{CO}_2 do not change much, but P\text{O}_2 declines.

Sensitivity of respiratory centers to hypoxia or hypercapnia decreases.

Ability to initiate an immune response against infection decreases.

Note: Maximum P\text{O}_2 at sea level can be estimated by multiplying person's age by 0.3 and subtracting the product from 100.

Exercise

Decreased P\text{O}_2 and diminished ventilatory reserve lead to decreased exercise tolerance.
Early airway closure inhibits expiratory flow.

Changes depend on activity and fitness levels earlier in life.

An active, physically fit individual has fewer changes in function at any age than does a sedentary individual.

Respiratory muscle strength and endurance decrease but can be enhanced by exercise.

**Lung Immunity**

Alterations in alveolar complement and surfactant and an increase in proinflammatory cytokines increase the risk for pulmonary disease and infection.
Did you Understand?

Structures of the Pulmonary System

1. The pulmonary system consists of the lungs, upper and lower airways, chest wall, and pulmonary and bronchial circulation.

2. Air is inspired and expired through the conducting airways: nasopharynx, oropharynx, trachea, bronchi, and bronchioles.

3. Gas exchange occurs in structures beyond the respiratory bronchioles: in the alveolar ducts and the alveoli. Together these structures compose the acinus.

4. The chief gas-exchange units of the lungs are the alveoli. The membrane that surrounds each alveolus and contains the pulmonary capillaries is called the alveolocapillary membrane.

5. The gas-exchange airways are perfused by the pulmonary circulation, a separate division of the circulatory system. The bronchi and other lung structures are perfused by a branch of the systemic circulation called the bronchial circulation.

6. The chest wall, which contains and protects the contents of the thoracic cavity, consists of the skin, ribs, and intercostal muscles, which lie between the ribs.

7. The chest wall is lined by a serous membrane called the parietal pleura; the lungs are encased in a separate membrane called the visceral pleura. The pleural space is the area where these two pleurae contact and slide over one another.

Function of the Pulmonary System

1. The pulmonary system enables oxygen to diffuse into the blood and carbon dioxide to diffuse out of the blood.

2. Ventilation is the process by which air flows into and out of the gas-exchange airways.

3. Most of the time, ventilation is involuntary. It is controlled by the sympathetic and parasympathetic divisions of the autonomic nervous system, which adjust airway caliber (by causing bronchial smooth muscle to contract or relax) and control the rate and depth of ventilation.
4. Neuroreceptors in the lungs (lung receptors) monitor the mechanical aspects of ventilation. Irritant receptors sense the need to expel unwanted substances, stretch receptors sense lung volume (lung expansion), and J-receptors sense pulmonary capillary pressure.

5. Chemoreceptors in the circulatory system and brainstem sense the effectiveness of ventilation by monitoring the pH status of cerebrospinal fluid and the oxygen content ($P_{O_2}$) of arterial blood.

6. Successful ventilation involves the mechanics of breathing: the interaction of forces and counterforces involving the muscles of inspiration and expiration, alveolar surface tension, elastic properties of the lungs and chest wall, and resistance to airflow.

7. The major muscle of inspiration is the diaphragm. When the diaphragm contracts, it moves downward in the thoracic cavity, creating a vacuum that causes air to flow into the lungs.

8. The type II alveolar cells produce surfactant, a lipoprotein that lines the alveoli. Surfactant reduces alveolar surface tension and permits the alveoli to expand as air enters.

9. Compliance is the ease with which the lungs and chest wall expand during inspiration. Lung compliance is ensured by an adequate production of surfactant, whereas chest wall expansion depends on elasticity.

10. Elastic recoil is the tendency of the lungs and chest wall to return to their resting state after inspiration. The elastic recoil forces of the lungs and chest wall are in opposition and pull on each other, creating the normally negative pressure of the pleural space.

11. Gas transport depends on ventilation of the alveoli, diffusion across the alveolocapillary membrane, perfusion of the pulmonary and systemic capillaries, and diffusion between systemic capillaries and tissue cells.

12. Efficient gas exchange depends on an even distribution of ventilation and perfusion within the lungs. Both ventilation and perfusion are greatest in the bases of the lungs because the alveoli in the bases are more compliant (their resting volume is low) and perfusion is greater in the bases as a result of gravity.
13. Almost all the oxygen that diffuses into pulmonary capillary blood is transported by hemoglobin, a protein contained within red blood cells. The remainder of the oxygen is transported dissolved in plasma.

14. Oxygen enters the body by diffusing down the concentration gradient, from high concentrations in the alveoli to lower concentrations in the capillaries. Diffusion ceases when alveolar and capillary oxygen pressures equilibrate.

15. Oxygen is loaded onto hemoglobin by the driving pressure exerted by $\text{P}ao_2$ in the plasma. As pressure decreases at the tissue level, oxygen dissociates from hemoglobin and enters tissue cells by diffusion, again down the concentration gradient.

16. Compared with oxygen, carbon dioxide is more soluble in plasma. Therefore carbon dioxide diffuses readily from tissue cells into plasma and from plasma into the alveoli. Carbon dioxide returns to the lungs dissolved in plasma, as bicarbonate, or in carbamino compounds (e.g., bound to hemoglobin).

17. The pulmonary circulation is innervated by the autonomic nervous system (ANS), but vasodilation and vasoconstriction are controlled mainly by local and humoral factors, particularly arterial oxygenation and acid-base status.

**Geriatric Considerations: Aging & the Pulmonary System**

1. Aging affects the mechanical aspects of ventilation by decreasing chest wall compliance and elastic recoil of the lungs. Changes in these elastic properties reduce the ventilatory reserve.

2. With aging, the surface area for gas exchange and capillary perfusion may decrease, reducing exercise capacity.

3. Level of fitness and associated systemic disease affect individual lung function.

Pulmonary disease is often classified as acute or chronic, obstructive or restrictive, or infectious or noninfectious. Symptoms of lung disease are common and associated not only with primary lung disorders but also with diseases of other organ systems, particularly the heart.
Clinical Manifestations of Pulmonary Alterations

Signs and Symptoms of Pulmonary Disease

Pulmonary disease is associated with many signs and symptoms, the most common of which are dyspnea and cough. Others include abnormal sputum, hemoptysis, altered breathing patterns, hypoventilation and hyperventilation, cyanosis, clubbing, and chest pain.

Dyspnea

Dyspnea is a subjective experience of breathing discomfort that is comprised of qualitatively distinct sensations that vary in intensity. Dyspnea is an individual experience and derives from interactions among multiple physiologic, psychologic, social, and environmental factors, and it may induce secondary physiologic and behavioral responses. It is often described as breathlessness, air hunger, shortness of breath, labored breathing, and preoccupation with breathing. Dyspnea may be the result of pulmonary disease, or many other conditions such as pain, heart disease, trauma, and psychogenic disorders.

The severity of the experience of dyspnea may not directly correlate with the severity of underlying disease. Either diffuse or focal disturbances of ventilation, gas exchange, or ventilation-perfusion relationships can cause dyspnea, as can increased work of breathing or any disease that damages lung tissue (lung parenchyma). Neurophysiologic mechanisms of dyspnea involve an impaired sense of effort in which the perceived work of breathing is greater than the actual motor response that is generated. Stimulation of many receptors can contribute to the sensation of dyspnea, including afferent receptors in the cortex and medulla and mechanoreceptors in the chest wall, upper airway receptors, and central and peripheral chemoreceptors.

The more severe signs of dyspnea include flaring of the nostrils and use of accessory muscles of respiration. Retraction (pulling back) of the supracostal or intercostal muscles is predominant in children. Dyspnea can be quantified by the use of both ordinal rating scales and visual analog scales and is frequently associated with significant anxiety.

Dyspnea may occur transiently or can become chronic. Dyspnea first presents during exercise and is called dyspnea on exertion. Orthopnea is dyspnea that occurs during heart failure when an individual lies flat, which causes the abdominal contents to exert pressure on the diaphragm, and decreases the efficiency of the
respiratory muscles. **Paroxysmal nocturnal dyspnea (PND)** occurs when individuals with pulmonary or cardiac disease awake at night gasping for air and have to sit or stand to relieve the dyspnea. Dyspnea may be unrecognized in mechanically ventilated individuals and is often accompanied by pain and anxiety. A focused assessment and change in ventilator settings may be required.4

**Cough**

**Cough** is a protective reflex that helps clear the airways by an explosive expiration. Inhaled particles, accumulated mucus, inflammation, or the presence of a foreign body initiates the cough reflex by stimulating the irritant receptors in the airway. There are few such receptors in the most distal bronchi and the alveoli; thus it is possible for significant amounts of secretions to accumulate in the distal respiratory tree without cough being initiated. The cough reflex consists of inspiration, closure of the glottis and vocal cords, contraction of the expiratory muscles, and reopening of the glottis, causing a sudden, forceful expiration that removes the offending matter. The effectiveness of the cough depends on the depth of the inspiration and the degree to which the airways narrow, increasing the velocity of expiratory gas flow. Those with an inability to cough effectively are at greater risk for pneumonia.

*Acute cough* is cough that resolves within 2 to 3 weeks of the onset of illness or resolves with treatment of the underlying condition. It is most commonly the result of upper respiratory tract infections, allergic rhinitis, acute bronchitis, pneumonia, congestive heart failure, pulmonary embolus, or aspiration. *Chronic cough* is defined as cough that is persistent and in individuals who do not smoke. Chronic cough is commonly caused or triggered by postnasal drainage syndrome, asthma, eosinophilic bronchitis, laryngeal hypersensitivity, and gastroesophageal reflux disease or there may be no identifiable underlying cause.5 In persons who smoke, chronic bronchitis is the most common cause of chronic cough, although lung cancer must always be considered. Individuals taking angiotensin-converting enzyme inhibitors for cardiovascular disease may develop chronic cough that resolves with discontinuation of the drug.

**Abnormal Sputum**

Changes in the amount, color, and consistency of sputum provide information about progression of disease and effectiveness of therapy. The gross and microscopic appearances of sputum enable the clinician to identify cellular debris or microorganisms, which aids in diagnosis and choice of therapy.

**Hemoptysis**
Hemoptysis is the coughing up of blood or bloody secretions. This is sometimes confused with hematemesis, which is the vomiting of blood. Blood produced with coughing is usually bright red, has an alkaline pH, and is mixed with frothy sputum. Blood that is vomited is dark, has an acidic pH, and is mixed with food particles.

Hemoptysis usually indicates infection or inflammation that damages the bronchi (bronchitis, bronchiectasis) or the lung parenchyma (pneumonia, tuberculosis, lung abscess). Other causes include cancer, pulmonary infarction, or pulmonary venous stenosis. The amount and duration of bleeding provide important clues about its source. Bronchoscopy, combined with chest computed tomography (CT), is used to confirm the site of bleeding.

Abnormal Breathing Patterns

Normal breathing (eupnea) is rhythmic and effortless. The resting ventilatory rate is 8 to 16 breaths per minute, and tidal volume ranges from 400 to 800 ml. A short expiratory pause occurs with each breath, and the individual takes an occasional deeper breath, or sighs. Sigh breaths, which help to maintain normal lung function, are usually 1.5 to 2 times the normal tidal volume and occur approximately 10 to 12 times per hour.

The rate, depth, regularity, and effort of breathing undergo characteristic alterations in response to physiologic and pathophysiologic conditions. Patterns of breathing automatically adjust to minimize the work of respiratory muscles.

Strenuous exercise or metabolic acidosis induces Kussmaul respiration (hyperpnea), which is characterized by a slightly increased ventilatory rate, very large tidal volumes, and no expiratory pause.

Laborated breathing occurs whenever there is an increased work of breathing, especially if the airways are obstructed. In large airway obstruction, a slow ventilatory rate, large tidal volume, increased effort, prolonged inspiration and expiration, and stridor or audible wheezing (depending on the site of obstruction) are typical. In small airway obstruction, such as that seen in asthma and chronic obstructive pulmonary disease, a rapid ventilatory rate, small tidal volume, increased effort, prolonged expiration, and wheezing are often present. Restricted breathing is commonly caused by disorders, such as pulmonary fibrosis, that stiffen the lungs or chest wall and decrease compliance, resulting in small tidal volumes and rapid ventilatory rate (tachypnea).

Shock and severe cerebral hypoxia (insufficient oxygen in the brain) contribute to gasping respirations that consist of irregular, quick inspirations with an expiratory pause. Anxiety can cause sighing respirations, which consist of irregular breathing characterized by frequent, deep sighing inspirations. Cheyne-Stokes respirations
are characterized by alternating periods of deep and shallow breathing. Apnea lasting from 15 to 60 seconds is followed by ventilations that increase in volume until a peak is reached; then ventilation (tidal volume) decreases again to apnea. Cheyne-Stokes respirations result from any condition that reduces blood flow to the brainstem, which in turn slows impulses sending information to the respiratory centers of the brainstem. Neurologic impairment above the brainstem is also a contributing factor (see Figure 15-1).

**Hypoventilation and Hyperventilation**

**Hypoventilation** is inadequate alveolar ventilation in relation to metabolic demands. Hypoventilation occurs when minute volume (tidal volume × respiratory rate) is reduced. It is caused by alterations in pulmonary mechanics or in the neurologic control of breathing. When alveolar ventilation is normal, carbon dioxide (CO₂) is removed from the lungs at the same rate as it is produced by cellular metabolism and arterial and alveolar P CO₂ values remain at normal levels (40 mm Hg). With hypoventilation, CO₂ removal does not keep up with CO₂ production and Paco₂ increases, causing hypercapnia (Paco₂ greater than 44 mm Hg) (see Table 26-2 for a definition of gas partial pressures and other pulmonary abbreviations). This results in respiratory acidosis that can affect the function of many tissues throughout the body. Hypoventilation is often overlooked until it is severe because breathing pattern and ventilatory rate may appear to be normal and changes in tidal volume can be difficult to detect clinically. Blood gas analysis (i.e., measurement of the Paco₂ of arterial blood) reveals the hypoventilation. Pronounced hypoventilation can cause secondary hypoxemia, somnolence, or disorientation.

**Hyperventilation** is alveolar ventilation exceeding metabolic demands. The lungs remove CO₂ faster than it is produced by cellular metabolism, resulting in decreased Paco₂, or **hypocapnia** (Paco₂ less than 36 mm Hg). Hypocapnia results in a respiratory alkalosis that also can interfere with tissue function. Like hypoventilation, hyperventilation can be determined by arterial blood gas analysis. Hyperventilation commonly occurs with severe anxiety, acute head injury, pain, and in response to conditions that cause hypoxemia.

**Cyanosis**

**Cyanosis** is a bluish discoloration of the skin and mucous membranes caused by increasing amounts of desaturated or reduced hemoglobin (which is bluish) in the blood. It generally develops when 5 g of hemoglobin is desaturated, regardless of
hemoglobin concentration.

*Peripheral cyanosis* (slow blood circulation in fingers and toes) is most often caused by poor circulation resulting from intense peripheral vasoconstriction, like that observed in persons who have Raynaud disease, are in cold environments, or are severely stressed. Peripheral cyanosis is best seen in the nail beds. *Central cyanosis* is caused by decreased arterial oxygenation (low Pao₂) from pulmonary diseases or pulmonary or cardiac right-to-left shunts. Central cyanosis is best detected in buccal mucous membranes and lips.

Lack of cyanosis does not necessarily indicate that oxygenation is normal. In adults, cyanosis is not evident until severe hypoxemia is present and, therefore, is an insensitive indication of respiratory failure. For example, severe anemia (inadequate hemoglobin concentration) and carbon monoxide poisoning (in which hemoglobin binds to carbon monoxide instead of to oxygen) can cause inadequate oxygenation of tissues without causing cyanosis. Individuals with polycythemia (an abnormal increase in numbers of red blood cells), however, may have cyanosis when oxygenation is adequate. Therefore, cyanosis must be interpreted in relation to the underlying pathophysiologic condition. If cyanosis is suggested, the Pao₂ should be measured.

**Clubbing**

*Clubbing* is the selective bulbous enlargement of the end (distal segment) of a digit (finger or toe) (*Figure 27-1*); its severity can be graded from 1 to 5 based on the extent of nail bed hypertrophy and the amount of changes in the nails themselves. It is usually painless. Clubbing is commonly associated with diseases that disrupt the normal pulmonary circulation and cause chronic hypoxemia, such as bronchiectasis, cystic fibrosis, pulmonary fibrosis, lung abscess, and congenital heart disease, and is rarely reversible. It is proposed that whole megakaryocytes enter the systemic circulation and become impacted in the fingertip circulation. Megakaryocytes and megakaryocyte fragments are activated to release platelet-derived growth factor (PDGF). PDGF promotes growth, vascular permeability, and monocyte and neutrophil chemotaxis and leads to an increased number of vascular smooth muscle cells and fibroblasts, all of which are seen in the pathology of clubbing.⁷ It can sometimes be seen in individuals with lung cancer even without hypoxemia because of the effects of inflammatory cytokines and growth factors (*hypertrophic osteoarthropathy*).⁸
Pain

Pain caused by pulmonary disorders originates in the pleurae, airways, or chest wall. Infection and inflammation of the parietal pleura cause sharp or stabbing pain (pleurodynia) when the pleura stretches during inspiration. The pain is usually localized to a portion of the chest wall, where a unique breath sound called a pleural friction rub may be heard over the painful area. Laughing or coughing makes pleural pain worse. Pleural pain is common with pulmonary infarction (tissue death) caused by pulmonary embolism and emanates from the area around the infarction.

Infection and inflammation of the trachea or bronchi (tracheitis or tracheobronchitis, respectively) can cause central chest pain that is pronounced after coughing. It can be difficult to differentiate from cardiac pain. High blood pressure in the pulmonary circulation (pulmonary hypertension) can cause pain during exercise that is often mistaken for cardiac pain (angina pectoris).

Pain in the chest wall is muscle pain or rib pain. Excessive coughing (which makes the muscles sore) and rib fractures or thoracic surgery produce such pain. Inflammation of the costochondral junction (costochondritis) also can cause chest wall pain. Chest wall pain can often be reproduced by pressing on the sternum or ribs.
Conditions Caused by Pulmonary Disease or Injury

**Hypercapnia**

Hypercapnia, or increased carbon dioxide concentration in the arterial blood (increased PaCO₂), is caused by hypoventilation of the alveoli. As discussed in Chapter 26, carbon dioxide is easily diffused from the blood into the alveolar space; thus, minute volume (respiratory rate × tidal volume) determines not only alveolar ventilation but also PaCO₂. Hypoventilation is often overlooked because the breathing pattern and ventilatory rate may appear to be normal; therefore it is important to obtain blood gas analysis to determine the severity of hypercapnia and resultant respiratory acidosis (acid-base balance is described in Chapter 5).

There are many causes of hypercapnia. Most are a result of a decreased drive to breathe or an inadequate ability to respond to ventilatory stimulation. Some of these causes include (1) depression of the respiratory center by drugs; (2) diseases of the medulla, including infections of the central nervous system or trauma; (3) abnormalities of the spinal conducting pathways, as in spinal cord disruption or poliomyelitis; (4) diseases of the neuromuscular junction or of the respiratory muscles themselves, as in myasthenia gravis or muscular dystrophy; (5) thoracic cage abnormalities, as in chest injury or congenital deformity; (6) large airway obstruction, as in tumors or sleep apnea; and (7) increased work of breathing or physiologic dead space, as in emphysema.

Hypercapnia and the associated respiratory acidosis result in electrolyte abnormalities that may cause dysrhythmias. Individuals also may present with somnolence and even coma because of changes in intracranial pressure associated with high levels of arterial carbon dioxide, which causes cerebral vasodilation. Alveolar hypoventilation with increased alveolar CO₂ concentration limits the amount of oxygen available for diffusion into the blood, thereby leading to secondary hypoxemia.

**Hypoxemia**

Hypoxemia, or reduced oxygenation of arterial blood (reduced Pao₂), is caused by respiratory alterations, whereas hypoxia (or ischemia) is reduced oxygenation of cells in tissues. Although hypoxemia can lead to tissue hypoxia, tissue hypoxia can result from other abnormalities unrelated to alterations of pulmonary function, such as low cardiac output or cyanide poisoning.

Hypoxemia results from problems with one or more of the major mechanisms of oxygenation:
1. Oxygen delivery to the alveoli

a. Oxygen content of the inspired air (\( F_{\text{O}_2} \))

b. Ventilation of alveoli

2. Diffusion of oxygen from the alveoli into the blood

a. Balance between alveolar ventilation and perfusion (\( \dot{V}/\dot{Q} \) match)

b. Diffusion of oxygen across the alveolar capillary barrier

3. Perfusion of pulmonary capillaries

The amount of oxygen in the alveoli is called the \( P_{A\text{O}_2} \) and is dependent on two factors. The first factor is the presence of adequate oxygen content of the inspired air. The amount of oxygen in inspired air is expressed as the percentage or fraction of air that is composed of oxygen, called the \( F_{\text{O}_2} \). The \( F_{\text{O}_2} \) of air at sea level is approximately 21% or 0.21. Anything that decreases the \( F_{\text{O}_2} \) (such as high altitude) decreases the \( P_{A\text{O}_2} \). A second factor is the amount of alveolar minute volume (tidal volume × respiratory rate). Hypoventilation results in an increase in \( P_{A\text{CO}_2} \) and a decrease in \( P_{A\text{O}_2} \) such that there is less oxygen available in the alveoli for diffusion into the blood. This type of hypoxemia can be completely corrected if alveolar ventilation is improved by increases in the rate and depth of breathing. Hypoventilation causes hypoxemia in unconscious persons; in persons with neurologic, muscular, or bone diseases that restrict chest expansion; and in individuals who have chronic obstructive pulmonary disease.

Diffusion of oxygen from the alveoli into the blood is also dependent on two factors. The first is the balance between the amount of air that enters alveoli (\( \dot{V} \)) and the amount of blood perfusing the capillaries around the alveoli (\( \dot{Q} \)). An abnormal ventilation-perfusion ratio (\( \dot{V}/\dot{Q} \)) is the most common cause of hypoxemia (Figure 27-2). The normal \( \dot{V}/\dot{Q} \) is 0.8 because perfusion is somewhat greater than ventilation in the lung bases and because some blood is normally shunted to the bronchial
circulation. \( V/Q \) mismatch refers to an abnormal distribution of ventilation and perfusion. Hypoxemia can be caused by inadequate ventilation of well-perfused areas of the lung (low \( V/Q \)). Mismatching of this type, called \textit{shunting}, occurs in atelectasis, in asthma as a result of bronchoconstriction, and in pulmonary edema and pneumonia when alveoli are filled with fluid. When blood passes through portions of the pulmonary capillary bed that receive no ventilation, the pulmonary capillaries in that area constrict and a right-to-left shunt occurs, resulting in decreased systemic \( \text{PaO}_2 \) and hypoxemia. Hypoxemia also can be caused by poor perfusion of well-ventilated portions of the lung (high \( V/Q \)), resulting in wasted ventilation. The most common cause of high \( V/Q \) is a pulmonary embolus that impairs blood flow to a segment of the lung. An area where alveoli are ventilated but not perfused is termed \textit{alveolar dead space}.

The second factor affecting diffusion of oxygen from the alveoli into the blood is
the alveolocapillary membrane. Diffusion of oxygen through the alveolocapillary membrane is impaired if the membrane is thickened or the surface area available for diffusion is decreased. Thickened alveolocapillary membranes, as occur with edema (tissue swelling) and fibrosis (formation of fibrous lesions), increase the time required for oxygen to diffuse from the alveoli into the capillaries. If diffusion is slowed enough, the Po2 levels of alveolar gas and capillary blood do not have time to equilibrate during the fraction of a second that blood remains in the capillary. Destruction of alveoli, as in emphysema, decreases the alveolocapillary membrane surface area available for diffusion. Hypercapnia is seldom produced by impaired diffusion because carbon dioxide diffuses so easily from capillary to alveolus that the individual with impaired diffusion would die from hypoxemia before hypercapnia could occur.

Hypoxemia can result from blood flow bypassing the lungs. This can occur because of intracardiac defects that cause right-to-left shunting or because of intrapulmonary arteriovenous malformations.

Hypoxemia is most often associated with a compensatory hyperventilation and the resultant respiratory alkalosis (i.e., decreased Paco2 and increased pH). However, in individuals with associated ventilatory difficulties, hypoxemia may be complicated by hypercapnia and respiratory acidosis. Hypoxemia results in widespread tissue dysfunction and, when severe, can lead to organ infarction. In addition, hypoxic pulmonary vasoconstriction can contribute to increased pressures in the pulmonary artery (pulmonary artery hypertension) and lead to right heart failure or cor pulmonale. Clinical manifestations of acute hypoxemia may include cyanosis, confusion, tachycardia, edema, and decreased renal output.

Quick Check 27-1

1. List the primary signs and symptoms of pulmonary disease.

2. What abnormal breathing patterns are seen with pulmonary disease?

3. What mechanisms produce hypercapnia?

4. What mechanisms produce hypoxemia?

Acute Respiratory Failure

Respiratory failure is defined as inadequate gas exchange such that Paco2 ≤60 mm Hg or Paco2 ≥50 mm Hg, with pH ≤7.25.10 Respiratory failure can result from direct
injury to the lungs, airways, or chest wall or indirectly because of disease or injury involving another body system, such as the brain, spinal cord, or heart. It can occur in individuals who have an otherwise normal respiratory system or in those with underlying chronic pulmonary disease. Most pulmonary diseases can cause episodes of acute respiratory failure. If the respiratory failure is primarily hypercapnic, it is the result of inadequate alveolar ventilation and the individual must receive ventilatory support, such as with a bag-valve mask, noninvasive positive pressure ventilation, or intubation and placement on mechanical ventilation. If the respiratory failure is primarily hypoxemic, it is the result of inadequate exchange of oxygen between the alveoli and the capillaries and the individual must receive supplemental oxygen therapy. Many people will have combined hypercapnic and hypoxemic respiratory failure and will require both kinds of support.

Respiratory failure is an important potential complication of any major surgical procedure, especially those that involve the central nervous system, thorax, or upper abdomen. The most common postoperative pulmonary problems are atelectasis, pneumonia, pulmonary edema, and pulmonary emboli. People who smoke are at risk, particularly if they have preexisting lung disease. Limited cardiac reserve, neurologic disease, chronic renal failure, chronic hepatic disease, and infection also increase the tendency to develop postoperative respiratory failure.

Prevention of postoperative respiratory failure includes frequent turning and position changes, deep-breathing exercises, and early ambulation to prevent atelectasis and accumulation of secretions. Humidification of inspired air can help loosen secretions. Incentive spirometry gives individuals immediate feedback about tidal volumes, which encourages them to breathe deeply. Supplemental oxygen is given for hypoxemia, and antibiotics are given as appropriate to treat infection. If respiratory failure develops, the individual may require mechanical ventilation or extracorporeal membrane oxygenation.

Disorders of the Chest Wall and Pleura

There are many conditions that can affect the chest wall or pleura, or both, and influence the function of the respiratory system. Chest wall disorders primarily affect tidal volume and, therefore, result in hypercapnia. Pleural diseases impact both ventilation and oxygenation.

Chest Wall Restriction

If the chest wall is deformed, traumatized, immobilized, or heavy from the accumulation of fat, the work of breathing increases and ventilation may be compromised because of a decrease in tidal volume. The degree of ventilatory
impairment depends on the severity of the chest wall abnormality. Grossly obese individuals are often dyspneic on exertion or when recumbent. Individuals with severe kyphoscoliosis (lateral bending and rotation of the spinal column, with distortion of the thoracic cage) often present with dyspnea on exertion that can progress to respiratory failure. Obesity and kyphoscoliosis are risk factors for respiratory failure or infections in individuals admitted to the hospital for other problems, particularly those who require surgery. Other musculoskeletal abnormalities that can impair ventilation are ankylosing spondylitis (see Chapter 39) and pectus excavatum (a deformity characterized by depression of the sternum).

Impairment of respiratory muscle function caused by neuromuscular diseases such as poliomyelitis, muscular dystrophy, myasthenia gravis, and Guillain-Barré syndrome (see Chapter 16) also can restrict the chest wall and impair pulmonary function. Muscle weakness can result in hypoventilation, inability to remove secretions, and hypoxemia.

Pain from chest wall injury, surgery, or disease can cause significant hypoventilation, especially in those with underlying lung disease. Trauma to the thorax not only can restrict chest expansion because of pain but also can cause structural and mechanical changes that impair the ability of the chest to expand normally. Flail chest results from the fracture of several consecutive ribs in more than one place or fracture of the sternum and several consecutive ribs. These multiple fractures result in instability of a portion of the chest wall, causing paradoxical movement of the chest with breathing. During inspiration the unstable portion of the chest wall moves inward and during expiration it moves outward, impairing movement of gas in and out of the lungs (Figure 27-3).
Chest wall restriction results in a decrease in tidal volume. An increase in respiratory rate can compensate for small decreases in tidal volume, but many individuals will progress to hypercapnic respiratory failure. Diagnosis of chest wall restriction is made by pulmonary function testing (reduction in forced vital capacity [FVC]), arterial blood gas measurement (hypercapnia), and radiographs. Treatment is aimed at any reversible underlying cause but is otherwise supportive. In severe cases, mechanical ventilation may be indicated.

**Pleural Abnormalities**

**Pneumothorax**

_Pneumothorax_ is the presence of air or gas in the pleural space caused by a rupture in the visceral pleura (which surrounds the lungs) or the parietal pleura and chest wall. As air separates the visceral and parietal pleurae, it destroys the negative pressure of the pleural space and disrupts the equilibrium between elastic recoil forces of the lung and chest wall. The lung then tends to recoil by collapsing toward the hilum (Figure 27-4).
Primary (spontaneous) pneumothorax occurs unexpectedly in healthy individuals (usually men) between 20 and 40 years of age and is caused by the spontaneous rupture of blebs (blister-like formations) on the visceral pleura. Bleb rupture can occur during sleep, rest, or exercise. The ruptured blebs are usually located in the apexes of the lungs. The cause of bleb formation is not known, although more than 80% of these individuals have been found to have emphysema-like changes in their lungs even if they have no history of smoking or no known genetic disorder. Approximately 10% of affected individuals have a significant family history of primary pneumothorax that has been linked to mutations in the folliculin gene.11 Secondary pneumothorax can be caused by chest trauma (such as a rib fracture or stab and bullet wounds that tear the pleura; rupture of a bleb or bulla [larger vesicle], as occurs in emphysema; or mechanical ventilation, particularly if it includes positive end-expiratory pressure [PEEP]). Iatrogenic pneumothorax is most commonly caused by transthoracic needle aspiration.

Primary pneumothorax and secondary pneumothorax can present as either open or tension. In open (communicating) pneumothorax, air pressure in the pleural space equals barometric pressure because air that is drawn into the pleural space during inspiration (through the damaged chest wall and parietal pleura or through the lungs and damaged visceral pleura) is forced back out during expiration. In tension pneumothorax, however, the site of pleural rupture acts as a one-way valve, permitting air to enter on inspiration but preventing its escape by closing during expiration. As more and more air enters the pleural space, air pressure in the pneumothorax begins to exceed barometric pressure. Air pressure in the pleural
space pushes against the already recoiled lung, causing compression atelectasis, and against the mediastinum, compressing and displacing the heart, great vessels, and trachea (mediastinal shift). The pathophysiologic effects of tension pneumothorax are life-threatening (see Figure 27-4).

Clinical manifestations of spontaneous or secondary pneumothorax begin with sudden pleural pain, tachypnea, and dyspnea. Depending on the size of the pneumothorax, physical examination may reveal absent or decreased breath sounds and hyperresonance to percussion on the affected side. Tension pneumothorax may be complicated by severe hypoxemia, tracheal deviation away from the affected lung, and hypotension (low blood pressure). Deterioration occurs rapidly and immediate treatment is required. Diagnosis of pneumothorax is made with chest radiographs, ultrasound, and computed tomography (CT). Pneumothorax is treated by aspiration, usually with insertion of a chest tube that is attached to a water-seal drainage system with suction or a small-bore catheter with a one-way valve. After the pneumothorax is evacuated and the pleural rupture is healed, the chest tube is removed. For individuals with persistent air leaks, other interventions may be needed including thoracoscopic surgical techniques or pleurodesis (instillation of a caustic substance, such as talc, into the pleural space).

**Pleural Effusion**

**Pleural effusion** is the presence of fluid in the pleural space. The source of the fluid is usually from blood vessels or lymphatic vessels lying beneath the pleural space, but occasionally an abscess or other lesion may drain into the pleural space. Pleural effusions that enter the pleural space from intact blood vessels can be **transudative** (watery) or **exudative** (high concentrations of white blood cells and plasma proteins). Other types of pleural effusion are characterized by the presence of pus (empyema), blood (hemothorax), or chyle (chylothorax). Mechanisms of pleural effusion are summarized in Table 27-1.
**TABLE 27-1**

**Mechanism of Pleural Effusion***

<table>
<thead>
<tr>
<th>Type of Fluid/Effusion</th>
<th>Source of Accumulation</th>
<th>Primary or Associated Disorder</th>
</tr>
</thead>
<tbody>
<tr>
<td>Transudate (hydrothorax)</td>
<td>Watery fluid that diffuses out of capillaries beneath pleura (i.e., capillaries in lung or chest wall)</td>
<td>Cardiovascular disease that causes high pulmonary capillary pressures; liver or kidney disease that disrupts plasma protein production, causing hypoproteinemia (decreased oncotic pressure in blood vessels)</td>
</tr>
<tr>
<td>Exudate</td>
<td>Fluid rich in cells and proteins (leukocytes, plasma proteins of all kinds; see Chapter 5) that migrates out of capillaries</td>
<td>Infection, inflammation, or malignancy of pleura that stimulates mast cells to release biochemical mediators that increase capillary permeability</td>
</tr>
<tr>

<td>Hemorrhage into pleural space</td>
<td>Traumatic injury, surgery, rupture, or malignancy that damages blood vessels</td>
</tr>
<tr>
<td>Chyle (chylothorax)</td>
<td>Chyle (milky fluid containing lymph and fat droplets) that moves from lymphatic vessels into pleural space instead of passing from gastrointestinal tract to thoracic duct</td>
<td>Traumatic injury, infection, or disorder that disrupts lymphatic transport</td>
</tr>
</tbody>
</table>

*The principles of diffusion are described in Chapter 1; mechanisms that increase capillary permeability and cause exudation of cells, proteins, and fluid are discussed in Chapter 5.

Small collections of fluid may not affect lung function and remain undetected. Most will be removed by the lymphatic system once the underlying condition is resolved. In larger effusions, dyspnea, compression atelectasis with impaired ventilation, and pleural pain are common. Mediastinal shift and cardiovascular manifestations occur in a large, rapidly developing effusion. Physical examination shows decreased breath sounds and dullness to percussion on the affected side. A pleural friction rub can be heard over areas of inflamed pleura.

Diagnosis is confirmed by chest x-ray and thoracentesis (needle aspiration), which can determine the type of effusion and provide symptomatic relief. If the effusion is large, drainage usually requires the placement of a chest tube and surgical interventions may be needed to prevent recurrence of the effusion.

**Empyema**

**Empyema (infected pleural effusion)** is the presence of pus in the pleural space and develops when the pulmonary lymphatics become blocked, leading to an outpouring of contaminated lymphatic fluid into the pleural space. Empyema occurs most commonly in older adults and children and usually develops as a complication of pneumonia, surgery, trauma, or bronchial obstruction from a tumor. Commonly documented infectious organisms include *Staphylococcus aureus*, *Escherichia coli*, anaerobic bacteria, and *Klebsiella pneumoniae*.

Individuals with empyema present clinically with cyanosis, fever, tachycardia (rapid heart rate), cough, and pleural pain. Breath sounds are decreased directly over the empyema. Diagnosis is made by chest radiographs, thoracentesis, and sputum culture. The treatment for empyema includes the administration of appropriate antimicrobials and drainage of the pleural space with a chest tube. In
severe cases, ultrasound-guided pleural drainage, instillation of fibrinolytic agents, or introduction of deoxyribonuclease (DNase) into the pleural space is needed for adequate drainage. Surgical debridement may be required.\textsuperscript{13}

Pulmonary Disorders

Restrictive Lung Diseases

Restrictive lung diseases are characterized by decreased compliance of the lung tissue. This means that it takes more effort to expand the lungs during inspiration, which increases the work of breathing. Individuals with lung restriction have dyspnea, an increased respiratory rate, and a decreased tidal volume. Pulmonary function testing reveals a decrease in FVC. Restrictive lung diseases can cause \( V/Q \) mismatch and affect the alveolocapillary membrane, which reduces the diffusion of oxygen from the alveoli into the blood and results in hypoxemia. Some of the most common restrictive lung diseases in adults are aspiration, atelectasis, bronchiectasis, bronchiolitis, pulmonary fibrosis, inhalation disorders, pneumoconiosis, allergic alveolitis, pulmonary edema, and acute respiratory distress syndrome.

Aspiration

Aspiration is the passage of fluid and solid particles into the lung. It tends to occur in individuals whose normal swallowing mechanism and cough reflex are impaired by central or peripheral nervous system abnormalities. Predisposing factors include an altered level of consciousness caused by substance abuse, sedation, or anesthesia; seizure disorders; stroke; neuromuscular disorders that cause dysphagia; and feeding through a nasogastric tube. The right lung, particularly the right lower lobe, is more susceptible to aspiration than the left lung because the branching angle of the right mainstem bronchus is straighter than the branching angle of the left mainstem bronchus.

Aspiration of large food particles or gastric fluid with pH of less than 2.5 has serious consequences. Solid food particles can obstruct a bronchus, resulting in bronchial inflammation and collapse of airways distal to the obstruction. If the aspirated solid is not identified and removed by bronchoscopy, a chronic, local inflammation develops that may lead to recurrent infection and bronchiectasis (permanent dilation of the bronchus).

Aspiration of oral or pharyngeal secretions can lead to aspiration pneumonia. Intubation of the trachea also can cause aspiration and bacterial pneumonia. Aspiration of acidic gastric fluid may cause severe pneumonitis. Bronchial damage includes inflammation, loss of ciliary function, and bronchospasm. In the alveoli, acidic fluid damages the alveolocapillary membrane. This allows plasma and blood cells to move from capillaries into the alveoli, resulting in hemorrhagic pneumonitis. The lung becomes stiff and noncompliant as surfactant production is
disrupted, leading to further edema and collapse. Hypoventilation may develop as this process progresses and systematic complications, such as hypotension, may occur.

Clinical manifestations of aspiration include the sudden onset of choking and intractable cough with or without vomiting, fever, dyspnea, and wheezing. Some individuals have no symptoms acutely; instead they have recurrent lung infections, chronic cough, or persistent wheezing over months and even years.

Preventive measures for individuals at risk are more effective than treatment of known aspiration. The most important preventive measures include use of a semirecumbent position, surveillance of enteral feeding, use of promotility agents, and avoidance of excessive sedation. Nasogastric tubes, which are often used to remove stomach contents, are used to prevent aspiration but also can cause aspiration if fluid and particulate matter are regurgitated as the tube is being placed.

Treatment of aspiration pneumonitis includes use of supplemental oxygen and mechanical ventilation with positive end-expiratory pressure (PEEP) and administration of corticosteroids. Fluids are restricted to decrease blood volume and minimize pulmonary edema. Bacterial pneumonia may develop as a complication of aspiration pneumonitis and must be treated with broad-spectrum antimicrobials.

**Atelectasis**

Atelectasis is the collapse of lung tissue. There are three types of atelectasis:

1. **Compression atelectasis** is caused by external pressure exerted by tumor, fluid, or air in the pleural space or by abdominal distention pressing on a portion of lung, causing alveoli to collapse.

2. **Absorption atelectasis** results from removal of air from obstructed or hypoventilated alveoli or from inhalation of concentrated oxygen or anesthetic agents.

3. **Surfactant impairment** results from decreased production or inactivation of surfactant, which is necessary to reduce surface tension in the alveoli and thus prevent lung collapse during expiration. Surfactant impairment can occur because of premature birth, acute respiratory distress syndrome, anesthesia induction, or mechanical ventilation.

Atelectasis tends to occur after surgery, especially in those who have been administered general anesthetics. Postoperative individuals are often in pain,
breathe shallowly, are reluctant to change position, and produce viscous secretions that tend to pool in dependent portions of the lung, especially following thoracic or upper abdominal surgery. Atelectasis increases shunt, decreases compliance, and may lead to perioperative hypoxemia.

Clinical manifestations of atelectasis are similar to those of pulmonary infection including dyspnea, cough, fever, and leukocytosis. Prevention and treatment of postoperative atelectasis usually include deep-breathing exercises (often with the aid of an incentive spirometer), frequent position changes, and early ambulation. Deep breathing promotes ciliary clearance of secretions, stabilizes the alveoli by redistributing surfactant, and promotes collateral ventilation through the *poles of Kohn*, promoting expansion of collapsed alveoli (Figure 27-5). Postoperative noninvasive positive-pressure ventilation (NIPPV) has been shown to improve oxygenation and ventilation for high-risk individuals (i.e., individuals who are obese or in respiratory distress).

![Figure 27-5](image)

**Bronchiectasis**

Bronchiectasis is persistent abnormal dilation of the bronchi. There may be a genetic predisposition or a defect in host defense. It usually occurs in conjunction with other respiratory conditions that are associated with chronic bronchial inflammation, such as obstruction of an airway with mucous plugs, atelectasis,
aspiration of a foreign body, infection, cystic fibrosis (see Chapter 28), tuberculosis, congenital weakness of the bronchial wall, or immunocompromised health status. Chronic inflammation of the bronchi leads to destruction of elastic and muscular components of their walls, obstruction of the bronchial lumen, traction from adjacent fibrosis, and permanent dilation. Bronchiectasis also is associated with a number of systemic disorders, such as rheumatologic disease, inflammatory bowel disease, and immunodeficiency syndromes (e.g., acquired immunodeficiency syndrome [AIDS]). There may be no known cause.

The primary symptom of bronchiectasis is a chronic productive cough that may date back to a childhood illness or infection. The disease is commonly associated with recurrent lower respiratory tract infections and expectoration of voluminous amounts of foul-smelling purulent sputum (measured in cupfuls). Hemoptyis and clubbing of the fingers (from chronic hypoxemia) are common. Pulmonary function studies show decreases in FVC and expiratory flow rates. Hypoxemia eventually leads to cor pulmonale (see p. 708). Diagnosis is usually confirmed by the use of high-resolution computed tomography. Bronchiectasis is treated with sputum culture, antibiotics, anti-inflammatory drugs, bronchodilators, chest physiotherapy, and supplemental oxygen.

**Bronchiolitis**

**Bronchiolitis** is a diffuse, inflammatory obstruction of the small airways or bronchioles occurring most commonly in children. In adults it usually occurs with chronic bronchitis but can occur in otherwise healthy individuals in association with an upper or lower respiratory tract viral infection or with inhalation of toxic gases, or be of unknown etiology. Bronchiolitis also is a serious complication of stem cell and lung transplantation and can progress to **bronchiolitis obliterans**, a fibrotic process that occludes airways and causes permanent scarring of the lungs. **Bronchiolitis obliterans organizing pneumonia (BOOP)** is a complication of bronchiolitis obliterans in which the alveoli and bronchioles become filled with plugs of connective tissue.

Clinical manifestations include a rapid ventilatory rate; marked use of accessory muscles; low-grade fever; dry, nonproductive cough; and hyperinflated chest. A decrease in the ventilation-perfusion ratio results in hypoxemia. Diagnosis is made by spirometry and bronchoscopy with biopsy. Bronchiolitis is treated with appropriate antibiotics, corticosteroids, immunosuppressive agents, and chest physical therapy (humidified air administration, coughing and deep-breathing exercises, postural drainage).
**Pulmonary Fibrosis**

**Pulmonary fibrosis** is an excessive amount of fibrous or connective tissue in the lung. Pulmonary fibrosis can be caused by formation of scar tissue after active pulmonary disease (e.g., acute respiratory distress syndrome, tuberculosis), in association with a variety of autoimmune disorders (e.g., rheumatoid arthritis, progressive systemic sclerosis, sarcoidosis), or by inhalation of harmful substances (e.g., coal dust, asbestos). Chronic inflammation leads to fibrosis and causes a marked loss of lung compliance. The lung becomes stiff and difficult to ventilate, and the diffusing capacity of the alveolocapillary membrane may decrease, causing hypoxemia. Diffuse pulmonary fibrosis has a poor prognosis.

Pulmonary fibrosis is known as idiopathic pulmonary fibrosis when there is no specific cause. **Idiopathic pulmonary fibrosis (IPF)** is the most common idiopathic interstitial lung disorder. It is more common in men than in women and most cases occur after age 60. Although IPF is characterized by chronic inflammation, recent studies suggest that it results from multiple injuries at different lung sites with aberrant healing responses to alveolar epithelial cell injury, which probably occurs in response to a combination of environmental insults and genetic predispositions. Fibroproliferation of the interstitial lung tissue around the alveoli causes decreased oxygen diffusion across the alveolocapillary membrane and hypoxemia. As the disease progresses, decreased lung compliance leads to increased work of breathing, decreased tidal volume, and resultant hypoventilation with hypercapnia.

The primary symptom of IPF is increasing dyspnea on exertion. Physical examination reveals diffuse inspiratory crackles. The diagnosis is confirmed by pulmonary function testing (decreased FVC), high-resolution computed tomography, and lung biopsy. Treatment includes oxygen, corticosteroids, and cytotoxic drugs, although success rates are low and toxicities are high. Newer therapies include antifibrotic drugs (N-acetylcysteine, pirfenidone), nintedanib (angiogenesis inhibitor), interferon, and anticoagulation therapy. Selected individuals may benefit from lung transplantation.

**Inhalation Disorders**

**Exposure to toxic gases.**

Inhalation of gaseous irritants can cause significant respiratory dysfunction. Commonly encountered toxic gases include smoke, ammonia, hydrogen chloride, sulfur dioxide, chlorine, phosgene, and nitrogen dioxide. Inhalation injuries in burns can include toxic gases from household or industrial combustants, heat, and smoke particles. Inhaled toxic particles cause damage to the airway epithelium and
promote mucus secretion, inflammation, mucosal edema, ciliary damage, pulmonary edema, and surfactant inactivation. The cellular effects of toxic gases and polluted air are described in Chapter 4. Acute toxic inhalation is frequently complicated by acute respiratory distress syndrome (ARDS) and pneumonia. Initial symptoms include burning of the eyes, nose, and throat; coughing; chest tightness; and dyspnea. Hypoxemia is common. Treatment includes administration of supplemental oxygen, mechanical ventilation with PEEP, and support of the cardiovascular system. Corticosteroids are sometimes used, although their effectiveness has not been well documented. Most individuals respond quickly to therapy. Some, however, may improve initially and then deteriorate as a result of bronchiectasis or bronchiolitis.

Prolonged exposure to high concentrations of supplemental oxygen can result in a relatively rare condition known as oxygen toxicity. The basic underlying mechanism of injury is a severe inflammatory response mediated by oxygen free radicals. Damage to alveolocapillary membranes results in disruption of surfactant production, production of interstitial and alveolar edema, and a reduction in lung compliance. In infants this can lead to a condition known as bronchopulmonary dysplasia in which there is severe scarring of the lung. Treatment involves ventilatory support and a reduction of inspired oxygen concentration to less than 60% as soon as tolerated.

**Pneumoconiosis.**

*Pneumoconiosis* represents any change in the lung caused by inhalation of inorganic dust particles, usually occurring in the workplace. As in all cases of environmentally acquired lung disease, the individual's history of exposure is important in determining the diagnosis. Pneumoconiosis often occurs after years of exposure to the offending dust, with progressive fibrosis of lung tissue.

The dusts of silica, asbestos, and coal are the most common causes of pneumoconiosis. Others include talc, fiberglass, clays, mica, slate, cement, cadmium, beryllium, tungsten, cobalt, aluminum, and iron. Deposition of these materials in the lungs causes the release of proinflammatory cytokines. This leads to chronic inflammation with scarring of the alveolocapillary membrane, resulting in pulmonary fibrosis and progressive pulmonary deterioration. Clinical manifestations with advancement of disease include cough, chronic sputum production, dyspnea, decreased lung volumes, and hypoxemia. In most cases, diagnosis is confirmed by performing chest x-ray or CT and obtaining a complete occupational history. Treatment is usually palliative and focuses on preventing further exposure and improving working conditions, along with pulmonary
Hypersensitivity pneumonitis.

Hypersensitivity pneumonitis (extrinsic allergic alveolitis) is an allergic, inflammatory disease of the lungs caused by inhalation of organic particles or fumes. Many allergens can cause this disorder, including grains, silage, bird droppings or feathers, wood dust (particularly redwood and maple), cork dust, animal pelts, coffee beans, fish meal, mushroom compost, and molds that grow on sugarcane, barley, and straw. The lung inflammation is a hypersensitivity response that occurs after repeated, prolonged exposure to the allergen causing pneumonitis. Lymphocytes and inflammatory cells infiltrate the interstitial lung tissue, releasing a variety of autoimmune and inflammatory cytokines.¹⁹

Hypersensitivity pneumonitis can be acute, subacute, or chronic. The acute form causes fever, cough, and chills a few hours after exposure. With continued exposure, the disease becomes chronic and pulmonary fibrosis develops. Diagnosis is made by obtaining a history of allergen exposure and by performing serum antibody testing, chest x-ray, bronchoalveolar lavage, CT, and, in some cases, lung biopsy. Treatment consists of removal of the offending agent and administration of corticosteroids.²⁰

Pulmonary Edema

Pulmonary edema is excess water in the lung. The normal lung is kept dry by lymphatic drainage and a balance among capillary hydrostatic pressure, capillary oncotic pressure, and capillary permeability. In addition, surfactant lining the alveoli repels water, keeping fluid from entering the alveoli. Predisposing factors for pulmonary edema include heart disease, acute respiratory distress syndrome, and inhalation of toxic gases. The pathogenesis of pulmonary edema is shown in Figure 27-6.
The most common cause of pulmonary edema is left-sided heart disease. When the left ventricle fails, filling pressures on the left side of the heart increase and cause a concomitant increase in pulmonary capillary hydrostatic pressure. When the hydrostatic pressure exceeds the oncotic pressure (which holds fluid in the capillary), fluid moves from the capillary into the interstitial space (the space within the alveolar septum between the alveolus and capillary). When the flow of fluid out of the capillaries exceeds the lymphatic system’s ability to remove it, pulmonary edema develops.

Another cause of pulmonary edema is capillary injury that increases capillary permeability, as in cases of adult respiratory distress syndrome or inhalation of toxic gases, such as ammonia. Capillary injury and inflammation causes water and plasma proteins to leak out of the capillary and move into the interstitial space, increasing the interstitial oncotic pressure (which is usually very low). As the interstitial oncotic pressure begins to exceed the capillary oncotic pressure, water moves out of the capillary and into the lung. (Mechanisms of edema are discussed in Chapter 5, Figures 5-1 and 5-2.) Pulmonary edema also can result from obstruction of the lymphatic system by tumors and fibrotic tissue and by increased systemic venous pressure.

Clinical manifestations of pulmonary edema include dyspnea, hypoxemia, and increased work of breathing. Physical examination may disclose inspiratory
crackles (rales) and dullness to percussion over the lung bases. In severe edema, pink frothy sputum is expectorated, hypoxemia worsens, and hypoventilation with hypercapnia may develop.

The treatment of pulmonary edema depends on its cause. If the edema is caused by increased hydrostatic pressure resulting from heart failure, therapy is directed toward improving cardiac output with diuretics, vasodilators, and drugs that improve the contraction of the heart muscle. If edema is the result of increased capillary permeability resulting from injury, the treatment is focused on removing the offending agent and implementing supportive therapy to maintain adequate ventilation and circulation. Individuals with either type of pulmonary edema require supplemental oxygen. Mechanical ventilation may be needed if edema significantly impairs ventilation and oxygenation.

**Acute Lung Injury/Acute Respiratory Distress Syndrome**

Acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) represents a spectrum of acute lung inflammation and diffuse alveolocapillary injury. Both ALI and ARDS are defined as (1) the acute onset of bilateral infiltrates on chest radiograph, (2) a low ratio of partial pressure of arterial oxygen to the fraction of inhaled oxygen under positive airway pressure, and (3) is not derived from hydrostatic pulmonary edema. Biomarkers that can be used to diagnose ARDS are under investigation. In the United States more than 30% of intensive care unit (ICU) admissions are complicated by ARDS. Advances in therapy have decreased overall mortality in people younger than 60 years to approximately 40%, although mortality in older adults and those with severe infections remains much higher. The most common predisposing factors are genetic factors, sepsis, and multiple trauma. There are many other causes, including pneumonia, burns, aspiration, cardiopulmonary bypass surgery, pancreatitis, blood transfusions, drug overdose, inhalation of smoke or noxious gases, fat emboli, high concentrations of supplemental oxygen, radiation therapy, and disseminated intravascular coagulation.

**Pathophysiology**

All disorders causing ALI/ARDS cause acute injury to the alveolocapillary membrane, producing massive pulmonary inflammation, increased capillary permeability, severe pulmonary edema, shunting, V/Q mismatch, and hypoxemia. ARDS can occur directly (from aspiration of highly acidic gastric contents, inhalation of toxic gases) or indirectly (from circulating inflammatory mediators released in response to systemic disorders, such as sepsis and trauma). Lung injury and inflammation damages the alveolocapillary membrane, causing pulmonary
edema, often referred to as noncardiogenic pulmonary edema. ARDS progresses through three overlapping phases characterized by histologic changes in the lung: exudative (inflammatory), proliferative, and fibrotic. The three phases are described as follows:

Exudative phase (within 72 hours): activation of neutrophils and other cells (platelets, macrophages, lung epithelial and endothelial cells) that release a cascade of inflammatory cytokines causing damage to the alveolocapillary membrane and greatly increased capillary membrane permeability. Fluids, proteins, and blood cells leak from the capillary bed into the pulmonary interstitium and flood the alveoli (hemorrhagic exudate). Surfactant is inactivated. The resulting pulmonary edema and hemorrhage severely reduce lung compliance and impair alveolar ventilation. The inflammatory mediators also cause pulmonary vasoconstriction, contributing to ventilation/perfusion mismatch. The inflammatory mediators causing the alveolocapillary damage of ARDS often cause inflammation, endothelial damage, and capillary permeability throughout the body, resulting in systemic inflammatory response syndrome (SIRS). SIRS then leads to multiple organ dysfunction syndrome (MODS) and may cause death (see Chapter 24 and Figure 24-46).

Proliferative phase (within 4 to 21 days): after the initial lung injury, resolution of the pulmonary edema and proliferation of type II pneumocytes, fibroblasts, and myofibroblasts. The intra-alveolar hemorrhagic exudate becomes a cellular granulation tissue appearing as hyaline membranes and there is progressive hypoxemia.

Fibrotic phase (within 14 to 21 days): remodeling and fibrosis of lung tissue. The fibrosis progressively obliterates the alveoli, respiratory bronchioles, and interstitium, leading to a decrease in functional residual capacity (FRC) and continuing V/Q mismatch with severe right-to-left shunt. The result of this overwhelming inflammatory response by the lungs is acute respiratory failure.
Acute Lung Injury
(e.g., pneumonia, aspiration, smoke inhalation, sepsis)

Release of inflammatory cytokines
(e.g., IL-1, IL-6, TNF)

Influx of inflammatory cells
(neutrophils, macrophages, platelets)

Neutrophil aggregation and release of mediators
(ROS, proteolytic enzymes, cytokines, PAF)
Complement activation

Platelet activation

Formation of microthrombi in pulmonary circulation

Vasoconstriction with decreased flow to some lung areas

Pulmonary hypertension

Damage to alveolar cells

Damage to endothelial cells

Disrupted alveolocapillary membrane

Exudation of fluid, protein, RBCs into interstitium

Pulmonary edema and hemorrhage with severe impairment of alveolar ventilation
(Exudative phase)

Decreased surfactant production
Impairment of surfactant function

Atelectasis and decreased lung compliance

Proliferation of type II pneumocytes, fibroblasts, and myofibroblasts
Formation of hyaline membranes
(Proliferative phase)

Progressive fibrosis and tissue remodeling
(destruction of alveoli and bronchioles)
(Fibrotic phase)

Acute Respiratory Failure
(hypoxemia, hypercapnea, acidosis)
Clinical manifestations
The clinical manifestations of ARDS are progressive as follows:

1. Dyspnea and hypoxemia with poor response to oxygen supplementation
2. Hyperventilation and respiratory alkalosis
3. Decreased tissue perfusion, metabolic acidosis, and organ dysfunction
4. Increased work of breathing, decreased tidal volume, and hypoventilation
5. Hypercapnia, respiratory acidosis, and worsening hypoxemia
6. Respiratory failure, decreased cardiac output, hypotension, and death

Evaluation and treatment
Diagnosis is based on a history of the lung injury, physical examination, blood gas analysis, and radiologic examination. Measurement of serum biomarkers (i.e., surfactant proteins, mucin-associated antigens and interleukins) may aid in the diagnosis and prognosis of ARDS. Treatment is based on early detection, supportive therapy, and prevention of complications. Supportive therapy is focused on maintaining adequate oxygenation and ventilation while preventing infection. This often requires various modes of mechanical ventilation. Pharmacologic therapy continues to be explored. Low-dose corticosteroids may improve survival in selected individuals but needs further investigation.

Quick Check 27-3

1. Contrast aspiration and atelectasis.
2. What are some of the causes of pulmonary fibrosis?
3. What symptoms are produced by inhalation of toxic gases?
4. Describe pneumoconiosis, and give two examples.
5. Briefly describe the role of neutrophils in acute respiratory distress syndrome (ARDS).

Obstructive Lung Diseases

Obstructive lung disease is characterized by airway obstruction that is worse with expiration. More force (i.e., use of accessory muscles of expiration) is required to expire a given volume of air and emptying of the lungs is slowed. The unifying symptom of obstructive lung diseases is dyspnea, and the unifying sign is wheezing. Individuals have an increased work of breathing, ventilation-perfusion mismatching, and a decreased forced expiratory volume in 1 second (FEV₁). The most common obstructive diseases are asthma, chronic bronchitis, and emphysema. Because many individuals have chronic bronchitis with emphysema, these diseases together are often called chronic obstructive pulmonary disease (COPD).

Asthma

Asthma is a chronic inflammatory disorder of the bronchial mucosa that causes bronchial hyperresponsiveness, constriction of the airways, and variable airflow obstruction that is reversible. Asthma occurs at all ages, with approximately 6.8 million cases among children (see Chapter 28) and 18.7 million cases among adults in the United States. The prevalence is increasing.26

Asthma is a familial disorder, and more than 100 genes have been identified that may play a role in the susceptibility, pathogenesis, and treatment response of asthma. Specific gene expressions may impart associated phenotypes with specific inflammatory markers (i.e., cells, cytokines, or exhaled nitric oxide) or endotypes including clinical characteristics, biomarkers, lung physiology, genetics, histopathology, epidemiology, and treatment response.27 Other risk factors include age at onset of disease, levels of allergen exposure, urban residence, exposure to indoor and outdoor air pollution, tobacco smoke, recurrent respiratory tract viral infections, gastroesophageal reflux disease, and obesity (which promotes a proinflammatory state).28-30 Exposure to inhaled irritants can cause inflammation and damage to airways independent of allergen sensitivity. This leads to irritant (or nonallergic) asthma, as well as increases the hyperresponsiveness of the airways to allergens in those with a history of atopy (allergy).31 Inhaled irritants affect both the epigenetics of asthma and asthma presentation, including age of onset, symptoms, and gender differences.32

Exposure to high levels of certain allergens during childhood increases the risk for asthma. Furthermore, decreased exposure to certain infectious organisms
appears to create an immunologic imbalance that favors the development of allergy and asthma. This complex relationship has been called the *hygiene hypothesis*.\textsuperscript{33} Recently, the relationship between the microbiome and asthma risk is shedding light on these complex interactions\textsuperscript{34} (see *Health Alert: The Microbiome and Asthma*).

**Health Alert**

**The Microbiome and Asthma**

The human body exists in balance with trillions of microorganisms that cover both the internal and the external surfaces of the body, especially the gut. This complex relationship between the body and its “microbiome” has profound effects on health and disease. The constant interaction of the immune system with an individual's own unique microbiome significantly affects innate and adaptive immune function from the neonate to the elder adult. Individuals with asthma have been found to have differences in their gut and lung microbiome as compared to those without asthma. These differences have been postulated to contribute to the risk for asthma, the severity of asthma, phenotypes of asthma, and the response to treatment. An increased understanding of the relationships between the lung microbiome and immune and inflammatory responses in asthma may provide opportunities for improved prevention and novel treatment approaches.

**Pathophysiology**

Airway epithelial exposure to antigen initiates both an innate and an adaptive immune response in sensitized individuals\textsuperscript{35} (see *Chapter 8*). Many cells and cellular elements contribute to the persistent inflammation of the bronchial mucosa and hyperresponsiveness of the airways, including dendritic cells (antigen-presenting macrophages), T helper 2 (Th2) lymphocytes, B lymphocytes, mast cells, neutrophils, eosinophils, and basophils. There is both an immediate (early asthmatic response) and a late (delayed) response.

During the *early asthmatic response*, antigen exposure to the bronchial mucosa activates dendritic cells, which present antigen to T-helper cells. T-helper cells differentiate into Th2 cells releasing inflammatory cytokines and interleukins that activate B lymphocytes (plasma cells) and eosinophils. Plasma cells produce
antigen-specific IgE, which binds to the surface of mast cells. Subsequent cross-linking of IgE molecules with the antigen causes mast cell degranulation with the release of inflammatory mediators including histamine, bradykinins, leukotrienes and prostaglandins, platelet-activating factor, and interleukins\textsuperscript{36} (see Figures 8-11 and 8-12 for additional details). These inflammatory mediators cause vasodilation, increased capillary permeability, mucosal edema, bronchial smooth muscle contraction (bronchospasm), and mucus secretion from mucosal goblet cells with narrowing of the airways and obstruction to airflow. Eosinophils cause direct tissue injury and release of toxic neuropeptides that contribute to increased bronchial hyperresponsiveness\textsuperscript{37} (Figures 27-8, 27-9, and 27-10).
FIGURE 27-9  Pathophysiology of Asthma. Allergen or irritant exposure results in a cascade of inflammatory events leading to acute and chronic airway dysfunction. IgE, Immunoglobulin E; IL, interleukin.
Acute Asthmatic Responses. Inhaled antigen (1) binds to mast cells covered with preformed IgE. Mast cells degranulate (2) and release inflammatory mediators such as histamine, bradykinins, leukotrienes, prostaglandins, platelet-activating factor, and interleukins. Secreted mediators (3) induce active bronchospasm (airway smooth muscle constriction), edema from increased capillary permeability, and airway mucus secretion from goblet cells. At the same time, antigen is detected by (4) dendritic cells that process and present it to Th2 cells (5), which produce interleukin-4 (IL-4) and many other interleukins (see text). IL-4 promotes switching of B cells to favor immunoglobulin E (IgE) production. Th2 cells also produce IL-5 (6), which activates eosinophils. Eosinophil products, such as major basic protein and eosinophil cationic protein, damage the respiratory epithelium. Many inflammatory cells, including neutrophils (7), also contribute to the inflammatory process and airway obstruction. IgE, Immunoglobulin E.

The late asthmatic response begins 4 to 8 hours after the early response. Chemotactic recruitment of eosinophils, neutrophils, and lymphocytes during the acute response causes a latent release of inflammatory mediators, again inciting bronchospasm, edema, and mucus secretion with obstruction to airflow. Synthesis of leukotrienes contributes to prolonged smooth muscle contraction. Eosinophils cause direct tissue injury with fibroblast proliferation and airway scarring. Damage to ciliated epithelial cells contributes to impaired mucociliary function, with the accumulation of mucus and cellular debris forming plugs in the airways. Untreated inflammation can lead to long-term airway damage that is irreversible and is known as airway remodeling (subepithelial fibrosis, smooth muscle hypertrophy).

Airway obstruction increases resistance to airflow and decreases flow rates, especially expiratory flow. Impaired expiration causes air trapping, hyperinflation distal to obstructions, and increased work of breathing. Changes in resistance to airflow are not uniform throughout the lungs and the distribution of inspired air is uneven, with more air flowing to the less resistant portions. Continued air trapping increases intrapleural and alveolar gas pressures and causes decreased perfusion of the alveoli. Increased alveolar gas pressure, decreased ventilation, and decreased perfusion lead to variable and uneven ventilation-perfusion relationships within
different lung segments. Hyperventilation is triggered by lung receptors responding to increased lung volume and obstruction. The result is early hypoxemia without CO₂ retention. Hypoxemia further increases hyperventilation through stimulation of the respiratory center, causing PaCO₂ to decrease and pH to increase (respiratory alkalosis). With progressive obstruction of expiratory airflow, air trapping becomes more severe and the lungs and thorax become hyperexpanded, positioning the respiratory muscles at a mechanical disadvantage. This leads to a decrease in tidal volume with increasing CO₂ retention and respiratory acidosis. Respiratory acidosis signals respiratory failure, especially when left ventricular filling, and thus cardiac output, becomes compromised because of severe hyperinflation.

**Clinical manifestations**

Individuals are asymptomatic between attacks and pulmonary function tests are normal. At the beginning of an attack, the individual experiences chest constriction, expiratory wheezing, dyspnea, nonproductive coughing, prolonged expiration, tachycardia, and tachypnea. Severe attacks involve the accessory muscles of respiration and wheezing is heard during both inspiration and expiration. A pulsus paradoxus (decrease in systolic blood pressure during inspiration of more than 10 mm Hg) may be noted. Peak flow measurements should be obtained. Because the severity of blood gas alterations is difficult to evaluate by clinical signs alone, arterial blood gas tensions should be measured if oxygen saturation falls below 90%. Usual findings are hypoxemia with an associated respiratory alkalosis. In the late asthma response, symptoms can be even more severe than the initial attack.

If bronchospasm is not reversed by usual treatment measures, the individual is considered to have acute severe bronchospasm or status asthmaticus. If status asthmaticus continues, hypoxemia worsens, expiratory flows and volumes decrease further, and effective ventilation decreases. Acidosis develops as the PaCO₂ level begins to rise. Asthma becomes life-threatening at this point if treatment does not reverse this process quickly. A silent chest (no audible air movement) and a PaCO₂ >70 mm Hg are ominous signs of impending death.

**Evaluation and treatment**

The diagnosis of asthma is supported by a history of allergies and recurrent episodes of wheezing, dyspnea, and cough or exercise intolerance. Further evaluation includes spirometry, which may document reversible decreases in FEV₁ during an induced attack.

The evaluation of an acute asthma attack requires the rapid assessment of arterial blood gases and expiratory flow rates (using a peak flow meter) and a search for
underlying triggers, such as infection. Hypoxemia and respiratory alkalosis are expected early in the course of an acute attack. The development of hypercapnia with respiratory acidosis signals the need for mechanical ventilation. Management of the acute asthma attack requires immediate administration of oxygen and inhaled beta-agonist bronchodilators. In addition, oral corticosteroids should be administered early in the course of management.\textsuperscript{40} Careful monitoring of gas exchange and airway obstruction in response to therapy provides information necessary to determine whether hospitalization is necessary. Antibiotics are not indicated for acute asthma unless there is a documented bacterial infection.

Management of asthma begins with avoidance of allergens and irritants. Individuals with asthma tend to underestimate the severity of their asthma and extensive education is important, including use of a peak flow meter and adherence to an action plan. In the mildest form of asthma (intermittent), short-acting beta-agonist inhalers are prescribed. For all categories of persistent asthma, anti-inflammatory medications are essential and inhaled corticosteroids are the mainstay of therapy. In individuals who are not adequately controlled with inhaled corticosteroids, leukotriene antagonists can be considered. In more severe asthma, long-acting beta agonists can be used to control persistent bronchospasm; however, these agonists can actually worsen asthma in some individuals with certain genetic polymorphisms.\textsuperscript{40a} Immunotherapy has been shown to be an important tool in reducing asthma exacerbations and can now be given sublingually.\textsuperscript{41} Monoclonal antibodies to IgE (omalizumab) have been found to be helpful as adjunctive therapy to inhaled steroids.\textsuperscript{42} The National Asthma Education and Prevention Program offers stepwise guidelines for the diagnosis and management of chronic asthma based on clinical severity; they may be reviewed at www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm. Biomarkers and epigenetic markers are being evaluated to personalize treatment and reduce mortality.\textsuperscript{43,44}

**Chronic Obstructive Pulmonary Disease**

**Chronic obstructive pulmonary disease (COPD)** is defined as a common preventable and treatable disease characterized by persistent airflow limitation that is usually progressive and associated with an enhanced chronic inflammatory response in the airways and the lung to noxious particles or gases. Exacerbations and comorbidities contribute to the overall severity of disease.\textsuperscript{45} COPD is the most common chronic lung disease in the world, and the fourth leading cause of death in the United States and globally. Overall mortality from COPD has increased in the United States over the past 30 years; however, COPD prevalence in women is higher throughout the life span. Risk factors for COPD include tobacco smoke (cigarette,
pipe, cigar, and environmental tobacco smoke), occupational dusts and chemicals (vapors, irritants, and fumes), indoor air pollution from biomass fuel used for cooking and heating (in poorly vented dwellings), outdoor air pollution, and any factor that affects lung growth during gestation and childhood (low birth weight, respiratory tract infections). Genetic and epigenetic susceptibilities have been identified including polymorphisms of genes that code for tumor necrosis factor, surfactant, proteases, and antiproteases and acquired failure of DNA repair. The clinical phenotypes of COPD discussed here are chronic bronchitis and emphysema. An inherited mutation in the α₁-antitrypsin gene results in the development of COPD at an early age, even in individuals who do not smoke.

**Chronic Bronchitis**

*Chronic bronchitis* is defined as hypersecretion of mucus and chronic productive cough for at least 3 months of the year (usually the winter months) for at least 2 consecutive years.

**Pathophysiology**

Inspired irritants result in airway inflammation with infiltration of neutrophils, macrophages, and lymphocytes into the bronchial wall. Continual bronchial inflammation causes bronchial edema, an increase in the size and number of mucous glands and goblet cells in the airway epithelium, smooth muscle hypertrophy with fibrosis, and narrowing of airways. Thick, tenacious mucus is produced and cannot be cleared because of impaired ciliary function (Figure 27-11). The lung's defense mechanisms are, therefore, compromised, increasing susceptibility to pulmonary infection and injury and ineffective repair. Frequent infectious exacerbations from bacterial colonization of damaged airways are complicated by bronchospasm with dyspnea and productive cough. The pathogenesis of chronic bronchitis is shown in Figure 27-12.
FIGURE 27-11 Chronic Bronchitis. Inflammation and thickening of mucous membrane with accumulation of mucus and pus leading to obstruction characterized by productive cough. (Modified from Des Jardins T, Burton GG: Clinical manifestations and assessment of respiratory disease, ed 3, St Louis, 1995, Mosby.)
This process initially affects only the larger bronchi, but eventually all airways are involved. The thick mucus and hypertrophied bronchial smooth muscle constrict the airways and lead to obstruction, particularly during expiration when the airways are narrowed (Figure 27-13). Obstruction eventually leads to ventilation-perfusion mismatch with hypoxemia. The airways collapse early in expiration, trapping gas in the distal portions of the lung (hyperinflation). Air trapping expands the thorax and positions the respiratory muscles at a mechanical disadvantage. This leads to
decreased tidal volume, hypoventilation, and hypercapnia.

**FIGURE 27-13** Mechanisms of Air Trapping in COPD. Mucous plugs and narrowed airways cause air trapping and hyperinflation of alveoli on expiration. During inspiration, the airways are pulled open, allowing gas to flow past the obstruction. During expiration, decreased elastic recoil of the bronchial walls results in collapse of the airways and prevents normal expiratory airflow.

**Clinical manifestations**

Table 27-2 lists the common clinical manifestations of chronic obstructive lung disease, chronic bronchitis, and emphysema.

Evaluation and treatment

Diagnosis is based on history of symptoms, physical examination, chest imaging, pulmonary function tests (i.e., a FEV₁/forced vital capacity ratio <0.7), and blood gas analyses. These tests reflect the progressive nature of the disease. Prevention of chronic bronchitis is essential because pathologic changes are not reversible. By the time an individual seeks medical care for symptoms, considerable airway damage is present. If the individual stops smoking, disease progression can be halted.\(^{51}\) Influenza and pneumococcal vaccinations should be up to date.

Bronchodilators, mucolytics, antioxidants, and anti-inflammatory drugs are prescribed as needed to control cough and reduce dyspnea. Chest physical therapy may be helpful and includes deep breathing and postural drainage. During acute exacerbations (infection and bronchospasm), individuals require treatment with antibiotics and steroids and may need mechanical ventilation.\(^{52}\) Chronic use of oral steroids may be needed late in the course of the disease but should be considered a last resort. Individuals with severe hypoxemia will require home oxygen therapy. Oxygen is administered with care to individuals with severe hypoxemia and CO\(_2\) retention. Chronic elevation of PaCO\(_2\) diminishes the sensitivity of central chemoreceptors and they no longer act as the primary stimulus for breathing. Teaching includes nutritional counseling, respiratory hygiene, recognition of the early signs of infection, and techniques that relieve dyspnea, such as pursed-lip breathing. In addition, many comorbidities accompany COPD and require monitoring and therapy, including cardiovascular disorders, metabolic diseases, bone disease, stroke, lung cancer, cachexia, skeletal muscle weakness, anemia, depression, and cognitive decline. Chronic low-grade systemic inflammation may be associated with these conditions.\(^{53}\)

**Emphysema**
Emphysema is abnormal permanent enlargement of gas-exchange airways (acini) accompanied by destruction of alveolar walls without obvious fibrosis. Obstruction results from changes in lung tissues, rather than mucus production and inflammation as in chronic bronchitis. The major mechanism of airflow limitation is loss of elastic recoil.

Primary emphysema, which accounts for 1% to 3% of all cases of emphysema, is commonly linked to an inherited deficiency of the enzyme \( \alpha_{1} \)-antitrypsin. Normally \( \alpha_{1} \)-antitrypsin inhibits the action of many proteolytic enzymes (i.e., elastases released by neutrophils); therefore \( \alpha_{1} \)-antitrypsin deficiency (an autosomal recessive trait) increases the likelihood of developing emphysema because proteolysis in lung tissues is not inhibited.\(^{54} \) \( \alpha_{1} \)-Antitrypsin deficiency is suggested in individuals who develop emphysema before 40 years of age and in individuals who do not smoke but still develop the disease. The major cause of secondary emphysema is the inhalation of cigarette smoke, although air pollution, occupational exposures, and childhood respiratory tract infections are known to be contributing factors.

Pathophysiology

Emphysema is characterized by destruction of alveoli through the breakdown of elastin within the septa by an imbalance between proteases and antiproteases, oxidative stress, and apoptosis of lung structural cells (see Figure 27-12).\(^{55} \) Alveolar destruction also produces large air spaces within the lung parenchyma (bullae) and air spaces adjacent to pleurae (blebs) (Figure 27-14). Bullae and blebs are not effective in gas exchange and result in significant ventilation-perfusion (\( \overline{V/Q} \)) mismatching and hypoxemia. Expiration becomes difficult because loss of elastic recoil reduces the volume of air that can be expired passively and air is trapped in the lungs (see Figure 27-13). Air trapping causes hyperexpansion of the chest, placing the muscles of respiration at a mechanical disadvantage. This results in increased workload of breathing, so that late in the course of disease, many individuals will develop hypoventilation and hypercapnia. Persistent inflammation in the airways can result in hyperreactivity of the bronchi with bronchoconstriction, which may be partially reversible with bronchodilators. Destruction of alveolar walls and pulmonary capillaries also causes pulmonary artery hypertension and cor pulmonale (see pp. 707-708). Chronic inflammation also can have significant systemic effects including weight loss, muscle weakness, and increased susceptibility to comorbidities, such as infection.
Clinical manifestations
The clinical manifestations of emphysema are listed in Table 27-2.

Evaluation and treatment
Emphysema is usually diagnosed and staged by pulmonary function measures. In COPD, pulmonary function tests indicate obstruction to gas flow during expiration with a marked decrease in FEV₁. Chronic management of emphysema begins with smoking cessation. Pharmacologic management is based on clinical severity (mild, moderate, severe, or very severe). Inhaled anticholinergic agents and beta agonists should be prescribed. Inhaled corticosteroids are indicated for severe COPD, although long-term therapy with oral steroids should be avoided if possible. Pulmonary rehabilitation, improved nutrition, and breathing techniques can improve symptoms. Progressive pulmonary dysfunction with hypoxemia and hypercapnia may require long-term oxygen therapy and ventilation if indicated. A class of drugs called phosphodiesterase E4 (PDE4) inhibitors is proving to be effective in selected individuals with severe COPD. α₁-Antitrypsin augmentation may be indicated for primary emphysema. Selected individuals with severe emphysema can benefit from lung volume reduction surgery.
1. What mechanisms cause airway obstruction in asthma?

2. How does emphysema affect oxygenation and ventilation?

3. Define chronic bronchitis.

**Respiratory Tract Infections**

Respiratory tract infections are the most common cause of short-term disability in the United States. Most of these infections—the common cold, pharyngitis (sore throat), and laryngitis—involve only the upper airways. Although the lungs have direct contact with the atmosphere, they usually remain sterile. Infections of the lower respiratory tract occur most often in the very young and very old or those with impaired immunity.

**Acute Bronchitis**

*Acute bronchitis* is acute infection or inflammation of the airways or bronchi and is usually self-limiting. The vast majority of cases of acute bronchitis are caused by viruses. Many of the clinical manifestations are similar to those of pneumonia (i.e., fever, cough, chills, malaise), but physical examination does not reveal signs of pulmonary consolidation and chest radiographs do not show infiltrates. Individuals with viral bronchitis usually have a nonproductive cough that often occurs in paroxysms and is aggravated by cold, dry, or dusty air. In some cases, purulent sputum is produced. Chest pain often develops from the effort of coughing. Treatment consists of rest, aspirin, humidity, and a cough suppressant, such as codeine. Bacterial bronchitis is treated with rest, antipyretics, humidity, and antibiotics.

**Pneumonia**

*Pneumonia* is infection of the lower respiratory tract caused by bacteria, viruses, fungi, protozoa, or parasites. It is the sixth leading cause of death in the United States. The incidence and mortality of pneumonia are highest in the elderly. Risk factors for pneumonia include advanced age, compromised immunity, underlying lung disease, alcoholism, altered consciousness, impaired swallowing, smoking, endotracheal intubation, malnutrition, immobilization, underlying cardiac or liver disease, and residence in a nursing home. The causative microorganism influences the clinical presentation of the individual, the treatment plan, and the prognosis.

Pneumonia can be categorized as community-acquired (CAP), health care–associated (HCAP), hospital-acquired (HAP), or ventilator-associated (VAP). CAP is
one of the most common reasons for hospitalization in the United States. HCAP is defined as occurring in individuals with recent hospitalization, residence in a nursing home or extended care facility, home infusion therapy, chronic dialysis, or home wound care, although more recent studies suggest nonambulatory status, tube feedings, and the use of gastric acid suppressive agents also should be considered as criteria for HCAP.\textsuperscript{59} It is estimated that nearly one third of all hospital admissions for pneumonia are now considered HCAP. HAP is the second most common nosocomial infection (urinary tract infection [UTI] is the most common) but has the greatest mortality (overall 20\% to 50\% mortality). VAP is a nosocomial infection that occurs in 9\% to 27\% of individuals who require intubation and mechanical ventilation.\textsuperscript{60-62}

The microorganisms that most commonly cause CAP are different from those infections that cause HCAP, HAP, and VAP (Box 27-1). The most common community-acquired pneumonia is caused by \textit{Streptococcus pneumoniae} (also known as pneumococcus), which results in hospitalization in more than half of affected individuals and an overall hospital mortality of about 10\%.\textsuperscript{63} \textit{Mycoplasma pneumoniae} is a common cause of atypical pneumonia in young people, especially those living in group housing such as dormitories and army barracks. Community-acquired methicillin-resistant \textit{Staphylococcus aureus} (MRSA) is becoming more common.\textsuperscript{64,65} Influenza and respiratory syncytial virus are the most common causes of viral community-acquired pneumonia in adults.\textsuperscript{66} VAP is a frequent complication in the intensive care unit (see Health Alert: Ventilator-Associated Pneumonia [VAP]). Immunocompromised individuals (e.g., those with human immunodeficiency virus [HIV] or those undergoing organ transplantation) are especially susceptible to \textit{Pneumocystis jirovecii} (formerly called \textit{P. carinii}), mycobacterial infections, and fungal infections of the respiratory tract. These infections can be difficult to treat and have a high mortality.

\textbf{Health Alert}

\textbf{Ventilator-Associated Pneumonia (VAP)}

Ventilator-associated pneumonia (VAP) is a common complication of mechanical ventilation and is the most serious infection in the intensive care unit. VAP is associated with higher mortality, morbidity, and costs. Although there are many risk factors, including age greater than 65 years, presence of comorbidities, use of sedation, supine posture, poor oral hygiene, and immunocompromised status, the principal determinant of VAP development is the presence of the endotracheal (ET)
tube. Common etiologic microorganisms include *Staphylococcus aureus* and *Pseudomonas aeruginosa*; multidrug-resistant strains are common. Bacterial colonization of the oropharynx occurs soon after placement of the ET tube with subsequent aspiration and pooling of bacteria near the ET tube cuff. Many bacteria are capable of forming a protective coating, called a biofilm, on the surface of the ET tube that contributes to bacterial replication and makes microorganisms less vulnerable to antibiotics. Injury to the tracheal mucosa and decreased mucociliary clearance contribute to lower airway infection. Analgesic and sedation agents alter cellular function and reduce the immune response. Implementation of certain treatment protocols has shown improved outcomes regarding VAP prevention and mortality reduction, especially the use of a “bundle” of techniques including raising the head of the bed, improving oral hygiene, providing continuous suction of subglottic secretions by antimicrobial-impregnated ET tubes, using checklists, and encouraging effective team communication. Recent studies have suggested that surveillance cultures could improve the prescribing of appropriate antibiotics and that the addition of aerosolized antibiotics may improve treatment outcomes.

**CAP,** Community-acquired pneumonia; **HAP,** hospital-acquired pneumonia; **HCAP,** health care–associated pneumonia; **VAP,** ventilator-associated pneumonia.

**Pathophysiology**

Aspiration of oropharyngeal secretions is the most common route of lower respiratory tract infection; thus, the nasopharynx and oropharynx constitute the first
line of defense for most infectious agents. Another route of infection is through the inhalation of microorganisms that have been released into the air when an infected individual coughs, sneezes, or talks, or from aerosolized water such as that from contaminated respiratory therapy equipment. This route of infection is most important in viral and mycobacterial pneumonias and in Legionella outbreaks. Endotracheal tubes become colonized with bacteria that form biofilms (protected colonies of bacteria that are resistant to host defenses and treatment with antibiotics) and can seed the lung with microorganisms, especially during endotracheal suctioning. Pneumonia also can occur when bacteria are spread to the lung in the blood from bacteremia that can result from infection elsewhere in the body or from intravenous (IV) drug abuse.

In healthy individuals, pathogens that reach the lungs are expelled or controlled by mechanisms of self-defense (see Chapters 6, 7, and 8). If a microorganism evades the upper airway defense mechanisms, such as the cough reflex and mucociliary clearance, the next line of defense is the airway epithelial cell. Airway epithelial cells can recognize some pathogens directly (e.g., Pseudomonas aeruginosa and Staphylococcus aureus). The most important guardian cell of the lower respiratory tract is the alveolar macrophage; it recognizes pathogens through its pattern-recognition receptors (e.g., Toll-like receptors). Macrophages present infectious antigens to the adaptive immune system, activating T cells and B cells with the induction of both cellular and humoral immunity. Release of tumor necrosis factor-alpha (TNF-α) and interleukin-1 (IL-1) from macrophages and chemokines and chemotactic signals from mast cells and fibroblasts contributes to widespread inflammation in the lung and recruitment of neutrophils from the capillaries of the lungs into the alveoli. The resulting inflammatory mediators and immune complexes can damage bronchial mucous membranes and alveolocapillary membranes, causing the acini and terminal bronchioles to fill with infectious debris and exudate. Some microorganisms release toxins from their cell walls that can cause further lung damage and consolidation of lung tissue. The accumulation of exudate in the acinus leads to dyspnea and to \( \frac{V}{Q} \) mismatching and hypoxemia.

Pneumococcus (Streptococcus pneumoniae) is the most common and lethal cause of outpatient and inpatient pneumonias. Pneumococci can infect the lungs through inhalation of aerosolized bacteria or more commonly by aspiration of colonized oropharyngeal secretions. These bacteria have several virulence factors; most importantly, they have capsules that make phagocytosis by alveolar macrophages more difficult and they have the ability to release a variety of toxins, including pneumolysin, which damages airway and alveolar cells. An intense inflammatory response is initiated with release of TNF-α and IL-1. Neutrophils and inflammatory exudates cause alveolar edema, which leads to the other changes
shown in Figure 27-15.

Viral pneumonia is a seasonal and usually mild and self-limiting CAP. It can set the stage for a secondary bacterial infection by damaging ciliated epithelial cells, which normally prevent pathogens from reaching the lower airways. Immunocompromised individuals are at risk for very serious viral infections, such as pneumonia caused by cytomegalovirus. Viral pneumonia also can be a complication of another viral illness, such as chickenpox or measles (spread from the blood). New or atypical forms of viral infection, such as swine influenza A (H1N1) virus, avian influenza A (H5N1) virus, and the coronavirus that causes the severe acute respiratory syndrome (SARS), are affecting previously healthy populations and pose a considerable threat for pandemics.\(^6\)

Viruses destroy the ciliated epithelial cells and invade the goblet cells and bronchial mucous glands. Sloughing of destroyed bronchial epithelium occurs throughout the respiratory tract, preventing mucociliary clearance. Bronchial walls
become edematous and infiltrated with leukocytes. In severe cases, the alveoli are involved with decreased compliance and increased work of breathing.

**Clinical manifestations**

Most cases of pneumonia are preceded by a viral upper respiratory tract infection. Individuals then develop fever, chills, productive or dry cough, malaise, pleural pain, and sometimes dyspnea and hemoptysis. Physical examination may show signs of pulmonary consolidation, such as dullness to percussion, inspiratory crackles, increased tactile fremitus, egophony, and whispered pectoriloquy. Individuals also may demonstrate symptoms and signs of underlying systemic disease or sepsis.

**Evaluation and treatment**

Diagnosis is made on the basis of history and physical examination (tachypnea, tachycardia, crackles, bronchial breath sounds, findings of pleural effusion), white blood cell count, oxygenation and pH, chest x-rays, stains and cultures of respiratory tract secretions, and blood cultures before starting antibiotics. The white blood cell count is usually elevated, although it may be low if the individual is debilitated or immunocompromised. Serum procalcitonin level can be used to help differentiate bacterial from viral infection and guide therapy. Chest radiographs show infiltrates that may involve a single lobe of the lung or may be more diffuse. Once the diagnosis of pneumonia has been made, the pathogen is identified by means of sputum characteristics (Gram stain, color, odor) and cultures or, if sputum is absent, blood cultures. Because many pathogens exist in the normal oropharyngeal flora, the specimen may be contaminated with pathogens from oral secretions. If sputum studies fail to identify the pathogen, the individual is immunocompromised, or the individual's condition worsens, further diagnostic studies may include thoracentesis, bronchoscopy, or lung biopsy. Urine antigen testing offers rapid pathogen identification for Legionella pneumophila, Streptococcus pneumoniae, and Histoplasma capsulatum but requires culture for microbial specificity.70

Prevention of pneumonia includes avoidance of aspiration, respiratory isolation of immunocompromised individuals, and vaccination. The first step in the management of pneumonia is establishing adequate ventilation and oxygenation. Adequate hydration and good pulmonary hygiene (e.g., deep breathing, coughing, chest physical therapy) also are important. Antibiotics are given within 4 hours to treat bacterial pneumonia; however, resistant strains of microorganisms are becoming more prevalent and require secondary antibiotics.71 When a specific microorganism is not identified, empirical antibiotics are chosen based on the likely causative microorganism.59 Viral pneumonia is usually treated with supportive
therapy alone; however, antivirals may be needed in severe cases. Infections with opportunistic microorganisms may be polymicrobial and require multiple drugs, including antifungals.

Tuberculosis

**Tuberculosis (TB)** is an infection caused by *Mycobacterium tuberculosis*, an acid-fast bacillus that usually affects the lungs but may invade other body systems. TB is a leading cause of death from a curable infectious disease in the world. TB cases increased greatly during the mid-1990s as a result of acquired immunodeficiency syndrome (AIDS) but both have decreased since 2000. Emigration of infected individuals from high-prevalence countries, transmission in crowded institutional settings, homelessness, substance abuse, and lack of access to screening and medical care have contributed to the spread of TB.

Pathophysiology

TB is highly contagious and is transmitted from person to person in airborne droplets. In immunocompetent individuals, the microorganism is usually contained by the inflammatory and immune response systems. This results in **latent TB infection (LTBI)** and is associated with no clinical evidence of disease.

Once the bacilli are inspired, they lodge in the lung periphery, usually in the upper lobe, and cause localized nonspecific pneumonitis (lung inflammation). Some bacilli migrate through the lymphatics and become lodged in the lymph nodes, where they encounter lymphocytes and initiate the immune response. Inflammation in the lung causes activation of alveolar macrophages and neutrophils. These phagocytes engulf the bacilli and begin the process by which the body's defense mechanisms isolate the bacilli, preventing them from spreading. However, the bacterium is successful as a pathogen because it can survive and multiply within macrophages and resist lysosomal killing, forming a granulomatous lesion called a **tubercle** (see Chapter 6). Infected tissues within the tubercle die, forming cheeseslike material called **caseation necrosis**. Collagenous scar tissue then grows around the tubercle, completing isolation of the bacilli. The immune response is complete after about 10 days, preventing further multiplication of the bacilli.

Once the bacilli are isolated in tubercles and immunity develops, tuberculosis may remain dormant for life. If the immune system is impaired, reactivation with progressive disease occurs and may spread through the blood and lymphatics to other organs. Infection with human immunodeficiency virus (HIV) is the single greatest risk factor for reactivation of tuberculosis infection. Cancer, immunosuppressive medications (e.g., corticosteroids), poor nutritional status, and
renal failure can also reactivate disease.

**Clinical manifestations**

LTBI is asymptomatic. Symptoms of active disease often develop so gradually that they are not noticed until the disease is advanced. Common clinical manifestations include fatigue, weight loss, lethargy, anorexia (loss of appetite), and a low-grade fever that usually occurs in the afternoon. A cough that produces purulent sputum develops slowly and becomes more frequent over several weeks or months. Night sweats and general anxiety are often present. Dyspnea, chest pain, and hemoptysis may occur as the disease progresses. Extrapulmonary TB disease is common in HIV-infected individuals and may cause neurologic deficits, meningitis symptoms, bone pain, and urinary symptoms.

**Evaluation and treatment**

Tuberculosis is diagnosed by a positive tuberculin skin test (TST; purified protein derivative [PPD]), sputum culture, immunoassays, and chest radiographs. A positive skin test indicates the need for yearly chest radiographs to detect active disease. In addition, individuals who have received the TB vaccine with bacille Calmette-Guérin (BCG) will have a positive TST even if they have never had TB. When active pulmonary disease is present, the tubercle bacillus can be cultured from the sputum and may be seen with an acid-fast stain. However, sputum culture can take up to 6 weeks to become positive. Two immunoassays (enzyme-linked immunospot and quantitative blood interferon-gamma assay) are available. These new tests are more sensitive and specific than TST for the diagnosis of latent TB and are not confounded by previous BCG vaccination.

Treatment consists of combination antibiotic therapy to control active disease or prevent reactivation of LTBI. Side effects are common and new drugs are being explored. Two worrisome treatment categories of TB have become more prevalent in recent years. “Multidrug-resistant TB” and “extensively resistant TB” now account for approximately 2% to 5% of cases worldwide. Multiple second-line drugs are required for treatment success. The bacillus Calmette-Guérin (BCG) vaccine is used in countries where TB is endemic but not in the United States, where TST is used for screening. New vaccines are in clinical trials. Treatment of TB HIV coinfection requires monitoring of drug interactions and toxicities.

**Abscess Formation and Cavitation**

An abscess is a circumscribed area of suppuration and destruction of lung parenchyma. Abscess formation follows consolidation of lung tissue, in which
inflammation causes alveoli to fill with fluid, pus, and microorganisms. Aspiration abscess can occur from aspiration of anaerobes, such as those found in individuals who have pneumonia or who are infected with *Klebsiella* or *Staphylococcus*. Aspiration abscess is usually associated with alcohol abuse, seizure disorders, general anesthesia, and swallowing disorders. Necrosis (death and decay) of consolidated tissue may progress proximally until it communicates with a bronchus. **Cavitation** is the process of the abscess emptying into a bronchus and cavity formation. Abscess communication with a bronchus causes production of copious amounts of often foul-smelling sputum, and occasionally hemoptysis. Other clinical manifestations include fever, cough, chills, and pleural pain. The diagnosis is made by chest radiography. Treatment includes appropriate antibiotics and chest physical therapy (chest percussion and postural drainage). Bronchoscopy may be performed to drain the abscess.

Quick Check 27-5

1. Compare pneumococcal and viral pneumonia as to severity of disease.

2. Describe the pathophysiologic features of tuberculosis.

3. How does lung abscess present clinically?

Pulmonary Vascular Disease

Blood flow through the lungs can be disrupted by disorders that occlude the vessels, increase pulmonary vascular resistance, or destroy the vascular bed. Effects of altered pulmonary blood flow may range from insignificant dysfunction to severe and life-threatening changes in ventilation-perfusion ratios. Major disorders include pulmonary embolism, pulmonary hypertension, and cor pulmonale.

Pulmonary Embolism

**Pulmonary embolism (PE)** is occlusion of a portion of the pulmonary vascular bed by an embolus. PE most commonly results from embolization of a clot from deep venous thrombosis involving the lower leg (see Chapter 24). Other less common emboli include tissue fragments, lipids (fats), a foreign body, an air bubble, or amniotic fluid. Risk factors for PE include conditions and disorders that promote blood clotting as a result of venous stasis (immobilization, heart failure), hypercoagulability (inherited coagulation disorders, malignancy, hormone
replacement therapy, oral contraceptives), and injuries to the endothelial cells that line the vessels (trauma, infection, caustic intravenous infusions). Genetic risks include factor V Leiden, antithrombin II, protein S, protein C, and prothrombin gene mutations. No matter its source, a blood clot becomes an embolus when all or part of it detaches from the site of formation and begins to travel in the bloodstream.

**Pathophysiology**

The effect of the embolus depends on the extent of pulmonary blood flow obstruction, the size of the affected vessels, the nature of the embolus, and the secondary effects. Pulmonary emboli can result in any of the following:

1. **Embolus with infarction**: an embolus that causes infarction (death) of a portion of lung tissue

2. **Embolus without infarction**: an embolus that does not cause permanent lung injury (perfusion of the affected lung segment is maintained by the bronchial circulation)

3. **Massive occlusion**: an embolus that occludes a major portion of the pulmonary circulation (i.e., main pulmonary artery embolus)

4. **Multiple pulmonary emboli**: multiple emboli may be chronic or recurrent

Significant obstruction of the pulmonary vasculature leads to increased pulmonary artery vasoconstriction, pulmonary hypertension and right ventricular dilation and afterload. The pathogenesis of pulmonary embolism caused by a thrombus is summarized in Figure 27-16.
If the embolus does not cause infarction, the clot is dissolved by the fibrinolytic system and pulmonary function returns to normal. If pulmonary infarction occurs, shrinking and scarring develop in the affected area of the lung.

**Clinical manifestations**
In most cases, the clinical manifestations of PE are nonspecific; therefore, evaluation of risk factors and predisposing factors is an important aspect of diagnosis. Although most emboli originate from clots in the lower extremities, deep vein thrombosis is often asymptomatic, and clinical examination has low sensitivity for the presence of clot, especially in the thigh and pelvis.

An individual with PE usually presents with the sudden onset of pleuritic chest pain, dyspnea, tachypnea, tachycardia, and unexplained anxiety. Occasionally syncope (fainting) or hemoptysis occurs. With large emboli, a pleural friction rub, pleural effusion, fever, and leukocytosis may be noted. Recurrent small emboli may not be detected until progressive incapacitation, precordial pain, anxiety, dyspnea, and right ventricular enlargement are exhibited. Massive occlusion causes severe pulmonary hypertension and shock.

**Evaluation and treatment**

Routine chest radiographs and pulmonary function tests are not definitive for pulmonary embolism in the first 24 hours. Arterial blood gas analyses usually demonstrate hypoxemia and hyperventilation (respiratory alkalosis). The diagnosis is made by measuring elevated levels of d-dimer in the blood (a product of thrombus degradation) in combination with CT scanning or MRI. Measurement of the levels of brain natriuretic peptide and troponin is useful in PE associated with right ventricular dysfunction.

Prevention of PE includes elimination of predisposing factors for individuals at risk. Venous stasis in hospitalized persons is minimized by leg elevation, bed exercises, position changes, early postoperative ambulation, and pneumatic calf compression. Clot formation is also prevented by prophylactic low-dose anticoagulant therapy.

Anticoagulant therapy is the primary treatment for pulmonary embolism. Initial anticoagulant therapy usually includes low-molecular-weight heparins (e.g., enoxaparin) and factor Xa inhibitors. If a massive life-threatening embolism occurs, a fibrinolytic agent, such as streptokinase, is sometimes used, and some individuals will require catheter directed therapies or surgical thrombectomy. A filter in the inferior vena cava can prevent emboli from reaching the lungs. After stabilization, anticoagulation is continued for several months.

**Pulmonary Artery Hypertension**

**Pulmonary artery hypertension (PAH)** is defined as a mean pulmonary artery pressure greater than 25 mm Hg at rest. PAH is classified into several groups:

1. No known cause or associated with inheritance, drugs or toxins, connective tissue
2. Pulmonary hypertension attributable to left heart disease (see Chapter 24)

3. Pulmonary hypertension caused by chronic lung disease or hypoxia, or both

4. Chronic thromboembolic pulmonary hypertension

5. Pulmonary hypertension caused by other multifactorial mechanisms including blood, metabolic and systemic disorders.

COPD is the most common lung disease associated with PAH, but any condition that causes chronic hypoxemia can result in pulmonary hypertension.

**Pathophysiology**

*Idiopathic pulmonary arterial hypertension (IPAH)* (also called pulmonary hypertension caused by unclear multifactorial mechanisms) is characterized by endothelial dysfunction with overproduction of vasoconstrictors, such as thromboxane and endothelin, and decreased production of vasodilators, such as prostacyclin and nitric oxide. Vascular growth factors are released, causing fibrosis and thickening of vessel walls (called *remodeling*) with luminal narrowing and abnormal vasoconstriction. These changes cause resistance to pulmonary artery blood flow, thus increasing the pressure in the pulmonary arteries and right ventricle. Gas exchange is reduced with restriction in lung volumes. As resistance and pressure increase, the workload of the right ventricle increases and subsequent right ventricular hypertrophy, followed by failure, may occur (cor pulmonale). The pathogenesis of PAH and cor pulmonale resulting from disease of the respiratory system or hypoxia is shown in Figure 27-17.
Pulmonary hypertension associated with lung respiratory disease or hypoxia, or both, is a serious complication of many acute and chronic pulmonary disorders, such as COPD and hypoventilation associated with obesity. These conditions are complicated by hypoxic pulmonary vasoconstriction, which further increases pulmonary artery pressure.

**Clinical manifestations**
Pulmonary hypertension may not be detected until it is quite severe. The symptoms
are often masked by other forms of pulmonary or cardiovascular disease. The first indication of PAH may be an abnormality seen on a chest radiograph (enlarged right heart border) or an electrocardiogram that shows right ventricular hypertrophy. Manifestations of fatigue, chest discomfort, tachypnea, and dyspnea (particularly with exercise) are common. Examination may reveal peripheral edema, jugular venous distention, a precordial heave, and accentuation of the pulmonary component of the second heart sound.

**Evaluation and treatment**

Definitive diagnosis of PAH can be made only with right heart catheterization. Common diagnostic modalities used to determine the cause include chest x-ray, echocardiography, and computed tomography. The diagnosis of IPAH is made when all other causes of pulmonary hypertension have been ruled out.

General therapies for PAH include administration of oxygen, diuretics, and anticoagulants and avoidance of contributing factors, such as air travel, decongestant medications, nonsteroidal anti-inflammatory medications, pregnancy, and tobacco use. Medications used in the treatment of PAH include prostacyclin and its analogs, endothelin antagonists, phosphodiesterase-5 inhibitors, and a soluble guanylate cyclase activator. None of these drugs are curative but there is improved morbidity and mortality.⁸⁴ Percutaneous catheter-based therapies are under development.⁸⁵ Individuals who do not achieve adequate clinical remission may require lung transplantation.

The most effective treatment for pulmonary hypertension associated with lung respiratory disease or hypoxia, or both, is treatment of the primary disorder. Supplemental oxygen may be indicated to reverse hypoxic vasoconstriction.

**Cor Pulmonale**

Cor pulmonale is defined as right ventricular enlargement (hypertrophy, dilation, or both) caused by PAH (see Figure 27-17).⁸⁶

**Pathophysiology**

Cor pulmonale develops as PAH exerts chronic pressure overload in the right ventricle. Pressure overload increases the work of the right ventricle and causes hypertrophy of the normally thin-walled heart muscle. This eventually progresses to dilation and failure of the ventricle.

**Clinical manifestations**

The clinical manifestations of cor pulmonale may be obscured by underlying
respiratory or cardiac disease and appear only during exercise testing. The heart may appear normal at rest, but with exercise, cardiac output falls. The electrocardiogram may show right ventricular hypertrophy. The pulmonary component of the second heart sound, which represents closure of the pulmonic valve, may be accentuated, and a pulmonic valve murmur also may be present. Tricuspid valve murmur may accompany the development of right ventricular failure. Increased pressures in the systemic venous circulation cause jugular venous distention, hepatosplenomegaly, and peripheral edema.

**Evaluation and treatment**

Diagnosis is based on physical examination, imaging, and electrocardiography or echocardiography, or both. The goal of treatment for cor pulmonale is to decrease the workload of the right ventricle by lowering pulmonary artery pressure. Treatment is the same as that for pulmonary hypertension, and its success depends on reversal of the underlying lung disease.

**Malignancies of the Respiratory Tract**

**Laryngeal Cancer**

*Cancer of the larynx (laryngeal cancer)* represents less than 1% of all cancers in the United States, with an estimated 13,560 new cases and 3640 deaths in 2015. The primary risk factor for laryngeal cancer is tobacco smoking; risk is further heightened with the combination of smoking and alcohol consumption. The human papillomavirus (HPV 6 and 11) also has been linked to both benign and malignant disease of the larynx. The highest incidence is in men between 50 and 75 years of age.

**Pathophysiology**

Carcinoma of the true vocal cords (glottis) is more common than that of the supraglottic structures (epiglottis, aryepiglottic folds, arytenoids, false cords).
Tumors of the subglottic area are rare. Squamous cell carcinoma is the most common cell type, although small cell carcinomas also occur (Figure 27-18). Metastasis develops by spread to the draining lymph nodes, and distant metastasis is rare.

**Clinical manifestations**

The presenting symptoms of laryngeal cancer include hoarseness, dyspnea, and cough. Progressive hoarseness can result in voice loss. Dyspnea is rare with supraglottic tumors but can be severe in subglottic tumors. Cough may follow swallowing. Laryngeal pain is likely with supraglottic lesions.

**Evaluation and treatment**

Evaluation of the larynx includes external inspection and palpation of the larynx and the lymph nodes of the neck. Indirect laryngoscopy provides a stereoscopic view of the structure and movement of the larynx. A biopsy also can be obtained during this procedure. Direct laryngoscopy provides more thorough visualization of the tumor. Imaging procedures facilitate the identification of tumor boundaries and the degree of extension to surrounding tissue.

Combined chemotherapy and radiation or surgical resection can result in cure in
selected cases; however, sequelae such as swallowing and speech difficulties may result.\textsuperscript{89} Total laryngectomy is required when lesions are extensive and involve the cartilage. Swallowing and speech therapy after treatment can significantly improve recovery.

**Lung Cancer**

The term **lung cancer** refers to tumors that arise from the epithelium of the respiratory tract (bronchogenic carcinomas). Other pulmonary tumors, such as mesotheliomas (associated with asbestos exposure), occur less commonly (Table 27-3). Lung cancer is the second most common cancer in the United States, with an estimated 221,200 new cases and 158,040 deaths in 2015, the most common cause of cancer deaths.\textsuperscript{87} Overall 5-year survival remains low at 17%.

The most common cause of lung cancer is tobacco smoking (see Figure 11-5). Smokers with obstructive lung disease (low FEV\textsubscript{1} measurements) are at much greater risk. Other risk factors for lung cancer include radon gas exposure, secondhand (environmental) smoke, occupational exposures to certain workplace toxins, radiation, and air pollution (see Chapter 11 and Figures 11-20 and 11-21). Genetic risks include polymorphisms of the genes responsible for growth factor receptors, angiogenesis, apoptosis, DNA repair, and detoxification of inhaled smoke.\textsuperscript{90} Lung cancers are classified by cell type and molecular profiling. The most
common types of lung cancer are presented here.

**Types of lung cancer.**

Primary lung cancers arise from cells that line the bronchi within the lungs and are therefore called *bronchogenic carcinomas*. Although there are many types of lung cancer, they can be divided into two major categories: non–small cell lung carcinoma (NSCLC) and neuroendocrine tumors of the lung. The category of non–small cell lung carcinoma accounts for 75% to 85% of all lung cancers and can be subdivided into three types of lung cancer: squamous cell carcinoma, adenocarcinoma, and large cell undifferentiated carcinoma. They are further described by genotyping (i.e., epidermal growth factor receptor \([EGFR]\) gene or anaplastic lymphoma kinase \([ALK]\) gene mutations and rearrangements), which is important for targeted personalized therapy.\(^9^1\) Neuroendocrine tumors of the lung arise from the bronchial mucosa and include small cell carcinoma, large cell neuroendocrine carcinoma, and typical carcinoid and atypical carcinoid tumors. Small cell carcinoma is the most common of these neuroendocrine tumors, accounting for 15% to 20% of all lung cancers. Characteristics of these tumors, including clinical manifestations, are listed in Table 27-3. Many cancers that arise in other organs of the body metastasize to the lungs; however, these are not considered lung cancers and are categorized by their primary site of origin.

**Non–small cell lung cancer.**

**Squamous cell carcinoma** accounts for about 30% of bronchogenic carcinomas and is associated with smoking and COPD. These tumors are typically located near the hila and project into bronchi (Figure 27-19, A). Because of this central location, symptoms of nonproductive cough or hemoptysis are common. Pneumonia and atelectasis are often associated with squamous cell carcinoma (see Figure 27-19, A). Chest pain is a late symptom associated with large tumors. These tumors are often fairly well localized and tend not to metastasize until late in the course of the disease.
Adenocarcinoma (tumor arising from glands) of the lung constitutes 35% to 40% of all bronchogenic carcinomas (Figure 27-19, B). Pulmonary adenocarcinoma develops in a stepwise fashion through atypical adenomatous hyperplasia, adenocarcinoma in situ, and minimally invasive adenocarcinoma to invasive carcinoma. These tumors, which are usually smaller than 4 cm, more commonly arise in the peripheral regions of the pulmonary parenchyma. They may be asymptomatic and discovered by routine chest roentgenogram in the early stages, or the individual may present with pleuritic chest pain and shortness of breath from pleural involvement by the tumor.

Included in the category of adenocarcinoma is bronchioloalveolar cell carcinoma. These tumors arise from terminal bronchioles and alveoli and are now being referred to as adenocarcinoma in situ or minimally invasive adenocarcinoma. They are slow-growing tumors with an unpredictable pattern of metastasis through the pulmonary arterial system and mediastinal lymph nodes.

Large cell carcinoma (undifferentiated).

Large cell carcinomas constitute approximately 10% of bronchogenic carcinomas.
These transformed epithelial cells have lost all evidence of differentiation and are considered an undifferentiated non–small cell carcinoma. Recent studies have confirmed that these tumors arise from squamous, glandular, or neuroendocrine precursor cells, and molecular analyses have made it possible to target some of these aggressive cancers for immunologic therapy. These tumors commonly arise centrally and can grow to distort the trachea and cause widening of the carina.

**Neuroendocrine tumors.**

**Small cell (oat cell) carcinomas** are the most common type of neuroendocrine lung tumors and have the highest correlation with tobacco smoking. Small cell carcinoma arises from neuroendocrine cells that contain neurosecretory granules. Most of these tumors are central in origin (hilar and mediastinal) (see Figure 27-19, C). Cell sizes range from 6 to 8 µm, have a rapid rate of growth, and tend to metastasize early and widely. Small cell carcinomas tend to present at TNM stage IV and have the worst prognosis. They are often associated with ectopic hormone production. Ectopic hormone production is important to the clinician because resulting signs and symptoms called *paraneoplastic syndromes* may be the first manifestation of the underlying cancer. Examples include hyponatremia (antidiuretic hormone), Cushing syndrome (adrenocorticotropic hormone), hypocalcemia (calcitonin), gynecomastia (gonadotropins), carcinoid syndrome (serotonin), and Lambert-Eaton myasthenic syndrome (paneoplastic cerebellar degeneration).

**Pathophysiology**

Tobacco smoke contains more than 30 carcinogens and is responsible for causing 80% to 90% of lung cancers. These carcinogens, along with inherited genetic predisposition to cancers, result in tumor development. Once lung cancer is initiated by these carcinogen-induced mutations, further tumor development is promoted by growth factors that alter cell growth and differentiation, such as epidermal growth factor, and by production of inflammatory mediators, such as toxic oxygen free radicals. The bronchial mucosa suffers multiple carcinogenic “hits” because of repetitive exposure to tobacco smoke and, eventually, epithelial cell changes begin to be visible on biopsy. These changes progress from metaplasia to carcinoma in situ and finally to invasive carcinoma. Further tumor progression includes invasion of surrounding tissues and finally metastasis to distant sites including the brain, bone marrow, and liver (see Chapter 10 for details of cancer biology).

**Clinical manifestations**

Table 27-3 summarizes the characteristic clinical manifestations according to tumor
type. Symptoms are often attributed to side effects of smoking; and when they are severe enough to motivate the individual to seek medical advice, the disease is usually advanced.

**Evaluation and treatment**

Screening for lung cancer remains controversial but low-dose spiral CT scans decrease the risk of dying from lung cancer by 20% in heavy smokers. Diagnostic tests for the evaluation of lung cancer include sputum cytologic studies, chest imaging, virtual bronchoscopy, radial probe endobronchial ultrasound, electromagnetic navigational bronchoscopy, and biopsy. Biopsy determines the cell type, and the evaluation of lymph nodes and other organ systems is used to determine the stage of the cancer. The histologic cell type, the genotype, and the stage of the disease are major factors that influence choice of therapy. The current accepted system for the staging of non–small cell cancer is the **TNM classification** (\(T\) denotes the extent of the primary tumor, \(N\) indicates the nodal involvement, \(M\) describes the extent of metastasis) (see Chapter 10). In contrast, small cell lung cancers are only staged as either limited (confined to the area of origin in the lung) or extensive.

The only proven way of reducing the risk for lung cancer is the cessation of smoking and avoidance of environmental toxins. For all types of early-stage lung carcinoma, the preferred treatment is surgical resection. Once metastasis has occurred, total surgical resection is more difficult and survival rates dramatically decrease. For individuals with non–small cell carcinoma with metastasis at diagnosis, adjunctive radiation and chemotherapy and treatment based on molecular markers may improve outcomes. Treatment modalities, including dose-intensified radiation, radiofrequency ablation, microwave ablation, cryotherapy, and brachytherapy, may be available as primary or palliative treatment for those for whom surgical removal is not an option. Research is in progress to advance personalized genetic and immunologic approaches to treatment (see **Health Alert: Molecular Targets in Lung Cancer Treatment**).

**Health Alert**

**Molecular Targets in Lung Cancer Treatment**

While newer chemotherapeutic agents have improved outcomes in the management of lung cancer, long-term survival rates remain poor. Better understanding of the genetic and immunologic features of lung cancer cells has led to new treatment
options. Molecular gene therapies have vastly improved treatment responses in non–small cell carcinoma. The most effective to date are epidermoid growth factor tyrosine kinase inhibitors (erlotinib, gefitinib, afatinib), which have increased the response rates to up to 60%. Other targets include drugs that block the effects of anaplastic lymphoma kinase (ALK) mutations (crizotinib, ceritinib) and angiogenesis (bevacizumab). New molecular targets are being explored with the goal of improving long-term survival. KRAS, which is the most common oncogene mutation in lung adenocarcinomas, has proven to be a difficult target, but new drugs are being evaluated in clinical trials.

Quick Check 27-7

1. Describe squamous cell carcinoma of the vocal cords.

2. Differentiate the two types of non–small cell lung cancer.

3. What are paraneoplastic syndromes?
Did You Understand?

Clinical Manifestations of Pulmonary Alterations

1. Dyspnea is the feeling of breathlessness and increased respiratory effort.

2. Coughing is a protective reflex that expels secretions and irritants from the lower airways.

3. Changes in the sputum volume, consistency, or color may indicate underlying pulmonary disease.

4. Hemoptysis is expectoration of bloody mucus.

5. Abnormal breathing patterns are adjustments made by the body to minimize the work of respiratory muscles. They include Kussmaul, obstructed, restricted, gasping, and Cheyne-Stokes respirations as well as sighing.

6. Hypoventilation is decreased alveolar ventilation caused by airway obstruction, chest wall restriction, or altered neurologic control of breathing and results in increased $\text{PacO}_2$ (hypercapnia).

7. Hyperventilation is increased alveolar ventilation produced by anxiety, head injury, or severe hypoxemia and causes decreased $\text{PacO}_2$ (hypocapnia).

8. Cyanosis is a bluish discoloration of the skin caused by desaturation of hemoglobin, polycythemia, or peripheral vasoconstriction.

9. Clubbing of the fingertips is associated with diseases that interfere with oxygenation of the tissues.

10. Chest pain can result from inflamed pleurae, trachea, bronchi, ribs, or respiratory muscles.

11. Hypoxemia is a reduced $\text{Pao}_2$ caused by (1) decreased oxygen content of inspired gas, (2) hypoventilation, (3) diffusion abnormality, (4) ventilation-perfusion mismatch, or (5) shunting.
Disorders of the Chest Wall and Pleura

1. Chest wall compliance is diminished by obesity and kyphoscoliosis, which compress the lungs, and by neuromuscular diseases that impair chest wall muscle function.

2. Flail chest results from rib or sternal fractures that disrupt the mechanics of breathing.

3. Pneumothorax is the accumulation of air in the pleural space. It can be caused by spontaneous rupture of weakened areas of the pleura or can be secondary to pleural damage caused by disease, trauma, or mechanical ventilation.

4. Tension pneumothorax is a life-threatening condition caused by trapping of air in the pleural space, producing displacement of the great vessels and heart.

5. Pleural effusion is the accumulation of fluid in the pleural space resulting from disorders that promote transudation or exudation from capillaries underlying the pleura or from blockage or injury to lymphatic vessels that drain into the pleural space.

6. Empyema is the presence of pus in the pleural space (infected pleural effusion); it usually occurs because of lymphatic drainage from sites of bacterial pneumonia.

Pulmonary Disorders

1. Pulmonary disorders can be restrictive (limiting lung volumes) or obstructive (limiting airflow) or both.

2. Aspiration of food particles or pharyngeal or gastric secretions can cause obstruction, inflammation, or pneumonitis.

3. Atelectasis is the collapse of alveoli resulting from compression of lung tissue or absorption of gas from obstructed alveoli.

4. Bronchiectasis is abnormal dilation of the bronchi secondary to another pulmonary disorder, usually infection or inflammation.

5. Bronchiolitis is the inflammatory obstruction of small airways. It is most common in children.
6. Pulmonary fibrosis is excessive connective tissue in the lung that diminishes lung compliance; it may be idiopathic or caused by disease and is associated with chronic inflammation.

7. Inhalation of noxious gases or prolonged exposure to high concentrations of oxygen can damage the bronchial mucosa or alveolocapillary membrane and cause inflammation or acute respiratory failure.

8. Pneumoconiosis, which is caused by inhalation of dust particles in the workplace, can cause pulmonary fibrosis, increase susceptibility to lower airway infection, and initiate tumor formation.

9. Hypersensitivity pneumonitis (extrinsic allergic alveolitis) is an allergic or hypersensitivity reaction to many allergens causing lung inflammation.

10. Pulmonary edema is excess water in the lung caused by increased capillary hydrostatic pressure, decreased capillary oncotic pressure, or increased capillary permeability. Causes include left heart failure that increases capillary hydrostatic pressure in the pulmonary circulation, inflammation of alveoli, or lymphatic obstruction.

11. Acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) results from an acute, diffuse injury to the alveolocapillary membrane and decreased surfactant production, which increases membrane permeability and causes edema, atelectasis, and hypoxemia.

12. Obstructive lung disease is characterized by airway obstruction that causes difficult expiration. Obstructive disease can be acute or chronic and includes asthma, chronic bronchitis, and emphysema.

13. Asthma is an inflammatory disease of the airways resulting from a type I hypersensitivity immune response involving the activity of antigen, IgE, mast cells, eosinophils, and other inflammatory cells and mediators.

14. In asthma, airway obstruction is caused by episodic attacks of bronchospasm, bronchial inflammation, mucosal edema, and increased mucus production.

15. Chronic obstructive pulmonary disease (COPD) is the coexistence of chronic bronchitis and emphysema and is an important cause of hypoxemic and hypercapnic respiratory failure.
16. Chronic bronchitis causes airway obstruction resulting from inflammation, bronchial smooth muscle hypertrophy, and production of thick, tenacious mucus.

17. In emphysema, destruction of the alveolar septa and loss of passive elastic recoil lead to alveolar enlargement, airway collapse, obstruction of gas flow, and air trapping during expiration.

18. Acute bronchitis is usually a self-limiting viral infection.

19. Pneumococcal pneumonia (Streptococcus pneumoniae) is the most common acute lung infection, resulting in an inflammatory response with four phases: (1) consolidation, (2) red hepatization, (3) gray hepatization, and (4) resolution.

20. Viral pneumonia can be severe, but is more often an acute, self-limiting lung infection usually caused by the influenza virus. Atypical forms and new forms can cause severe acute respiratory syndrome (SARS).

21. Tuberculosis (TB) is a lung infection caused by Mycobacterium tuberculosis (tubercle bacillus). In tuberculosis, the inflammatory response proceeds to isolate colonies of bacilli by enclosing them in tubercles and surrounding the tubercles with scar tissue. TB bacilli escape immune defenses by surviving within macrophages.

22. Pulmonary vascular diseases are caused by embolism or hypertension in the pulmonary circulation.

23. Pulmonary embolism is most often the result of embolism of part of a clot from deep venous thrombosis and causes vascular obstruction, $\dot{V}/Q$ mismatch, hypoxemia, and pulmonary hypertension; it may or may not cause infarction.

24. Pulmonary artery hypertension (pulmonary artery pressure >25 mm Hg) can be idiopathic or associated with left heart failure, lung disease, or recurrent pulmonary emboli that increase resistance to blood flow in the pulmonary artery or its branches.

25. Cor pulmonale is right ventricular enlargement or failure caused by pulmonary hypertension.

26. Laryngeal cancer occurs primarily in men and represents 2% to 3% of all cancers. Squamous cell carcinoma of the true vocal cords is most common and
presents with a clinical symptom of progressive hoarseness.

27. Lung cancer, the most common cause of cancer death in the United States, is commonly caused by tobacco smoking.

28. Lung cancer (bronchogenic carcinomas) cell types include non–small cell carcinoma (squamous cell, adenocarcinoma, and large cell) and, less commonly, neuroendocrine tumors (small cell carcinoma, large cell neuroendocrine carcinoma, and typical carcinoid and atypical carcinoid tumors). Each type arises in a characteristic site or type of tissue, causes distinctive clinical manifestations, and differs in likelihood of metastasis and prognosis.

  Cystic Fibrosis, 725

Sudden Infant Death Syndrome (SIDS), 726
Alterations of respiratory function in children are influenced by physiologic maturation, which is determined by age, genetics, and environmental conditions. Infants, especially premature infants, may present special problems because of incomplete development of the airways, circulation, chest wall, and immune system. A variety of upper and lower airway infections can cause respiratory compromise or play a role in the pathogenesis of more chronic pulmonary disease. Pulmonary dysfunction can be categorized into disorders of either the upper or the lower airways.
Disorders of the Upper Airways

Disorders of the upper airways can cause significant obstruction to airflow. Common causes of upper airway obstruction in children are infections, foreign body aspiration, obstructive sleep apnea, and trauma.

Infections of the Upper Airways

Table 28-1 compares some of the more common upper airway infections.

Croup

Croup illnesses can be divided into two categories: (1) acute laryngotracheobronchitis (croup) and (2) spasmodic croup. Diphtheria can also be considered a croup illness but is now rare because of vaccinations. Croup illnesses are all characterized by infection and obstruction of the upper airways.

**Croup** is an acute laryngotracheitis and almost always occurs in children between 6 months and 5 years of age with a peak incidence at 2 years of age. In 85% of cases, croup is caused by a virus, most commonly parainfluenza. Other causes include respiratory syncytial virus, rhinovirus, adenovirus, rubella virus, or atypical bacteria. The incidence of croup is higher in males and is most common during the winter months. Approximately 15% of affected children have a strong family history of croup. Spasmodic croup usually occurs in older children. The etiology is unknown but can be triggered by cold, allergy, or viral infection. Spasmodic croup develops acutely, usually without fever, and tends to recur.

Pathophysiology

The pathophysiology of viral croup is caused primarily by subglottic inflammation and edema from the infection. The mucous membranes of the larynx are tightly
adherent to the underlying cartilage, whereas those of the subglottic space are looser and thus allow accumulation of mucosal and submucosal edema (Figure 28-1). Furthermore, the cricoid cartilage is structurally the narrowest point of the airway, making edema in this area critical. Spasmodic croup also causes obstruction but with less inflammation and edema. As illustrated in Figure 28-2, increased resistance to airflow leads to increased work of breathing, which generates more negative intrathoracic pressure that, in turn, may exacerbate dynamic collapse of the upper airway.

FIGURE 28-1  The Larynx and Subglottic Trachea. A, Normal trachea. B, Narrowing and obstruction from edema caused by croup. (From HockenberryMJ, Wilson D: Wong’s nursing care of infants and children, ed 10, St Louis, 2015, Mosby)
Clinical manifestations

Typically, the child experiences rhinorrhea, sore throat, and low-grade fever for a few days, and then develops a harsh (seal-like) barking cough, inspiratory stridor, and hoarse voice. The quality of voice, cough, and stridor may suggest the location of the obstruction (Figure 28-3). Most cases resolve spontaneously within 24 to 48 hours and do not warrant hospital admission. A child with severe croup usually displays deep retractions (Figure 28-4), stridor, agitation, tachycardia, and sometimes pallor or cyanosis.
FIGURE 28-3 Listening Can Help Locate the Site of Airway Obstruction. A loud, gasping snore suggests enlarged tonsils or adenoids. In inspiratory stridor, the airway is compromised at the level of the supraglottic larynx, vocal cords, subglottic region, or upper trachea. Expiratory stridor results from a narrowing or collapse in the trachea or bronchi. Airway noise during both inspiration and expiration often represents a fixed obstruction of the vocal cords or subglottic space. Hoarseness or a weak cry is a by-product of obstruction at the vocal cords. If a cough is croupy, suspect constriction below the vocal cords. (Redrawn from Eavey RD: Contemp Ped 3[6]:79, 1986; original illustration by Paul Singh-Roy)
Spasmodic croup is characterized by similar hoarseness, barking cough, and stridor. It is of sudden onset and usually occurs at night and without prodromal symptoms. It usually resolves quickly.

**Evaluation and treatment**

The degree of symptoms determines the level of treatment. The most common tool for estimating croup severity is the Westley croup score. Most children with croup require no treatment; however, some cases require outpatient treatment. These children usually have only mild stridor or retractions and appear alert, playful, and able to eat. There has been much debate about the most effective outpatient treatments for croup. Humidified air does not improve symptoms in mild to moderate croup.

Gluocorticoids—either injected, oral (dexamethasone), or nebulized (budesonide)—have been shown to improve symptoms. The presence of stridor at rest, moderate or severe retractions of the chest, or agitation suggests more severe disease and does require inpatient observation and treatment. For acute respiratory distress, nebulized epinephrine stimulates α- and β-adrenergic receptors and decreases mucosal edema and airway secretions.
Oxygen should be administered. Heliox (helium-oxygen mixture) also can be used in severe cases although it is not yet considered a mainstay of routine treatment. This works by improving gas flow and thus decreasing the flow resistance of the narrowed airway. In rare cases, croup and spasmodic croup may require placement of an endotracheal tube.

**Bacterial tracheitis.**

**Bacterial tracheitis** (pseudomembranous croup) is the most common potentially life-threatening upper airway infection in children. It is most often caused by *Staphylococcus aureus* (*S. aureus*) (including methicillin-resistant *S. aureus* [MRSA] strains), *Haemophilus influenzae* (*H. influenzae*), or group A beta-hemolytic *Streptococcus* (GABHS). Treatment of viral croup with corticosteroids has increased the risk for bacterial tracheitis. The presence of airway edema and copious purulent secretions leads to airway obstruction that can be worsened by the formation of a tracheal pseudomembrane and mucosal sloughing. Bacterial tracheitis is treated with immediate administration of antibiotics and endotracheal intubation to prevent total upper airway obstruction.

**Acute Epiglottitis**

Historically, acute epiglottitis was caused by *Haemophilus influenzae* type B (HiB). Since the advent of *H. influenzae* vaccine, the overall incidence of acute epiglottitis has been reduced; however, up to 25% of epiglottitis cases are still caused by HiB, which is now more common in adults. Current cases in children usually are related to vaccine failure or are caused by other pathogens.

**Pathophysiology**

The epiglottis arises from the posterior tongue base and covers the laryngeal inlet during swallowing. Bacterial invasion of the mucosa with associated inflammation leads to the rapid development of edema, causing severe, life-threatening obstruction of the upper airway.

**Clinical manifestations**

In the classic form of the disease, a child between 2 and 7 years of age suddenly develops high fever, irritability, sore throat, inspiratory stridor, and severe respiratory distress. The child appears anxious and has a voice that sounds muffled (“hot potato” voice). Drooling, absence of cough, preference to sit, and dysphagia (inability to swallow) are common. In addition to appearing ill, the child will generally adopt a position of leaning forward (tripoding) to try to improve
breathing. Death can occur in a few hours. Pneumonia, cervical lymph node inflammation, otitis, and, rarely, meningitis or septic arthritis may occur concomitantly because of bacterial sepsis.

**Evaluation and treatment**

Acute epiglottitis is a life-threatening emergency. Efforts should be made to keep the child calm and undisturbed. Examination of the throat should not be attempted because it may trigger laryngospasm and cause respiratory collapse. With severe airway obstruction, the airway may be secured with intubation, and antibiotics are administered promptly. Racemic epinephrine and corticosteroids may be given until definitive management of the airway can be achieved. Resolution with treatment is usually rapid. Postexposure prophylaxis with rifampin is recommended for all household unvaccinated contacts after a child is diagnosed.

**Tonsillar Infections**

*Tonsillar infections* (tonsillitis) are occasionally severe enough to cause upper airway obstruction. As with other infections of the upper airway, the incidence of tonsillitis secondary to group A beta-hemolytic *Streptococcus* (GABHS) and methicillin-resistant *Staphylococcus aureus* (MRSA) has risen in the past 15 years. Upper airway obstruction because of tonsillitis is a well-known complication of infectious mononucleosis, especially in a young child. Tonsillitis may be complicated by formation of a **tonsillar abscess**, which can further contribute to airway obstruction. **Peritonsillar abscess** is usually unilateral and is most often a complication of acute tonsillitis. The abscess must be drained and the child given antibiotics. The development of significant obstruction in tonsillar infections may require the use of corticosteroids, especially in the case of mononucleosis. The management of severe bacterial tonsillitis requires the use of antibiotics. Some children with recurrent tonsillitis benefit from adenotonsillectomy.

**Aspiration of Foreign Bodies**

Aspiration of foreign bodies (FBs) into the airways usually occurs in children 1 to 4 years of age. More than 100,000 cases and 100 deaths occur each year. Most objects are expelled by the cough reflex, but some objects may lodge in the larynx, trachea, or bronchi. Large objects (e.g., hard candy, a bite of hot dog, nuts, popcorn, grapes, beans, toy pieces, fragments of popped balloons, or coins) may occlude the airway and become life-threatening. Items of particular concern would be batteries and magnets. The aspiration event commonly is not witnessed or is not recognized when it happens because the coughing, choking, or gagging symptoms may resolve.
quickly. Foreign bodies lodged in the larynx or upper trachea cause cough, stridor, hoarseness or inability to speak, respiratory distress, and agitation or panic; the presentation is often dramatic and frightening. If the child is acutely hypoxic and unable to move air, immediate action such as sweeping the oral airway or performing abdominal thrusts (formerly called the Heimlich maneuver) may be required to prevent tragedy. Otherwise, bronchoscopic removal should be performed urgently. If an aspirated foreign body is small enough, it will be transferred to a bronchus before becoming lodged. If the foreign body is lodged in the airway for a notable period of time, local irritation, granulation, obstruction, and infection will ensue. Thus children may present with cough or wheezing, atelectasis, pneumonia, lung abscess, or blood-streaked sputum. These children are treated by prompt bronchoscopic removal of the object and administration of antibiotics as necessary.\(^\text{17}\)

**Obstructive Sleep Apnea**

**Obstructive sleep apnea syndrome (OSAS)** is defined by partial or intermittent complete upper airway obstruction during sleep with disruption of normal ventilation and sleep patterns. Childhood OSAS is common, with an estimated prevalence of 2% to 3% of children 12 to 14 years of age and up to 13% of children between 3 and 6 years of age.\(^\text{18,19}\) Prevalence is estimated to be two to four times higher in vulnerable populations (blacks, Hispanics, and preterm infants).\(^\text{18}\) In children, unlike adults, OSAS occurs equally among girls and boys. Possible influences early in life may include passive smoke inhalation, socioeconomic status, and snoring together with genetic modifiers that promote airway inflammation.

**Pathophysiology**

Reduced airway diameter and increased upper airway collapsibility are the common causes of OSAS. Obstruction of the upper airway during sleep results in cyclic episodes of increasing respiratory effort and changes in intrathoracic pressures with oxygen desaturation, hypercapnia, and arousal. The child goes back to sleep and the cycle repeats. Adenotonsillar hypertrophy, obesity, and craniofacial anomalies are associated with decreased airway diameter. Infants are at risk because they have both anatomic and physiologic predispositions toward airway obstruction and gas exchange abnormalities.\(^\text{20}\)

Reduced motor tone of the upper airways may be seen in neurologic disorders, such as cerebral palsy, and Down syndrome. Upper airway inflammation and altered neurologic reflexes involving respiratory control of upper airway muscles are significant factors in reducing airway diameter. Allergy and asthma may contribute
to inflammation, and children who have a history of a clinically significant episode of respiratory syncytial virus (RSV) bronchiolitis in infancy may exhibit altered neuroimmunomodulatory pathways toward inflammation in the upper airway.\textsuperscript{21} In obese children, current research links OSAS with airway inflammation and elevated levels of C-reactive protein, which also contribute to increased risk for cardiovascular and metabolic disease.\textsuperscript{22,23} OSAS also may cause pulmonary disease, insulin resistance, and growth failure.\textsuperscript{24}

**Clinical manifestations**

Common manifestations of OSAS include snoring and labored breathing, sweating, and restlessness during sleep, which may be continuous or intermittent. There may be episodes of increased respiratory effort but no audible airflow, often terminated by snorting, gasping, repositioning, or arousal. Daytime sleepiness/napping is occasionally reported, as well as nocturnal enuresis. There is no correlation between sleep position and OSAS in children, except for those children who are notably obese. Obese children may adopt the prone position to attempt improved ventilation. Cognitive and neurobehavioral impairment, excessive daytime sleepiness, impaired school performance, and poor quality of life are consequences of OSAS.\textsuperscript{25}

**Evaluation and treatment**

All parents should be asked if their child exhibits snoring, followed by a careful history and physical examination. A variety of screening tools are available. Imaging of the upper airway may be used to rule out adenoidal hypertrophy or upper airway narrowing.\textsuperscript{26} The most definitive evaluation is the polysomnographic sleep study, which documents obstructed breathing and physiologic impairment. If obstructive sleep apnea is documented or strongly suspected clinically, children are most often referred for tonsillectomy and adenoidectomy (T & A) on the basis of described symptoms and physical findings, such as enlarged tonsils, adenoidal facies, and mouth breathing. For severely affected children who do not respond to T & A or who have different problems, such as obesity, continuous positive airway pressure (CPAP), anti-inflammatories, dental treatments, high-flow nasal cannula, and weight loss can be considered. Treatment is important to minimize associated morbidities.\textsuperscript{27,28}

**Quick Check 28-1**

1. Compare and contrast pathology, clinical presentations, and severity of croup and
epiglottitis.

2. What symptoms indicate aspiration of a foreign body?

3. What signs and symptoms suggest obstructive sleep apnea?
Disorders of the Lower Airways

Lower airway disease is one of the leading causes of morbidity in the first year of life and continues to be an important component of other illnesses progressing into childhood. Pulmonary disorders commonly observed include neonatal respiratory distress syndrome, bronchopulmonary dysplasia, infections, asthma, cystic fibrosis, and acute respiratory distress syndrome (ARDS).

Respiratory Distress Syndrome of the Newborn

Respiratory distress syndrome (RDS) of the newborn (previously known as hyaline membrane disease [HMD]) is a significant cause of neonatal morbidity and mortality. It occurs almost exclusively in premature infants and the incidence has increased in the United States over the past 2 decades. RDS occurs in 50% to 60% of infants born at 29 weeks' gestation and decreases significantly by 36 weeks. Risk factors are summarized in Risk Factors: Respiratory Distress Syndrome of the Newborn. Death rates have declined significantly since the introduction of antenatal steroid therapy and postnatal surfactant therapy.

Risk Factors

Respiratory Distress Syndrome of the Newborn

- Premature birth/low birth weight
- Male gender
- Cesarean delivery without labor
- Diabetic mother
- Perinatal asphyxia

Pathophysiology

RDS is caused by surfactant deficiency, which decreases the alveolar surface area available for gas exchange. Surfactant is a lipoprotein with a detergent-like effect that separates the liquid molecules inside the alveoli, thereby decreasing alveolar surface tension. Without surfactant, alveoli collapse at the end of each exhalation. Surfactant normally is not secreted by the alveolar cells until approximately 30
weeks' gestation. In addition to surfactant deficiency, premature infants are born with underdeveloped and small alveoli that are difficult to inflate and have thick walls and inadequate capillary blood supply such that gas exchange is significantly impaired. Furthermore, the infant's chest wall is weak and highly compliant and, thus, the rib cage tends to collapse inward with respiratory effort. The net effect is **atelectasis** (collapsed alveoli), resulting in significant hypoxemia. Atelectasis is difficult for the neonate to overcome because it requires a significant negative inspiratory pressure to open the alveoli with each breath. This increased work of breathing may result in hypercapnia. Hypoxia and hypercapnia cause pulmonary vasoconstriction and increase intrapulmonary resistance and shunting. This results in hypoperfusion of the lung and a decrease in effective pulmonary blood flow. Increased pulmonary vascular resistance may even cause a partial return to fetal circulation, with right-to-left shunting of blood through the ductus arteriosus and foramen ovale. Inadequate perfusion of tissues and hypoxemia contribute to metabolic acidosis.

Inadequate alveolar ventilation can be further complicated by increased pulmonary capillary permeability. Many premature infants with RDS will require mechanical ventilation, which damages the alveolar epithelium. Together these conditions result in the leakage of plasma proteins into the alveoli. Fibrin deposits in the air spaces create the appearance of "**hyaline membranes**," for which the disorder was originally named. The plasma proteins leaked into the air space have the additional adverse effect of inactivating any surfactant that may be present. The pathogenesis of RDS is summarized in **Figure 28-5**.
**Clinical manifestations**

Signs of RDS appear within minutes of birth and include tachypnea (respiratory rate greater than 60 breaths/min), expiratory grunting, intercostal and subcostal retractions, nasal flaring, and cyanosis. Severity tends to increase over the first 2 days of life. Apnea and irregular respirations occur as the infant tires. Severity of hypoxemia and difficulty in providing supplemental oxygenation have resulted in the Vermont Oxford Neonatal Network definition of RDS: a Pao$_2$ less than 50 mm Hg in room air, central cyanosis in room air, or a need for supplemental oxygen to maintain Pao$_2$ greater than 50 mm Hg, as well as classic chest film appearance. The typical chest radiograph shows diffuse, fine granular densities within the first 6
hours of life. This “ground glass” appearance is associated with alveolar flooding. Ventilatory support is often required. In most cases the clinical manifestations reach a peak within 3 days, after which there is gradual improvement.

**Evaluation and treatment**

Diagnosis is made on the basis of premature birth or other risk factors, chest radiographs, pulse oximetry measurements, and, if needed, analysis of amniotic fluid or tracheal aspirates to estimate lung maturity (lecithin/sphingomyelin ratio [L/S ratio]). Some neonates require immediate resuscitation because of asphyxia or severe respiratory distress. The ultimate treatment for RDS would be prevention of premature birth. For women at risk of preterm birth, antenatal treatment with glucocorticoids induces a significant and rapid acceleration of lung maturation and stimulation of surfactant production in the fetus and significantly reduces the incidence of RDS and death.\(^{31,32}\)

Current recommendations for infants weighing less than 1000 g include prophylaxis beginning within 15 to 30 minutes of birth by administration of exogenous surfactant (either synthetic or natural) through nebulizer or nasal continuous positive airway pressure (CPAP) ventilation. Repeat doses are given every 12 hours for the first few days. There is usually a dramatic improvement in oxygenation as well as a decreased incidence of RDS death, pneumothorax, and pulmonary interstitial emphysema. For infants weighing more than 1000 g, surfactant replacement is based on clinical need. Surfactant therapy should be considered complementary to antenatal glucocorticoids. The two therapies together appear to have an additive effect on improving lung function.\(^{33}\)

Supportive care includes oxygen administration and often such measures as mechanical ventilation. Mechanical ventilation can result in a proinflammatory state that may contribute to the development of chronic lung disease, such as bronchopulmonary dysplasia (BPD). Strategies that are lung protective include greater reliance on nasal CPAP, permissive hypercapnia, lower oxygen saturation targets, modulation of tidal volume \(V_t\) settings, and use of high-frequency oscillation. Further studies are needed to evaluate the effectiveness of inhaled nitric oxide (iNO) in preterm infants.\(^{34}\) Most infants survive RDS and, in many cases, recovery may be complete within 10 to 14 days. However, the incidence of subsequent chronic lung disease (i.e., bronchopulmonary dysplasia) is significant among very low birth weight infants.\(^{35}\)

**Bronchopulmonary Dysplasia**

*Bronchopulmonary dysplasia (BPD)*, also known as *chronic lung disease (CLD)* of
Prematurity is the major cause of pulmonary disease in infants. It is associated with premature birth (usually before 28 weeks' gestation), prolonged (at least 28 days) perinatal supplemental oxygen, and positive pressure ventilation. There are approximately 60,000 U.S. infants born weighing less than 1500 g on an annual basis. About 20% to 30% of these infants develop BPD. Risk factors for BPD are summarized in *Risk Factors: Bronchopulmonary Dysplasia (BPD).*

**Risk Factors**

**Bronchopulmonary Dysplasia (BPD)**

- Premature birth (especially ≤28 weeks)
- Positive-pressure ventilation
- Supplemental oxygen administration
- Antenatal chorioamnionitis
- Postnatal sepsis or pneumonia
- Patent ductus arteriosus
- Nutritional deficiencies
- Early adrenal insufficiency
- Genetic susceptibility

The widespread use of antenatal glucocorticoids and postnatal surfactant has lessened the incidence and severity of RDS, and BPD is occurring primarily in the smallest premature infants (23 to 28 weeks' gestation) who have received mechanical ventilation. The presence of antenatal chorioamnionitis with fetal involvement, postnatal sepsis, a patent ductus arteriosus, and genetic susceptibility confer additional risks of developing BPD. Surprisingly, some of these tiny infants who develop BPD have shown few or no clinical signs of RDS at birth or have initially received only low levels of supplemental oxygen or ventilatory support, sometimes for other reasons such as apnea.
Pathophysiology

Lung immaturity and inflammation contributes to the development of BPD. Before the widespread use of surfactant therapy, BPD was a disease characterized by airway injury, inflammation, and parenchymal fibrosis (classic BPD). With the initiation of surfactant therapy, what is called the new BPD is most common and is a form of arrested lung development. There is poor formation of the alveolar structure with fewer and larger alveoli and decreased surface area for gas exchange. Persistent inflammation contributes to pulmonary capillary fibrosis, perfusion mismatch, pulmonary hypertension, and decreased exercise capacity.\(^{38,39}\) The predominant mediators of new BPD are profibrotic and angiogenic cytokines rather than proinflammatory cytokines, which contribute to pulmonary hypertension.\(^{40}\) Table 28-2 and Figure 28-6 illustrate the pathophysiology of BPD.

Clinical manifestations
The clinical definition of BPD includes need for supplemental oxygen at 36 weeks' postmenstrual age or gestational age (the time elapsed between the first day of the last normal menstrual period and the day of birth), and for at least 28 days after birth. It also details a graded severity dependent on required respiratory support at term (mild, moderate, and severe, based on oxygen requirements and ventilatory needs). Clinically, the infant exhibits hypoxemia and hypercapnia caused by ventilation-perfusion mismatch and diffusion defects. The work of breathing increases and the ability to feed may be impaired. Intermittent bronchospasm, mucus plugging, and pulmonary hypertension characterize the clinical course. Of the most severely affected infants, dusky spells may occur with agitation, feeding, or gastroesophageal reflux. Infants with mild BPD may demonstrate only mild tachypnea and difficulty handling respiratory tract infections.

Evaluation and treatment
Infants with severe BPD require prolonged assisted ventilation. Prevention of lung
damage with noninvasive respiratory support, such as early nasal CPAP or nasal intermittent positive-pressure ventilation (IPPV), is used in clinical situations when permitted. When compared to mechanical ventilation, use of CPAP has resulted in fewer days of oxygen and ventilator requirement by reducing the amount of lung injury. 

Diuretics are used to control pulmonary edema. Bronchodilators reduce airway resistance. Inhaled corticosteroids improve the rate of extubation and reduce the time that mechanical ventilation is required. Prophylactic caffeine citrate administration, vitamin A supplementation, and careful fluid and nutritional support are routinely used and have resulted in improved outcomes. Children with BPD will need to be monitored into adulthood for the development of chronic lung disease.

Quick Check 28-2

1. Why are premature infants susceptible to RDS?

2. Describe the pathologic findings of “new BPD.”

Respiratory Tract Infections

Respiratory tract infections are common in children and are a frequent cause for emergency department visits and hospitalizations. Clinical presentation, age of the child, and season of the year can often provide clues to the etiologic agent, even when the agent cannot be proved.

Bronchiolitis

**Bronchiolitis** is a common, viral respiratory tract infection of the small airways that occurs almost exclusively in infants and young toddlers and is a major reason for hospitalization. It has a seasonal, yearly incidence, from approximately November to April, and is the leading cause of hospitalization for infants during the winter season. The most common associated pathogen is respiratory syncytial virus (RSV), but bronchiolitis also may be associated with human metapneumovirus and human bocavirus. Healthy infants usually make a full recovery from RSV bronchiolitis, but infants who were premature (birth weight <2500 g) or who have underlying BPD or heart disease may have a much higher risk for a more severe or even deadly course. Bronchiolitis has been linked to an increased risk for asthma later in childhood. Associations with rhinovirus and low vitamin D levels also are being investigated because they appear to correlate with the increased likelihood that children develop
asthma after they have experienced bronchiolitis.\textsuperscript{45}

**Pathophysiology**

Viral infection causes necrosis of the bronchial epithelium and destruction of ciliated epithelial cells. There is infiltration with lymphocytes around the bronchioles and a cell-mediated hypersensitivity to viral antigens with release of lymphokines causing inflammation, as well as activation of eosinophils, neutrophils, and monocytes. The submucosa becomes edematous and cellular debris and fibrin form plugs within the bronchioles. Edema of the bronchiolar wall, accumulation of mucus and cellular debris, and bronchospasm narrow many peripheral airways. Other airways become partially or completely occluded. Atelectasis occurs in some areas of the lung and hyperinflation in others.

The mechanics of breathing are disrupted by bronchiolitis. Airway narrowing causes obstruction of airflow that is worse on expiration. This leads to air trapping, hyperinflation, and increased functional residual capacity (FRC). Airway resistance and hyperinflation result in increased work of breathing and the development of hypercapnia in severe cases.

**Clinical manifestations**

Symptoms usually begin with significant rhinorrhea followed by a tight cough over the next several days, along with systemic signs of decreased appetite, lethargy, and fever. Infants typically have tachypnea, variable degrees of respiratory distress, and abnormal auscultatory findings of the chest. Wheezing is most common, but rales or rhonchi also may be present. Chest radiographs often reveal hyperexpanded lungs, patchy or peribronchial infiltrates, and, sometimes, atelectasis of the right upper lobe. Very young infants may present with severe apnea before lower respiratory tract symptoms appear, and these apneas frequently require mechanical ventilation. Many children also may present with conjunctivitis or otitis media.

**Evaluation and treatment**

Guidelines from the American Academy of Pediatrics are available for the evaluation, treatment, and prevention of bronchiolitis.\textsuperscript{46} Diagnosis of bronchiolitis is made by review of history, signs, and symptoms (e.g., rhinitis, cough, wheezing, chest retractions, tachypnea). Laboratory and radiologic examination are not routinely performed.

Treatment for bronchiolitis is determined by the severity of the disease and the age of the child. Most cases are mild and require no specific treatment and may be monitored as outpatients. When treatment is indicated, it is primarily supportive in nature. Preventive treatment with RSV-specific monoclonal antibody (palivizumab),
provided as a monthly injection for 5 months through the RSV season, is recommended for high-risk infants younger than 2 years who meet specific criteria (e.g., hemodynamically significant heart disease and chronic lung disease of prematurity). Other preventive measures include use of hand washing and alcohol-based decontamination, prevention of exposure to tobacco smoke, and promotion of infant breast feeding.

**Pneumonia**

Pneumonia is infection and inflammation in the terminal airways and alveoli. Community-acquired pneumonia (CAP) is a major cause of morbidity and mortality in children, particularly in developing countries. The most common agents are viruses, followed by bacteria and atypical microorganisms (e.g., mycoplasma) (Table 28-3), and clinical symptoms often do not differentiate viral from bacterial or atypical pneumonia. Risk factors for developing CAP are age younger than 2 years, overcrowded living conditions, winter season, recent antibiotic treatment, daycare attendance, and passive smoke exposure. Nutritional status, age, and underlying disease process influence morbidity and mortality rates related to CAP.

**Pathophysiology**

Viral pneumonia is two to three times more likely to occur in children than in adults, and incidence generally follows a seasonal pattern. Bacterial coinfections are common. RSV (respiratory syncytial virus) is the most common viral pneumonia in young children. A number of other viruses are important, including parainfluenza, influenza, human rhinovirus, human metapneumovirus, adenoviruses, and
*Mycoplasma pneumoniae.* Acquisition of these viruses is by direct contact, droplet transmission, or aerosol exposure. There is initial destruction of the ciliated epithelium of the distal airway with sloughing of cellular material. A mononuclear-predominant inflammatory response occurs, in the interstitium initially, and later may involve the alveoli as well. Early in the course of the disease, it is often difficult to determine whether the pneumonia is viral or bacterial. Viral pneumonia often presents with cough and no fever. Differences in the clinical presentation can help to determine origin, such as degree of elevation of temperature, absolute neutrophil counts, and percentage of bands. Ultimately, diagnosis requires laboratory confirmation using immunofluorescence tests. Development of safe agents to treat and prevent viral pneumonia continues to be a focus of much research.

**Bacterial pneumonia** beyond the neonatal period is most commonly the result of infection with streptococci and staphylococci microorganisms. Pneumococcal (*Streptococcus pneumoniae*) pneumonia is the most common cause of community-acquired bacterial pneumonia and presents acutely and with variable severity. Childhood immunization with polyvariant pneumococcal conjugate vaccine appears to decrease the incidence of pneumococcal pneumonia in children younger than 2 years of age. Staphylococcal pneumonia and group A streptococcal pneumonia can be particularly fulminant (sudden, severe) and necrotizing (causing cell death) with a high incidence of accompanying empyema, pneumatocele (a lung lesion filled with air), and sepsis. *H. influenzae* pneumonia has become rare because of widespread immunization.

Bacterial pneumonia usually begins with aspiration of nasopharyngeal bacteria. A preceding viral infection sometimes sets the stage for bacterial infection by causing epithelial damage, reduced mucociliary clearance in the trachea and major bronchi, and a reduced immune response. Once in the alveolar region, bacteria encounter local host defenses, such as antibodies, complement, and cytokines, which prepare bacteria for ingestion by alveolar macrophages. Alveolar macrophages recognize bacteria with their surface receptors and phagocytose them. If these mechanisms fail, macrophages release numerous inflammatory cytokines and neutrophils will be recruited into the lung. An intense, cytokine-mediated inflammation will ensue. Vascular engorgement, edema, and a fibrinopurulent exudate occur. Alveolar filling precludes gas exchange and, if extensive, can lead to respiratory failure. If sepsis occurs at the same time, shock and end-organ hypoperfusion will cause metabolic acidosis.

The clinical presentation of bacterial pneumonia, particularly pneumococcal, may include a preceding viral illness followed by fever with chills and rigors, shortness of breath, and an increasingly productive cough. Occasionally, there is
blood streaking of the sputum. Respiratory rate and oxygen saturation also are important clinical indicators. Auscultation usually shows such abnormalities as crackles or decreased breath sounds. Other, less specific findings may include malaise, emesis, abdominal pain, and chest pain. Chest films will usually present with a lobar pattern in older children and adolescents but may appear patchier with a bronchopneumonic pattern in younger children.

**Atypical pneumonia (Mycoplasma pneumoniae, Chlamydia pneumoniae)** is the most common cause of community-acquired pneumonia for school-age children and young adults. *Chlamydia pneumoniae* pneumonia is clinically indistinguishable from and is typically grouped with *Mycoplasma* as “atypical pneumonia.” Transmission is from person-to-person with a 2- to 3-week incubation period.

Mycoplasma microorganisms lack cell walls but have a limiting membrane and a specialized receptor for attaching to ciliated respiratory epithelial cells. Local sloughing of cells occurs. Peribronchial lymphocytic infiltration develops, along with neutrophil recruitment to the airway lumen. The pattern resembles bronchitis or bronchopneumonia. Onset is usually gradual, resembling a typical upper respiratory tract infection but with low-grade fever, cough, and chest pain. Mycoplasma can cause a wide spectrum of disease and is more extensive as a cause of complications than previously noted. It also is occurring more frequently in infants and younger children. Most cases are not clinically severe and full recovery should be expected. Complications, when they do occur, can include bronchopneumonia, parapneumonic effusions, and necrotizing pneumonitis.

**Evaluation and treatment**

Guidelines have been developed to improve and aid assessment and management of pediatric pneumonia. Diagnosis of pneumonia is based on clinical and laboratory findings. The etiologic agent can sometimes be inferred from the age of the child and clinical scenario. Chest x-ray in bacterial pneumonia often will initially produce a patchy infiltration and later reveal a segmental or lobar disease. A viral infection is more likely to be associated with an interstitial pattern. Biomarkers (i.e., procalcitonin) facilitate more rapid diagnosis and guide antibiotic therapy. The highly sensitive C-reactive protein (hs-CRP) is less specific and its level is elevated in both viral and bacterial infections. Several microbiologic tests are available, such as polymerase chain reaction (PCR) and nucleic acid amplification tests (NAATs).

Some pneumonias may be treated on an outpatient basis; however, many children require oxygen supplementation and, occasionally, assisted ventilation. This is particularly true with infants who have a viral interstitial pneumonia, such as RSV. In addition, adequate hydration, proper nutrition, and supportive pulmonary therapy
are required to reduce the duration and severity of illness. Many infants are markedly tachypneic and unable to coordinate their breathing with swallowing; they may require enteral feeding. Aspiration is always a risk with infants in respiratory distress.

Appropriate antibiotic administration for bacterial pneumonias is dependent on age and severity assessment. Local patterns of resistance must be considered when choosing appropriate antibiotics. Pneumococcal and mycoplasmal pneumonias present some unique treatment obstacles and may need a multifaceted approach to care including vaccine antigens and immune adjuvant therapies in addition to antibiotics.\textsuperscript{57} Children should be vaccinated against influenza and pneumococcus.

\textbf{Quick Check 28-3}

1. Describe the typical presentation of RSV bronchiolitis.

2. What clinical features distinguish bacterial pneumonia from atypical pneumonia?

\textbf{Aspiration Pneumonitis}

\textbf{Aspiration pneumonitis} is caused by a foreign substance, such as food, meconium, secretions (saliva or gastric), or environmental compounds, entering the lung and resulting in inflammation of the lung tissue. The aspiration of meconium from amniotic fluid can occur at birth.\textsuperscript{58} Neurologically compromised children or children with chronic lung disease may have chronic pulmonary aspiration (CPA), which can cause progressive lung disease, bronchiectasis, and respiratory failure. This is the leading cause of death in children who are neurologically compromised because of failure of protective reflexes and difficulty swallowing.\textsuperscript{59} Children undergoing sedation or anesthesia also may aspirate oral secretions contaminated with anaerobic bacteria or acidic stomach contents. The severity of lung injury after an aspiration incident is determined by the volume and pH of the material aspirated and the presence of pathogenic bacteria. Very low pH or extremely high pH will cause a significant inflammatory response. With hydrocarbon ingestions, lung injury is determined by the volatility and viscosity of the aspirated substance. A low-viscosity substance, such as gasoline or lighter fluid, is the most toxic, and high-viscosity hydrocarbons, such as petroleum jelly or mineral oil, are much less likely to cause a pneumonitis. Treatment for aspiration pneumonitis depends on the material aspirated but can include broad-spectrum antibiotics with failure to improve after 48 hours. Children with CPA and a large amount of upper respiratory
tract secretions may benefit from salivary gland injection with botulinum toxin A (BTX-A) to suppress secretion.⁶₀

**Bronchiolitis Obliterans**

**Bronchiolitis obliterans (BO)** is fibrotic obstruction of the respiratory bronchioles and alveolar ducts secondary to intense inflammation. It is relatively rare in children. There are two types: proliferative and constrictive (obstructive), with the latter being the more common form. BO most often occurs as a sequela of a severe viral pulmonary infection (e.g., influenza, adenovirus, pertussis [whooping cough], or measles). Other cases may be secondary to parainfluenza, RSV, human immunodeficiency virus (HIV), or *M. pneumoniae* infection or lung transplant. It also may occur after lung, heart-lung, or bone marrow transplantation, or be associated with collagen vascular disease, toxic fume inhalation, chronic hypersensitivity pneumonitis, Crohn disease, and Stevens-Johnson syndrome.⁶¹,⁶²

Although the child may initially improve after the acute insult, the progression of disease is then reflected by increasing tachypnea, dyspnea, cough, sputum production, crackles, wheezing, increased chest anteroposterior diameter (APD), and hypoxemia.

There is no specific treatment for bronchiolitis obliterans and, because it is so rare, there have been no randomized clinical trials. Therapeutic options include inhaled corticosteroids, bronchodilators, antibiotics, and oxygen supplementation. Mechanical ventilation may contribute to the progression of the disease. Some children deteriorate rapidly and die within weeks, whereas others follow a more chronic course. Antiviral agents may assist in blunting the initial viral response but otherwise have limited effect on the illness. Anti-inflammatory agents are showing promise in reducing airway inflammation and improving pulmonary function. For those children having undergone lung transplantation, increased immunosuppressive regimens are sometimes helpful.⁶³,⁶⁴

**Asthma**

**Asthma** is a chronic inflammatory disease characterized by bronchial hyperreactivity and reversible airflow obstruction, usually in response to an allergen (see Chapter 27). It is the most prevalent chronic disease in childhood, affecting about 10% of U.S. children between birth and 17 years of age, and prevalence is increasing. Populations most affected include black, American Indian, Alaska Native, and Hispanic children; those living in an urban setting; and those of low socioeconomic status.⁶⁵
Childhood asthma results from a complex interaction between genetic susceptibility and environmental factors. Many genotypes are associated with susceptibility and phenotypes of asthma, including early-onset mild allergic asthma, asthma with severe exacerbations, later-onset asthma associated with obesity, severe nonatopic asthma, and corticosteroid-dependent asthma. Important risk factors include early exposure to allergens (e.g., air pollution, dust mites, cockroach antigen, cat exposure, and tobacco smoke), respiratory tract infections, preterm birth, and childhood obesity.\textsuperscript{66-69} The hygiene hypothesis proposes that infants and children exposed to a highly hygienic environment and who receive vaccinations to prevent certain infections lack adequate exposure to common pathogens and therefore do not achieve balanced immune responses as they mature\textsuperscript{70} (see Chapter 27).

About 70\% to 80\% of acute wheezing episodes in children with asthma are associated with viral respiratory tract infection (i.e., respiratory syncytial virus, human rhinoviruses, and parainfluenza viruses). In infants and toddlers less than 2 years old, the most common of these is respiratory syncytial virus (RSV). In older children and adults, the major viral trigger is rhinovirus (the “common cold” virus). Bacterial respiratory tract infections also can trigger asthma.\textsuperscript{71} Vitamin D insufficiency may be a risk factor for airway inflammation and wheezing in children because vitamin D suppresses Th2-mediated allergic disease.\textsuperscript{72}

**Pathophysiology**

The pathophysiology of asthma in children is similar to that for adults and is described in Chapter 27. Asthma is initiated by a type I hypersensitivity reaction primarily mediated by Th2 lymphocytes whose cytokines activate mast cells, eosinophilia, leukocytosis, and enhanced B-cell IgE production (see Chapter 8) (see Figures 27-8, 27-9, 27-10). As in adults, inflammation, bronchospasm, and mucus production in the airways lead to ventilation and perfusion mismatch with hypoxemia and expiratory airway obstruction with air trapping and increased work of breathing. In young children, airway obstruction can be more severe because of the smaller diameter of their airways.

**Clinical manifestations**

Clinical manifestations of an acute asthma attack include coughing, expiratory wheezing, and shortness of breath. Breath sounds may become faint when air movement is poor. The child may speak in clipped sentences or not at all because of dyspnea. Sometimes hyperinflation (barrel chest) is visible. Respiratory rate and heart rate are elevated. Nasal flaring and use of accessory muscles with retractions in the substernal, subcostal, intercostal, suprasternal, or sternocleidomastoid areas
are evident. Infants may appear to be “head bobbing” because of sternocleidomastoid muscle use. Pulsus paradoxus (decrease in systolic blood pressure of more than 10 mm Hg during inspiration) may be present. The child may appear anxious or diaphoretic, important signs of respiratory compromise.

Findings in chronic asthma may include hyperinflation of the thorax or pectus excavatum. Clubbing should not be seen with asthma and, if present, should trigger evaluation for other conditions such as cystic fibrosis. Exercise intolerance may indicate underlying asthma (see Health Alert: Exercise-Induced Bronchoconstriction).

**Health Alert**

**Exercise-Induced Bronchoconstriction**

Exercise-induced bronchoconstriction (EIB) occurs in 90% of children diagnosed with asthma. It is estimated to occur in 10% to 15% of all U.S. children without diagnosed asthma and is surprisingly common among young, elite athletes, who have been found to have EIB prevalence rates of 20% to 40%. A proposed mechanism for EIB is epithelial injury and inflammation, which results from drying of the mucosa and changes in the osmolarity in the airway epithelium leading to degranulation of mast cells. Another contributing factor is the inhalation of particles and toxins at high flow rates; this is of particular importance in urban areas and in swimmers in chlorinated pools. These changes result in increased type I hypersensitivity and airway hyperresponsiveness (AHR) in those with asthma and are associated with an increase in leukotriene release. Eosinophil activation also plays a role in airway hyperreactivity and tissue damage. Finally, it has been found that obese children who have high levels of the inflammatory adipokine leptin are more likely to develop EIB than nonobese children. Symptoms are a poor indicator of the severity of bronchoconstriction, especially in obese children, and spirometry with exercise challenge testing is needed to make the diagnosis. Warm-up exercises and cooling down slowly after exercise, along with the use of facemasks in cold weather, can be helpful. A recent study reported that yoga training can markedly improve EIB in children aged 6 to 17. Although bronchodilators remain the most commonly used medications for EIB, studies suggest that inhaled corticosteroids or leukotriene inhibitors are more effective and safer in children with EIB and asthma.

Evaluation and treatment

Asthma is often underdiagnosed and undertreated, especially in preschool-age children because asthma symptoms overlap with other respiratory illnesses, such as bronchitis or upper respiratory tract infections. Diagnosis of asthma is based on episodes of wheezing as well as a variety of risk factors including parental history of asthma, atopic dermatitis, sensitization to aeroallergens or foods, blood eosinophilia, or wheezing not associated with upper respiratory tract illnesses. The modified Asthma Predictive Index (API) can be used to help with asthma diagnosis and is recommended by the National Institutes of Health (NIH) guidelines. Confirmation of the diagnosis of asthma relies on pulmonary function testing using spirometry, which can be accomplished only after the child is 5 to 6 years of age. For younger children, an empirical trial of asthma medications is commonly initiated.

The goal of asthma therapy is to achieve long-term control by reduction in impairment and risk. Child/family education and appropriate allergen avoidance techniques should begin immediately. Care providers need to periodically assess asthma control in children. Key features for assessment include nighttime awakenings, interference with normal activities, use of short-acting beta₂ agonists, pulmonary function testing, and exacerbations requiring steroids. Peak flow meters are often used to help guide treatment. Before therapy is augmented, care providers need to assess medication administration techniques, environmental controls, and comorbidities. For reduction in therapy, the asthma needs to be under good control for a minimum of 3 months.

The pharmacologic treatment of asthma in children is essentially the same as that for adults and is initiated in a stepwise sequence based on asthma severity and response to treatment (see Chapter 27). Management of asthma medications in children is often difficult because fluctuation in severity of symptoms is common.

Quick Check 28-4

1. What are the key features of the early and late asthmatic responses?

2. Explain the full progression of blood gas abnormalities in a severe asthma attack.

3. What is air trapping and how is it manifested in children?

Acute Lung Injury/Acute Respiratory Distress
Syndrome

**Acute respiratory distress syndrome (ARDS)** occurs in all children and is a dramatic, life-threatening condition resulting from a direct *acute lung injury (ALI)*, such as pneumonia, aspiration, near drowning, or smoke inhalation; or from a systemic insult, such as sepsis or multiple trauma, either of which activates an inflammatory response that causes alveolocapillary injury. ARDS accounts for approximately 10% of total patient days and one third of all deaths in pediatric intensive care units. Mortality in pediatric ARDS remains high, at approximately 40%.\(^{75}\)

Pathophysiology

The pathophysiology of ARDS in children is the same as that described for adults in Chapter 27 (see Figure 27-7).

Clinical manifestations

ARDS develops acutely after ALI, usually within 24 hours, though occasionally it is delayed up to a few days. ARDS is characterized by progressive respiratory distress, severe hypoxemia, decreased pulmonary compliance, and diffuse densities on chest radiograph. Initially, hyperventilation occurs, but CO\(_2\) retention may ultimately occur as well because of inadequate functional air space and respiratory muscle fatigue. The severity of the overall picture is modified by comorbid factors, such as the presence of sepsis or multiorgan failure, and by the presence or absence of complications, such as nosocomial pneumonia. Some children who recover have residual pulmonary abnormalities.

Evaluation and treatment

Treatment for ARDS remains supportive in nature, and the goals are to maintain adequate tissue oxygenation, minimize acute lung injury, and avoid iatrogenic pulmonary complications. Most individuals with ARDS require mechanical ventilation and often relatively high levels of positive end-expiratory pressure (PEEP) to promote alveolar ventilation and stabilization, and redistribution of alveolar edema fluid into the interstitium. Lung-protective ventilation strategies may include low tidal volume and permissive hypercapnia, permissive hypoxemia to prevent oxygen toxicity, prone positioning, high-frequency oscillatory ventilation, and airway pressure release ventilation. Use of corticosteroids in children with ARDS is controversial and remains at the discretion of the clinician. Extracorporeal membrane oxygenation (ECMO) can provide cardiac or respiratory support, or both, but does not heal the underlying condition.\(^{76}\)
Cystic Fibrosis

Cystic fibrosis (CF) is an autosomal recessive inherited disease that results from defective epithelial chloride ion transport. The CF gene is located on chromosome 7. There are more than 1800 known mutations of this gene divided into 6 classes with varying severity of disease expression. Classes 1 through 3 are associated with more severe disease and 4 through 6 with milder pulmonary disease and pancreatic sufficiency. Mortality correlates respectively with the aforementioned classes. CF primarily affects whites (approximately 1 in 3000 whites). There are approximately 1000 new cases of CF diagnosed each year and the median age at diagnosis is 6 months. The projected mean age of survival is the early forties. The estimated carrier frequency is high, 1 in 29 whites in the United States. Carriers are not affected by the mutation. The median age of survival in the United States is projected at 37 years for females and 40 years for males; mortality has decreased by 1.8% per year from 2000 to 2010.

Pathophysiology

CF is a multiorgan disease that affects the lungs, digestive tract (see Chapter 37), and reproductive organs. The cystic fibrosis transmembrane conductance regulator (CFTCR) gene mutation results in the abnormal expression of cystic fibrosis transmembrane conductance regulator (CFTCR) protein, which is an activated chloride channel present on the surface of many types of epithelial cells, including those lining airways, bile ducts, pancreas, sweat ducts, and vas deferens. The most important effects are on the lungs, and respiratory failure is almost always the cause of death. The typical features of CF lung disease are mucus plugging, chronic inflammation, and chronic infection of the small airways. The mucus plugging results from both increased production and altered physicochemical properties of the mucus. Mucus-secreting airway cells (goblet cells and submucosal glands) are increased in number and size. CF mucus is dehydrated and viscous because of defective chloride secretion and excess sodium absorption. The periciliary fluid layer is depleted in volume, impairing the mobility of the cilia and thereby allowing mucus to adhere to the airway epithelium, along with bacteria and injurious by-products from neutrophils. Neutrophils are present in great excess in the airways and release damaging oxidants and proteases (i.e., elastase) that cause direct damage to lung structural proteins, induce airway cells to produce interleukin-8 (IL-8) (which attracts more neutrophils and stimulates mucus secretion), and destroy immunoglobulin G (IgG) and complement components important for opsonization and phagocytosis of pathogens (Figure 28-7).
The CF airway microenvironment favors bacterial colonization. *Staphylococcus aureus* and *Haemophilus influenzae* are common in younger children and *Pseudomonas aeruginosa* ultimately colonizes airways in at least 75% of children with CF. Their biofilm resists beta-lactam antibiotics, and rapid mutation of the biofilm makes these children antibiotic resistant. Persistence of these microorganisms incites chronic local inflammation and airway damage with microabscess formation, bronchiectasis, patchy consolidation and pneumonia, peribronchial fibrosis, and cyst formation (Figure 28-8). Peripheral bullae may develop and pneumothorax may occur. Hemoptysis, sometimes life-threatening, may occur because of the erosion of enlarged bronchial arteries. Over time, pulmonary vascular remodeling occurs because of localized hypoxia and arteriolar vasoconstriction. Pulmonary hypertension and cor pulmonale may develop in the
late stages of disease.

**Clinical manifestations**

The most common presenting symptoms of CF are respiratory or gastrointestinal (see Chapter 37). Respiratory symptoms include persistent cough or wheeze, excessive sputum production, and recurrent or severe pneumonia. Physical signs
that develop over time include barrel chest and digital clubbing. More subtle presentations include chronic sinusitis and nasal polyps. Newborn screening for CF is universal throughout the United States and will increase the numbers of children provided early, presymptomatic diagnosis and treatment (see Health Alert: Newborn Screening for Cystic Fibrosis).

**Health Alert**

**Newborn Screening for Cystic Fibrosis**

Newborn screening for cystic fibrosis (CF) is now conducted in all 50 states in the United States and many other countries. The newborn screen for CF is a quantitative measure of immunoreactive trypsinogen (IRT) performed on a dried blood spot on a filter paper card. IRT is a pancreatic enzyme precursor that is persistently elevated in infants with CF. If a child is found to have an elevated IRT concentration, the next step is defined by state newborn screening protocols. Some states repeat the IRT level measurement, whereas others proceed to genetic testing for common mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. If the secondary testing is suggestive of a diagnosis of CF, the child is then referred to a Cystic Fibrosis Center for further evaluation and confirmatory sweat chloride testing. Research suggests that early diagnosis of CF has favorable effects on outcome. Children who are diagnosed with CF in infancy have improved nutritional outcomes compared to children who are diagnosed later in life. Establishing good nutrition in infants with CF has been correlated with improved lung function later in life. It is these improved clinical outcomes that have led the Centers for Disease Control and Prevention to support universal screening for CF.

**Evaluation and treatment**

The standard method of diagnosis (screening) are the immunoreactive trypsinogen (IRT) blood test and the sweat test, which reveal sweat chloride concentration in excess of 60 mEq/L. Alternative or supplemental methods include genotyping for CFTR mutations. Newborn screening for CF is universal in the United States. Treatment is primarily focused on pulmonary health and nutrition (see Chapter 37). Common pulmonary therapies include techniques to promote mucus clearance,
such as chest physical therapy and related mechanical devices; use of bronchodilators; and administration of aerosolized dornase alfa and hypertonic saline, which liquefy mucus. Oral, inhaled, or intravenous antibiotics are used to treat exacerbations of pulmonary infection. Different classes of antibiotics are used to treat different pathogens and to overcome antibiotic resistance. Recombinant human growth hormone has been shown to improve lung function, height, and weight in children with severe CF. Individuals with end-stage lung disease may consider lung transplantation. Newer approaches to gene therapy are being explored including mutation-specific targets.
Sudden Infant Death Syndrome (SIDS)

Sudden infant death syndrome (SIDS)/sudden unexpected infant death remains a disease of unknown cause and is the most common cause of unexplained infant death in Western countries. It is defined as “sudden death of an infant under 1 year of age which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history.”

The incidence of SIDS is low during the first month of life with the peak incidence at 2 to 4 months of age. It is unusual after 6 months of age. The incidence of SIDS in the United States is about 3500 deaths per year. SIDS almost always occurs during nighttime sleep, when infants are least likely to be observed. A seasonal variation has been noted, with higher frequencies during the winter months. This has been related to a higher rate of respiratory tract infections during those months, and such infections are often reported to have preceded the death. The sleeping room also may be overheated or the infant overwrapped.

Clinical risk groups are summarized in Risk Factors: Sudden Infant Death Syndrome (SIDS). About 75% of all SIDS victims have no known predisposing clinical risk factor. SIDS rates decreased where massive public campaigns warned against prone sleeping for infants (e.g., the Back-to-Sleep campaign).

Risk Factors

Sudden Infant Death Syndrome (SIDS)

- Prone and side-lying sleeping positions
- Sleeping on soft bedding
- Overheated sleeping environment
- Lower socioeconomic status
- Mothers younger than 20
- Blacks, Native Americans, Alaska Natives
- Low birth weight or growth restricted infants
• Male infants
• Preterm delivery
• Multiple gestations
• Sibling who died of SIDS
• Smoking during pregnancy
• Exposure to tobacco smoke
• Lack of prenatal care
• Illicit drug use or binge-drinking
• Larger family size

The etiology of SIDS remains unknown but probably involves a combination of predisposing factors, including a vulnerable infant and environmental stressors. There has been long-standing interest in hypotheses involving impaired autonomic regulation and failure of cardiovascular, ventilatory, and arousal responses to hypoxemia or hypercapnia. There also is a potential relationship between SIDS, auditory function, and central chemosensitivity to CO$_2$.\textsuperscript{96,97}

Alternative theories involve airway obstruction events, such as control of tongue movements related to inspiratory activity, increased vagal tone, sudden intrapulmonary shunting because of abnormalities of surfactant or pulmonary vessels, exaggerated inflammation, or exaggerated inflammation in response to bacterial pathogens from the nasopharynx or viral respiratory tract infections.\textsuperscript{98} Genetic factors may predispose certain individuals to SIDS. The most important risk factor genes include those involved in the regulation of the immune system, cardiac abnormalities, and brainstem function.\textsuperscript{99-102}

Currently, the best strategies for reducing SIDS seem to be avoidance of all the controllable risk factors. Parents of infants with clinical risk should be taught cardiopulmonary resuscitation (CPR) as a precaution. Home monitoring has not been demonstrated to decrease the incidence of SIDS, and more research is needed.\textsuperscript{103} Some at-risk infants may warrant cardiorespiratory monitoring after
careful consideration of the individual situation.

Quick Check 28-5

1. How are the alveoli and capillaries affected by the inflammation of acute respiratory distress syndrome (ARDS)?

2. What aspects of lung disease in cystic fibrosis are the focus of current therapies?

3. What are the risk factors for SIDS?
Did You Understand?

Disorders of the Upper Airways

1. Croup is an acute laryngotracheobronchitis, usually caused by parainfluenza virus. This infection causes swelling of the upper trachea. The typical sign is a seal-like barking cough, which appears after a few days of rhinorrhea, sore throat, and low-grade fever.

2. Spasmodic croup is characterized by a similar barking cough but occurs in older children, is of sudden onset at night and without fever, and has unknown etiology.

3. Acute epiglottitis is a potentially life-threatening airway infection whose incidence in children has decreased dramatically since the advent of *H. influenzae* vaccine. Now other pathogens, such as group A beta-hemolytic *Streptococcus*, *Candida* species, *S. aureus*, MRSA, or viral pathogens, are usually the causative agents.

4. Tonsillar infections are usually caused by group A beta-hemolytic *Streptococcus* and can be complicated by tonsillar abscesses.

5. Aspiration of foreign bodies that lodge in the airways may cause cough, hoarseness, stridor or wheezing, and dyspnea. The severity depends on the location of the foreign body within the airway and the degree of obstruction. Blockage of the larynx or trachea can be fatal, whereas bronchial obstruction may not be diagnosed immediately.

6. Obstructive sleep apnea syndrome (OSAS) is defined by partial or intermittent upper airway obstruction during sleep with disruption of normal ventilation and normal sleep patterns.

Disorders of the Lower Airways

1. Respiratory distress syndrome (RDS) of the newborn usually occurs in premature infants who are born before surfactant production and alveolocapillary development are complete. Atelectasis and hypoventilation cause shunting, hypoxemia, and hypercapnia. Prenatal steroids and postnatal surfactant are beneficial preventive therapies.
2. Bronchopulmonary dysplasia (BPD) is the result of tissue injury and repair and disrupted alveolar development in the lungs of infants who required ventilatory support during a time when their lungs were underdeveloped because of their prematurity. Surfactant therapy has improved outcomes. Infants with BPD may require oxygen and additional therapies for many months.

3. Bronchiolitis is a viral lower respiratory tract infection that presents with runny nose, wheezing, cough, and tachypnea in infants and is usually caused by infection with respiratory syncytial virus (RSV). Infants with risk factors of prematurity or underlying lung or heart disease are at high risk and may receive RSV-specific monoclonal antibody to prevent RSV disease.

4. Viral pneumonia and bacterial pneumonia cause varying degrees of illness in children and viral pneumonia is the most common and frequently precedes bacterial pneumonia. Community-acquired bacterial pneumonia is one of the leading causes of hospitalization and is prevented with polyvariant pneumococcal conjugate vaccine.

5. Aspiration pneumonitis is caused by inhalation of a foreign substance, such as food, milk, secretions, or environmental compounds, into the lung, and results in inflammation.

6. Bronchiolitis obliterans is a rare postinflammatory condition in which the bronchioles and some small bronchi are partially or completely obliterated by fibrous tissue, causing pulmonary impairment and disability.

7. Asthma is a chronic inflammatory disease characterized by bronchial hyperreactivity and reversible airflow obstruction, and is usually a type I hypersensitivity response to an antigen. Its origins are multifactorial, including genetic, allergic, and viral-triggered mechanisms.

8. Acute respiratory distress syndrome (ARDS) results from acute lung injury and can occur when there is an insult to the lung that activates an inflammatory response causing alveolar capillary injury, usually within 24 hours. There is progressive respiratory distress with severe hypoxemia and respiratory failure.

9. Cystic fibrosis is an autosomal recessive genetic disease that affects the epithelial lining of many organ systems, especially the respiratory and gastrointestinal systems. Airway secretions are particularly thick and tenacious, and the airways develop chronic bacterial infection with pathogens such as Pseudomonas aeruginosa.
and *Staphylococcus aureus*. Chronic infection, plugged airways, and severe inflammation cause long-term lung damage and ultimately death. However, the prognosis is improving, and most children with CF now survive to adulthood.

**Sudden Infant Death Syndrome (SIDS)**

1. Sudden infant death syndrome is the leading cause of postnatal death for infants outside of the hospital setting and is associated with low birth weight, prone sleeping position, and other environmental factors. There has been a significant reduction in SIDS since widespread adoption of recommendations for supine positioning of infants during sleep.
Key Terms

Acute epiglottitis, 717
Acute respiratory distress syndrome (ARDS), 725
Aspiration pneumonitis, 723
Asthma, 723
Atypical pneumonia (*Mycoplasma pneumoniae, Chlamydia pneumoniae*), 723
Bacterial pneumonia, 722
Bacterial tracheitis (pseudomembranous croup), 717
Bronchiolitis, 721
Bronchiolitis obliterans (BO), 723
Bronchopulmonary dysplasia (BPD), 720
Croup, 715
Cystic fibrosis (CF), 725
Cystic fibrosis transmembrane conductance regulator (CFTR) protein, 725
Obstructive sleep apnea syndrome (OSAS), 717
Peritonsillar abscess, 717
Pneumonia, 722
Respiratory distress syndrome (RDS) of the newborn, 718
Sudden infant death syndrome (SIDS)/sudden unexpected infant death, 726
Tonsillar abscess, 717
Tonsillar infections, 717
Upper airway obstruction, 715

Viral pneumonia, 722

</table>
The primary function of the kidney is to maintain a stable internal environment for optimal cell and tissue metabolism. The kidneys accomplish these life-sustaining tasks by balancing solute and water transport, excreting metabolic waste products, conserving nutrients, and regulating acids and bases. The kidney also has an endocrine function and secretes the hormones renin, erythropoietin, and 1,25-dihydroxy-vitamin D₃ for regulation of blood pressure, erythrocyte production, and calcium metabolism, respectively. The kidney also can release glucose into the circulation by the processes of glycogenolysis and gluconeogenesis. The formation of urine is achieved through the processes of glomerular filtration, tubular reabsorption, and secretion within the kidney. The bladder stores the urine received from the kidney by way of the ureters. Urine is then released from the bladder through the urethra.
**Structures of the Renal System**

**Structures of the Kidney**

The *kidneys* are paired organs located in the posterior region of the abdominal cavity behind the peritoneum. They lie on either side of the vertebral column with their upper and lower poles extending from the twelfth thoracic vertebra to the third lumbar vertebra (*Figure 29-1*). The right kidney is slightly lower and is displaced downward by the overlying liver. Each kidney is approximately 11 cm long, 5 to 6 cm wide, and 3 to 4 cm thick. A tightly adhering capsule (the *renal capsule*) surrounds each kidney, which is embedded in a mass of perirenal fat. The capsule and fatty layer are covered with a double layer of *renal fascia* composed of fibrous tissue. The cushion of adipose tissue (paranephric fat) and the position of the kidney between the abdominal organs and muscles of the back protect it from trauma. The *hilum* is a medial indentation in the kidney and is the location of the entry and exit for the renal blood vessels, nerves, lymphatic vessels, and ureter.

![Figure 29-1 Organs of the Urinary System. (From Patton KT, Thibodeau GA: The human body in health & disease, ed 6, St Louis, 2014, Mosby.](image)

The structures of the kidney are summarized in *Figure 29-2*. The outer layer of
The kidney is called the **cortex** and contains all of the glomeruli, most of the proximal tubules, and some segments of the distal tubule. The **medulla** forms the inner part of the kidney and consists of regions called **pyramids**. **Renal columns** are an extension of the cortex and extend between the pyramids to the renal pelvis. The pyramids extend into the renal pelvis and contain the loops of Henle and collecting ducts. The **minor and major calyces** are chambers receiving urine from the collecting ducts and form the entry into the renal pelvis, which is an extension of the upper ureter. The structural unit of the kidney is the lobe. Each **lobe** is composed of a pyramid and the overlying cortex. There are about 14 to 18 lobes in each kidney.

**FIGURE 29-2  Internal Structure of the Kidney.** (From Solomon E: Introduction to human anatomy and physiology, ed 4, St. Louis, 2016, Saunders.)

**Nephron**

The **nephron** is the functional unit of the kidney. Each kidney contains approximately 1.2 million nephrons. The nephron is a tubular structure with subunits that include the renal corpuscle, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting duct, all of which contribute to the
formation of final urine (Figure 29-3). The different structures of the epithelial cells lining various segments of the tubule facilitate the special functions of secretion and reabsorption (Figure 29-4).
FIGURE 29-3  Components of the Nephron.  (From Patton KT, Thibodeau GA, Douglas MM: Essentials of anatomy & physiology, St Louis, 2012, Mosby; Damjanov I: Pathology for the health professions, ed 4, St Louis, 2012, Mosby)
The kidney has three kinds of nephrons: (1) superficial **cortical nephrons** (85% of all nephrons), which extend partially into the medulla; (2) **midcortical nephrons** with short or long loops; and (3) **juxtamedullary nephrons** (about 12% of nephrons), which lie close to and extend deep into the medulla (about 40 mm) and are important for the concentration of urine (Figure 29-5). The **glomerulus** is a tuft of capillaries that loop into **Bowman capsule (Bowman space)**, like fingers pushed into bread dough. **Mesangial cells** (shaped like smooth muscle cells) secrete the **mesangial matrix** (a type of connective tissue) and lie between and support the capillaries (Figure 29-6). Mesangial cells also have phagocytic abilities similar to monocytes, release inflammatory cytokines, and can contract to regulate glomerular capillary blood flow. The **glomerulus, Bowman capsule, and mesangial cells are called the renal corpuscle.**
FIGURE 29-5  Nephron Unit with Its Blood Vessels. Blood flows through nephron vessels as follows: interlobular artery, afferent arteriole, glomerulus, efferent arteriole, peritubular capillaries (around the tubules), venules, interlobular vein. (From Patton KT, Thibodeau GA, Douglas MM: Essentials of anatomy & physiology, St Louis, 2012, Mosby)
The **glomerular filtration membrane** filters blood components through its three layers: (1) an inner capillary endothelium, (2) a middle basement membrane, and (3) an outer layer of capillary epithelium. The capillary endothelium is composed of cells in continuous contact with the basement membrane and contains pores. The middle basement membrane is a selectively permeable network of glycoproteins and mucopolysaccharides. The epithelium has specialized cells called **podocytes** from which pedicles (foot projections) radiate and adhere to the basement membrane. The pedicles interlock with the pedicles of adjacent podocytes, forming an elaborate network of intercellular clefts (**filtration slits**, or slit membranes). The endothelium, basement membrane, and podocytes are covered with protein molecules bearing anionic (negative) charges that retard the filtration of anionic proteins and prevent proteinuria. The glomerular filtration membrane separates the blood of the glomerular capillaries from the fluid in Bowman space and allows all components of the blood to be filtered, with the exception of blood cells and plasma proteins with a molecular weight greater than 70,000. The glomerular filtrate passes
through the three layers of the glomerular membrane and forms the primary urine. The glomerulus is supplied by the afferent arteriole and drained by the efferent arteriole. A group of specialized cells known as juxtaglomerular cells (renin-releasing cells) are located around the afferent arteriole where it enters the glomerulus (see Figure 29-3). Between the afferent and efferent arterioles is the macula densa (sodium-sensing cells) of the distal tubule (see Figure 29-6). Together the juxtaglomerular cells and macula densa cells form the juxtaglomerular apparatus (see Figure 29-3). Control of renal blood flow, glomerular filtration, and renin secretion occurs at this site.\(^2\)

The proximal convoluted tubule continues from Bowman space and has an initial convoluted segment (pars convoluta) and then a straight segment (pars recta) that descends toward the medulla (see Figure 29-3). The wall of the proximal tubule consists of one layer of cuboidal epithelial cells with a surface layer of microvilli (a brush border) that increases reabsorptive surface area. This is the only surface inside the nephron where the cells are covered with a brush border of microvilli (see Figure 29-4). The proximal convoluted tubule joins the loop of Henle, which extends into the medulla. The cells of the thick segment are cuboidal and actively transport several solutes, but not water. The thin ascending segment of the loop of Henle narrows and is composed of thin squamous cells with no active transport function.

The distal tubule has straight and convoluted segments. It extends from the macula densa to the collecting duct, a large tubule that descends down the cortex and through the renal pyramids of the inner and outer medullae, draining urine into the minor calyx. In the distal tubule principal cells reabsorb sodium and secrete potassium, and intercalated cells secrete hydrogen and reabsorb potassium and bicarbonate.

**Blood Vessels of the Kidney**

The blood vessels of the kidney closely parallel nephron structure. The major vessels are as follows:

1. **Renal arteries** arise as the fifth branches of the abdominal aorta, divide into anterior and posterior branches at the renal hilum, and then subdivide into lobar arteries supplying blood to the lower, middle, and upper thirds of the kidney.

2. **Interlobar artery** subdivisions travel down renal columns and between pyramids and form afferent glomerular arteries.

3. **Arcuate arteries** consist of branches of interlobar arteries at the cortical-
medullary junction; they arch over the base of the pyramids and run parallel to the surface.

4. **Glomerular capillaries** consist of four to eight vessels and are arranged in a fistlike structure; they arise from the **afferent arteriole** and empty into the **efferent arteriole**, which carries blood to the peritubular capillaries. They are the major resistance vessels for regulating intrarenal blood flow (see *Autoregulation of Intrarenal Blood Flow*, p. 735).

5. **Peritubular capillaries** surround convoluted portions of the proximal and distal tubules and the loop of Henle; they are adapted for cortical and juxtamedullary nephrons.

6. **Vasa recta** is a network of capillaries that forms loops and closely follow the loops of Henle; it is the only blood supply to the medulla (important for formation of concentrated urine).

7. **Renal veins** follow the arterial path in reverse direction and have the same names as the corresponding arteries; they eventually empty into the inferior vena cava. The lymphatic vessels also tend to follow the distribution of the blood vessels.

Quick Check 29-1

1. What is the major structural difference between the cortex and medulla of the kidney?

2. What is the function of the nephron?

3. Why are proteins not filtered at the glomerulus?

**Urinary Structures**

**Ureters**

The urine formed by the nephrons flows from the distal tubules and collecting ducts through the papillary ducts to the **renal papillae** (projections of the ducts) into the calyces, where it is collected in the renal pelvis (see **Figures 29-2** and **29-5**), and then funneled into the **ureters**. Each adult ureter is approximately 30 cm long and is composed of long, intertwining smooth muscle bundles. The lower ends pass obliquely through the posterior aspect of the bladder wall. The close approximation
of smooth muscle cells permits the direct transmission of electrical stimulation from one cell to another. The resulting downward peristaltic contraction from intrinsic pacemaker activity propels urine into the bladder. Contraction of the bladder during \textit{micturition} (urination) compresses the lower end of the ureter, preventing reflux. Peristalsis is maintained even when the ureter is denervated, so ureters can be transplanted.

Sensory innervation for the upper part of the ureter arises from sympathetic inputs from the tenth thoracic nerve roots, with referred pain to the umbilicus. The innervation of lower segments arises from the parasympathetic sacral nerves, with referred pain to the vulva or penis. The ureters have a rich blood supply. The primary arteries come from the kidney, with contributions from the lumbar and superior vesical arteries.

\textbf{Bladder and Urethra}

The \textbf{bladder} is a bag of smooth muscle fibers that forms the \textit{detrusor muscle} and its smooth lining of uroepithelium. As the bladder fills with urine, it distends and the layers of uroepithelium within the lining slide past each other and become thinner as bladder volume increases. The uroepithelium forms the interface between the urinary space and the underlying vasculature and connective, nervous, and muscle tissue. Uroepithelium also lines the urinary tract from the renal pelvis to the urethra. The uroepithelium maintains an important barrier function to prevent movement of water and solutes between the urine and the blood. It communicates information about urine pressure and composition to surrounding nerve and muscle cells.\textsuperscript{3} The \textbf{trigone} is a smooth triangular area between the openings of the two ureters and the urethra (\textit{Figure 29-7}). The position of the bladder varies with age and sex. The bladder has a profuse blood supply, accounting for the bleeding that readily occurs with trauma, surgery, or inflammation.
The urethra extends from the inferior side of the bladder to the outside of the body. A ring of smooth muscle forms the internal urethral sphincter at the junction of the urethra and bladder. The external urethral sphincter is composed of striated skeletal muscle and is under voluntary control. The entire urethra is lined with mucus-secreting glands. The female urethra is short (3 to 4 cm). The male urethra is long (18 to 20 cm) and has three main segments: prostatic, membranous, and penile. The prostatic urethra is closest to the bladder. It passes through the prostate gland and contains the openings of the ejaculatory ducts. The membranous urethra passes through the floor of the pelvis. The penile segment forms the remainder of the tube. It is surrounded by the corporal spongiosum erectile tissue and contains the openings of the bulbourethral mucous glands.

The innervation of the bladder and internal urethral sphincter is supplied by parasympathetic fibers of the autonomic nervous system. The reflex arc required for micturition is stimulated by mechanoreceptors that respond to stretching of tissue, sensing bladder fullness and sending impulses to the sacral level of the cord.
When the bladder accumulates 250 to 300 ml of urine, the bladder contracts and the internal urethral sphincter relaxes through activation of the spinal reflex arc (known as the *micturition reflex*). At this time, a person feels the urge to void. The reflex can be inhibited or facilitated by impulses coming from the brain, resulting in voluntary control of micturition by the relaxation or contraction of the external sphincter.
Renal Blood Flow

The kidneys are highly vascular organs and usually receive 1000 to 1200 ml of blood per minute, or about 20% to 25% of the cardiac output. With a normal hematocrit of 45%, about 600 to 700 ml of blood flowing through the kidney per minute is plasma. From the renal plasma flow (RPF), 20% (approximately 120 to 140 ml/min) is filtered at the glomerulus and passes into Bowman capsule. The filtration of the plasma per unit of time is known as the glomerular filtration rate (GFR), which is directly related to the perfusion pressure of the glomerular capillaries.

The remaining 80% (about 480 ml/min) of plasma flows through the efferent arterioles to the peritubular capillaries. The ratio of glomerular filtrate to renal plasma flow per minute \( \frac{125}{600} = 0.20 \) is called the filtration fraction. Normally all but 1 to 2 ml/min of the glomerular filtrate is reabsorbed from nephron tubules and returned to the circulation by the peritubular capillaries.

The GFR is directly related to renal blood flow (RBF), which is regulated by intrinsic autoregulatory mechanisms, by neural regulation, and by hormonal regulation. In general, blood flow to any organ is determined by the arteriovenous pressure differences across the vascular bed. If mean arterial pressure decreases or vascular resistance increases, RBF declines and urinary output decreases. Normal urinary output is about 30 ml/hour minimum in adults or 0.5 to 1.0 ml/kg/hr.

Autoregulation of Intrarenal Blood Flow

In the kidney, a local mechanism tends to keep the rate of glomerular perfusion and therefore the GFR fairly constant over a range of arterial pressures between 80 and 180 mm Hg (Figure 29-8). Changes in afferent arteriolar resistance occur in the same direction. Therefore, RBF and GFR are relatively constant, a relationship maintained by an intrinsic autoregulatory myogenic mechanism of contraction when blood vessels are stretched. The purpose of autoregulation of intrarenal blood flow is to keep RBF and GFR constant when there are increases or decreases in systemic blood pressure. Solute and water excretion, and thus blood volume, are regulated despite arterial pressure changes.\(^4\)
A second mechanism of autoregulation is **tubuloglomerular feedback**. Because the glomerular filtration rate in an individual nephron increases or decreases, the macula densa cells in the distal tubule sense the increasing or decreasing amounts of filtered sodium. When GFR and sodium concentration increase, the macula densa cells stimulate afferent arteriolar vasoconstriction and decrease GFR. The opposite occurs with decreases in GFR and sodium concentration at the macula densa. This mechanism prevents large fluctuations in body water and salt.\(^5\)

**Neural Regulation of Renal Blood Flow**

The blood vessels of the kidney are innervated by sympathetic nerve fibers located primarily on afferent arterioles. When systemic arterial pressure decreases, increased renal sympathetic nerve activity is mediated reflexively through the carotid sinus and the baroreceptors of the aortic arch. The sympathetic nerves release catecholamines. This stimulates afferent renal arteriolar vasoconstriction and decreases RBF and GFR, increases renal tubular sodium and water reabsorption, and increases blood pressure. Decreased afferent renal sympathetic nerve activity produces the opposite effects. The integrated response regulates water
and sodium balance. Renalase is a hormone released by the kidney and heart that promotes the metabolism of catecholamines and in this way participates in blood pressure regulation.\(^6\) The sympathetic nervous system also participates in hormonal (i.e., angiotensin II) regulation of renal blood flow. There is no significant parasympathetic innervation. The innervation of the kidney arises primarily from the celiac ganglion and greater splanchnic nerve.

**Hormones and Other Factors Regulating Renal Blood Flow**

Hormones and other mediators can alter the resistance of the renal vasculature by stimulating vasodilation or vasoconstriction. A major hormonal regulator of renal blood flow is the renin-angiotensin-aldosterone system (RAAS), which can increase systemic arterial pressure and change RBF. Renin is an enzyme formed and stored in the cells of the arterioles of the juxtaglomerular apparatus (see Figure 29-3). Renin release is triggered by decreased blood pressure in the afferent arterioles, decreased sodium chloride concentration in the distal convoluted tubule, sympathetic nerve stimulation of β-adrenergic receptors on the juxtaglomerular cells, and the release of prostaglandins.\(^7\) Numerous physiologic effects of the RAAS stabilize systemic blood pressure and preserve the extracellular fluid volume during hypotension or hypovolemia. Actions include sodium reabsorption, systemic vasoconstriction, sympathetic nerve stimulation, and thirst stimulation with increased fluid intake. The effects of aldosterone combine with those of antidiuretic hormone in regulating blood volume are summarized in Figure 29-9 (also see Figures 5-4 and 18-18).
FIGURE 29-9 Cooperative Roles of Antidiuretic Hormone (ADH) and Aldosterone in Regulating Urine and Plasma Volume. The drop in blood pressure that accompanies loss of fluid from the internal environment triggers the hypothalamus to rapidly release ADH from the posterior pituitary gland. ADH increases water reabsorption by the kidney by increasing water permeability of the distal tubules and collecting ducts. The drop in blood pressure also is detected by each nephron's juxtaglomerular apparatus, which responds by secreting renin. Renin triggers the formation of angiotensin II, which stimulates release of aldosterone from the adrenal cortex. Aldosterone then slowly boosts water reabsorption by the kidneys by increasing reabsorption of Na⁺. Because angiotensin II also stimulates secretion of ADH, it serves as an additional link between the ADH and aldosterone mechanisms. (From Patton KT, Thibodeau GA. Anatomy & physiology, ed 9, St Louis, 2016, Mosby.)

Natriuretic peptides are synthesized and released from the heart and are natural antagonists to the renin-angiotensin-aldosterone system. Natriuretic peptides cause vasodilation and increase sodium and water excretion and decrease blood pressure (see p. 741). They assist in protecting the heart from volume overload. *Urodilatin* is renal natriuretic peptide produced by cells in the distal tubule and collecting duct. It increases renal blood flow, causing diuresis.

Kidney Function

Nephron Function

The nephron can perform many functions simultaneously (Figure 29-10), as follows:

1. Filters plasma at glomerulus.
2. Reabsorbs and secretes different substances along tubular structures.
3. Forms a filtrate of protein-free fluid (ultrafiltration).
4. Regulates the filtrate to maintain body fluid volume, electrolyte composition, and pH within narrow limits.

**Glomerular filtration** is the movement of fluid and solutes across the glomerular
capillary membrane into the Bowman space. **Tubular reabsorption** is the movement of fluids and solutes from the tubular lumen to the peritubular capillary plasma. **Tubular secretion** is the transfer of substances from the plasma of the peritubular capillary to the tubular lumen. The transport mechanisms are both active and passive (processes defined in Chapter 1). **Excretion** is the elimination of a substance in the final urine (Figure 29-11).
Glomerular Filtration

The fluid filtered by the glomerular capillary filtration membrane and released into the proximal convoluted tubule is protein free but contains electrolytes (such as sodium, chloride, and potassium) and organic molecules (such as creatinine, urea, and glucose) in the same concentrations as found in plasma. Like other capillary membranes, the glomerulus is freely permeable to water and relatively
impermeable to large colloids, such as plasma proteins. The molecule's size and electrical charge and the small size of the filtration slits in the glomerular epithelium affect the permeability of substances crossing the glomerulus and entering the proximal convoluted tubule.

Capillary pressures also affect glomerular filtration. The hydrostatic pressure within the capillary is the major force for moving water and solutes across the filtration membrane and into Bowman capsule. Two forces oppose the filtration effects of the glomerular capillary hydrostatic pressure ($P_{GC}$): (1) the hydrostatic pressure in Bowman space ($P_{BC}$) and (2) the effective oncotic pressure of the glomerular capillary blood ($\pi_{GC}$). Because the fluid in Bowman space normally contains only minute amounts of protein, it does not usually have an oncotic influence on the plasma of the glomerular capillary (Figure 29-12).
The combined effect of forces favoring and forces opposing filtration determines the filtration pressure. The **net filtration pressure (NFP)** is the sum of forces favoring and opposing filtration. The estimated values contributing to the forces of net filtration are presented in **Table 29-1**.

As the protein-free fluid is filtered into Bowman capsule, the plasma oncotic pressure increases and the hydrostatic pressure decreases. The increase in glomerular capillary oncotic pressure is great enough to reduce the net filtration pressure to zero at the efferent end of the capillary and to stop the filtration process effectively. The low hydrostatic pressure and the increased oncotic pressure in the efferent arteriole then are transferred to the peritubular capillaries and facilitate reabsorption of fluid from the proximal convoluted tubules.

**Filtration rate.**

The total volume of fluid filtered by the glomeruli averages 180 L/day, or approximately 120 ml/min, a phenomenal amount considering the size of the kidneys. Because only 1 to 2 L of urine is excreted per day, 99% of the filtrate is reabsorbed into the peritubular capillaries and returned to the blood. The factors determining the GFR are directly related to the pressures that favor or oppose filtration (see Figure 29-12 and Table 29-1).

Obstruction to the outflow of urine (caused by strictures, stones, or tumors along the urinary tract) can cause a retrograde increase in hydrostatic pressure at Bowman space and a decrease in GFR. Low levels of plasma protein in the blood can result in a decrease in glomerular capillary oncotic pressure, which increases GFR. Excessive loss of protein-free fluid from vomiting, diarrhea, use of diuretics, or excessive sweating can increase glomerular capillary oncotic pressure and decrease the GFR. Renal disease also can cause changes in pressure relationships by altering capillary permeability and the surface area available for filtration (see Chapter 30).

**Proximal convoluted tubule.**

By the end of the proximal tubule, approximately 60% to 70% of filtered sodium and water and about 50% of urea have been actively reabsorbed, along with 90% or more of potassium, glucose, bicarbonate, calcium, phosphate, amino acids, and uric
acid. Chloride, water, and urea are reabsorbed passively but linked to the active transport of sodium (a cotransport mechanism). For some molecules, active transport in the renal tubules is limited as the carrier molecules become saturated, a phenomenon known as transport maximum ($T_m$). For example, when the carrier molecules for glucose reabsorption in the proximal convoluted tubule become saturated (i.e., with the development of hyperglycemia), the excess will be excreted in the urine.

**Proximal convoluted tubule.**

Active reabsorption of sodium is the primary function of the proximal convoluted tubule. Water, most other electrolytes, and organic substances are cotransported with sodium. The osmotic force generated by active sodium transport promotes the passive diffusion of water out of the tubular lumen and into the peritubular capillaries. Passive transport of water is further enhanced by the elevated oncotic pressure of the blood in the peritubular capillaries, which is created by the previous filtration of water at the glomerulus. The reabsorption of water leaves an increased concentration of urea within the tubular lumen, creating a gradient for its passive diffusion to the peritubular plasma. As the positively charged sodium ions leave the tubular lumen, negatively charged chloride ions passively follow to maintain electroneutrality. Because the inner membrane of the proximal tubular cell has a limited permeability to chloride, chloride reabsorption lags behind sodium.

Hydrogen ions are actively exchanged for sodium ions in the tubular lumen. The hydrogen ions ($H^+$) then combine with bicarbonate ($HCO_3^-$).

Bicarbonate is completely filtered at the glomerulus, and approximately 90% is reabsorbed in the proximal tubule. In the tubular lumen, hydrogen and bicarbonate ions form carbonic acid ($H_2CO_3$), which rapidly breaks down, or dissociates, to carbon dioxide ($CO_2$) and water ($H_2O$). These then diffuse into the tubular cell, where carbonic anhydrase again catalyzes the $CO_2$ and $H_2O$ to form $HCO_3^-$ and $H^+$. The $H^+$ is secreted again, and $HCO_3^-$ combines with sodium and is transported to the peritubular capillary blood as $NaHCO_3$ (a sodium bicarbonate buffer). Bicarbonate is thus conserved, and the hydrogen is reabsorbed as water. Therefore, these ions normally do not contribute to the urinary excretion of acid or the addition of acid to the blood.

In addition to the proximal tubular secretion of hydrogen ions, secretory transport mechanisms exist for creatinine, other organic bases, and endogenous and exogenous organic acids including para-aminohippurate (PAH) and penicillin (Box 29-1). These secretory mechanisms eliminate drugs and other exogenous chemical
products from the body, often after first conjugating them with sulfate and glucuronic acid in the liver. Many drugs and their metabolites are eliminated from the body in this way. When the renal tubules are damaged, metabolic by-products and drugs may accumulate, causing toxic levels in the body.

Normally, 99% of the glomerular filtrate is reabsorbed. When the GFR spontaneously decreases or increases, the renal tubules, primarily the proximal tubules, automatically adjust their rate of reabsorption of sodium and water to balance the change in GFR. This prevents wide fluctuations in the excretion of sodium and water into the urine and is known as glomerulotubular balance.

Loop of henle and distal convoluted tubule.

Urine can be hypotonic, isotonic, or hypertonic. Urine concentration or dilution occurs principally in the loop of Henle, distal tubules, and collecting ducts. The structural features of the medullary hairpin loops allow the kidney to concentrate urine and conserve water for the body. The transition of the filtrate into the final urine reflects the concentrating ability of the loops. Final adjustments in urine composition are made by the distal tubule and collecting duct according to body needs.

Production of concentrated urine involves a countercurrent exchange system, in which fluid flows in opposite directions through the parallel tubes of the loop of Henle. A concentration gradient causes fluid to be exchanged across the parallel pathways. The longer the loop, the greater the concentration gradient; the concentration gradient increases from the cortex to the tip of the medulla. The loops of Henle multiply the concentration gradient, and the vasa recta blood vessels act as a countercurrent exchanger for maintaining the gradient. The process is initiated in the thick ascending limb of the loop of Henle with the active transport of chloride.
and sodium out of the tubular lumen and into the medullary interstitium (Figure 29-13). Because the lumen of the ascending limb is impermeable to water, water cannot follow the sodium-chloride transport. This causes the ascending tubular fluid to become hypoosmotic and the medullary interstitium to become hyperosmotic. The descending limb of the loop, which receives fluid from the proximal tubule, is highly permeable to water but it is the only place in the nephron that does not actively transport either sodium or chloride. Sodium and chloride may, however, diffuse into the descending tubule from the interstitium. The hyperosmotic medullary interstitium causes water to move out of the descending limb, and the remaining fluid in the descending tubule becomes increasingly concentrated while it flows toward the tip of the medulla. While the tubular fluid rounds the loop and enters the ascending limb, sodium and chloride are removed and water is retained. The fluid then becomes more and more dilute as it encounters the distal tubule.

![FIGURE 29-13 Countercurrent Mechanism for Concentrating and Diluting Urine. A, Urine dilution; B, urine concentration. 1, Filtrate isotonic to plasma. 2, Descending thin limb permeable to water. 3, Ascending thin limb impermeable to water; permeable to ions. 4, Ascending thick limb actively transports NaCl; impermeable to water and urea. 5, Distal tubule actively resorbs NaCl; resorbs water in presence of antidiuretic hormone. 6, Medullary collecting duct actively resorbs NaCl, and slightly permeable to water and urea. (NOTE: Numbers on illustration represent milliosmoles [mOsm]). H2O, water; NaCl, sodium chloride. See text for details. (From Koeppen BM, Stanton BA: Berne and Levy physiology [updated], ed 6, St Louis, 2010, Mosby.)](image)

The slow rate of blood flow and the hairpin structure of the vasa recta blood vessels allow blood to flow through the medullary tissue without disturbing the osmotic gradient. When blood flows into the descending limb of the vasa recta, it encounters the increasing osmotic concentration gradient of the medullary interstitium. Water moves out and sodium and chloride diffuse into the descending vasa recta. The plasma becomes increasingly concentrated as it flows toward the tip of the medulla.

As blood flows away from the tip of the medulla and toward the cortex, the surrounding interstitial fluid becomes comparatively more dilute. Water then moves
back into the vasa recta, and sodium and chloride diffuse out and the plasma again becomes more dilute. The net result is a preservation of the medullary osmotic gradient. If blood were to flow rapidly through the vasa recta, as occurs in some renal diseases, the medullary concentration gradient would be washed away and the ability to concentrate urine and conserve water would be lost. The efficiency of water conservation is related to the length of the loops of Henle: the longer the loops, the greater the ability to concentrate the urine.

**Urea** is the major constituent of urine along with water. The glomerulus freely filters urea, and tubular reabsorption depends on urine flow rate, with less reabsorption at higher flow rates. Approximately 50% of urea is excreted in the urine, and 50% is recycled within the kidney. This recycling contributes to the osmotic gradient within the medulla and is necessary for the concentration and dilution of urine (see Figure 29-13). Because urea is an end product of protein metabolism, individuals with protein deprivation cannot maximally concentrate their urine.8

Another function of the loop of Henle is the production of **uromodulin** (also known as Tamm-Horsfall protein [THP]), the most abundant protein in human urine. This protein binds to uropathogens to prevent urinary tract infection, protects the uroepithelium from injury, protects against kidney stone formation and is associated with progression of kidney disease.9

The convoluted portion of the distal tubule is poorly permeable to water but readily reabsorbs ions and contributes to the dilution of the tubular fluid. The later, straight segment of the distal tubule and the collecting duct are permeable to water as controlled by antidiuretic hormone (ADH) released from the posterior pituitary gland. Sodium is readily reabsorbed by the later segment of the distal tubule and collecting duct under the regulation of the hormone aldosterone (see Chapter 18). Potassium is actively secreted in these segments and is also controlled by aldosterone and other factors related to the concentration of potassium in body fluids (see Chapter 5).

Hydrogen is secreted by the distal tubule and combines with nonbicarbonate buffers (i.e., ammonium and phosphate) for the elimination of acids in the urine (see Figure 5-11). The distal tubule thus contributes to the regulation of acid-base balance by excreting hydrogen ions into the urine and by adding new bicarbonate to the plasma. The mechanism is similar to the conservation of bicarbonate by the proximal tubule, except that the hydrogen ion is excreted in the urine and influences acid-base balance (see Figure 5-11). The specific mechanisms of acid-base balance and acid excretion are described in Chapter 5.

**Urine Composition**
Urine is normally clear yellow or amber in color. Cloudiness may indicate the presence of bacteria, cells, or high solute concentration. The pH ranges from 4.6 to 8.0, but it is normally acidic, providing protection against bacteria. Specific gravity ranges from 1.001 to 1.035. Normal urine does not contain glucose or blood cells and only occasionally contains traces of protein, usually in association with rigorous exercise.

**Hormones and Nephron Function**

**Antidiuretic Hormone**

The distal tubule in the cortex receives the hypoosmotic urine from the ascending limb of the loop of Henle. The concentration of the final urine is controlled by antidiuretic hormone (ADH), which is secreted from the posterior pituitary or neurohypophysis. ADH increases water permeability and reabsorption in the last segment of the distal tubule and along the entire length of the collecting ducts, which pass through the inner and outer zones of the medulla. The water diffuses into the ascending limb of the vasa recta and returns to the systemic circulation. The excreted urine can have a high osmotic concentration, up to 1400 mOsm. The volume is normally reduced to about 1% of the amount filtered at the glomerulus. (The mechanism for the regulation of ADH and plasma osmolality is described in Chapters 5 and 18.)

**Aldosterone**

Aldosterone is synthesized and secreted by the adrenal cortex under the regulation of the renin-angiotensin-aldosterone system (see Chapter 18, and the previous discussion of the renin-angiotensin-aldosterone system on p. 736). Aldosterone stimulates the epithelial cells of the distal tubule and collecting duct to reabsorb sodium (promoting water reabsorption) and increases the excretion of potassium and hydrogen ion.

**Natriuretic Peptides**

Natriuretic peptides are a group of peptide hormones, including atrial natriuretic peptide (ANP), secreted from myocardial cells in the atria, and brain natriuretic peptide (BNP), secreted from myocardial cells in the cardiac ventricles. When the heart dilates during volume expansion or heart failure, ANP and BNP inhibit sodium and water absorption by kidney tubules, inhibit secretion of renin and aldosterone, vasodilate the afferent arterioles, and constrict the efferent arterioles. The result is increased urine formation leading to a decrease in blood volume and blood
pressure. *C-type natriuretic peptide* is secreted from the vascular endothelium and causes vasodilation in the nephron. *Urodilatin* is secreted by the distal convoluted tubules and collecting ducts and causes vasodilation and natriuretic and diuretic effects.

### Diuretics as a Factor in Urine Flow

A **diuretic** is any agent enhancing the flow of urine. Clinically, diuretics interfere with renal sodium reabsorption and reduce extracellular fluid volume. Diuretics are commonly used to treat hypertension and edema caused by heart failure, cirrhosis, and nephrotic syndrome.

Diuretics are divided into five general categories: (1) osmotic diuretics, (2) carbonic anhydrase inhibitors (inhibitors of urinary acidification), (3) inhibitors of loop sodium or chloride transport, (4) aldosterone antagonists (potassium sparing), and (5) aquaretics. (The physiologic mechanism related to each category is summarized in Table 29-2.)

#### Renal Hormones

Certain hormones are either activated or synthesized by the kidney. These hormones have significant systemic effects and include urodilatin (see earlier text), the active form of vitamin D, and erythropoietin.
Vitamin D

Vitamin D is a hormone that can be obtained in the diet or synthesized by the action of ultraviolet radiation (sun exposure) on cholesterol in the skin. These forms of vitamin D₃ (cholecalciferol) are inactive and require two hydroxylations to establish a metabolically active form. The first step occurs in the liver and the second in the kidneys.

Vitamin D is necessary for the absorption of calcium and phosphate by the small intestine. The renal hydroxylation step is stimulated by parathyroid hormone (see Chapter 18). A decreased plasma calcium level (less than 10 mg/dl) stimulates the secretion of parathyroid hormone. Parathyroid hormone then stimulates a sequence of events to help restore plasma calcium concentration toward normal levels (9 to 10.5 mg/dl):

1. Calcium mobilization from bone
2. Synthesis of 1,25-dihydroxy-vitamin D₃
3. Absorption of calcium from the intestine
4. Increased renal calcium reabsorption
5. Decreased renal phosphate reabsorption

Serum phosphate concentration fluctuations also influence the renal hydroxylation of vitamin D. Decreased levels stimulate active 1,25-dihydroxy-vitamin D₃ formation, and increased levels inhibit formation. This results in compensatory changes in phosphate absorption from bone and intestine. Individuals with renal disease have a deficiency of 1,25-dihydroxy-vitamin D₃ (1,25-OH₂D₃) and manifest symptoms of disturbed calcium and phosphate balance (see Chapters 5, 18, and 30).

Erythropoietin

Erythropoietin (Epo) stimulates the bone marrow to produce red blood cells in response to tissue hypoxia and may have tissue protective effects¹¹ (see Health Alert: The Many Effects of Erythropoietin [Epo]). Erythrocyte production is discussed in Chapter 20. The stimulus for Epo release is decreased oxygen delivery in the kidneys. Oxygen-sensing erythropoietin-producing cells are peritubular fibroblasts located in the juxtamedullary cortex.¹² The anemia of chronic renal failure, in which kidney cells have become nonfunctional, can be related to the lack
of this hormone (see Chapter 30).

**Health Alert**

**The Many Effects of Erythropoietin (Epo)**

Receptors for Epo are found in many body cells other than hematopoietic cells (i.e., neurons, immune cells, cancer cell lines, endothelial cells, bone marrow myocardium, skeletal muscle, kidney cells, pancreatic cells, and cells of the reproductive system and gastrointestinal tract). Epo-related tissue protective effects include anti-apoptotic, anti-inflammatory, and angiogenic actions. In acute kidney injury, Epo reduces ischemia, oxidative stress, and inflammation, protecting cells from injury. These same effects, including angiogenesis, limit myocardial infarction size and left ventricular remodeling. Epo also is anti-inflammatory and inhibits inflammation in chronic inflammatory diseases. Epo is neuroprotective in conditions associated with hypoxia, neurodegeneration, and inflammation. Epo is used for the treatment of anemia in chronic kidney disease and anemia related to cancer chemotherapy. Studies are currently evaluating if the angiogenic and growth factor effects of Epo promote tumor growth.

**Quick Check 29-3**

1. Outline the process of glomerular filtration.

2. What types of absorption/reabsorption take place in the proximal tubule, the loops of Henle, and the distal tubule?

3. What is the countercurrent exchange system? What substances are involved?

4. What hormones are activated or synthesized by the kidney?

Kidney function changes throughout the life span and major changes are summarized in the boxes: *Pediatric Considerations: Pediatrics & Renal Function* and *Geriatric Considerations: Aging & Renal Function.*
Tests of Renal Function

Renal Clearance

A number of specific renal functions can be measured by renal clearance. Renal clearance techniques determine how much of a substance can be cleared from the blood by the kidneys per given unit of time. The application of this principle permits an indirect measure of GFR, tubular secretion, tubular reabsorption, and RBF.

Clearance and Renal Blood Flow

A clearance formula also can be used to estimate RPF and RBF using a molecule called para-aminohippuric acid (PAH). Some PAH is filtered at the glomerulus and most of the remainder is secreted into the tubules in one circulation through the kidney. If all the PAH were removed from the plasma during a single pass through the kidney, total RPF could be determined. Because the supporting and nonsecreting structures of the kidney receive 10% to 15% of the effective renal blood flow (ERBF), clearance of PAH measures only what is known as the effective renal plasma flow (ERPF), which is 85% to 90% of the true renal plasma flow.

Clearance and Glomerular Filtration Rate

The GFR provides the best estimate of functioning renal tissue and is important for assessing or monitoring kidney damage and drug dosing. Damage to the glomerular membrane or loss of nephrons leads to a corresponding decrease in GFR. The measurement of GFR requires the use of a substance that has a stable plasma concentration; is freely filtered at the glomerulus; is not secreted, reabsorbed, or metabolized by the tubules; and is easy to measure. Inulin (a fructose polysaccharide) is one substance that meets the criteria for measurement of GFR.

The accurate determination of inulin clearance requires constant infusion to maintain a stable plasma level. This is time-consuming and inconvenient. Therefore the clearance of creatinine, a natural substance produced by muscle and released into the blood at a relatively constant rate, is commonly used as an estimate clinically. It is freely filtered at the glomerulus, but a small amount is secreted by the renal tubules. Therefore creatinine clearance overestimates the GFR, but within tolerable limits. Creatinine clearance provides a good clinical measure of GFR because only one blood sample is required in addition to an accurately collected 24-hour volume of urine. Cystatin C is a stable protein in serum filtered at the glomerulus and metabolized in the tubules. Serum levels of cystatin C also are a marker for estimating GFR, particularly for mild to moderate impaired renal
function. A combined creatinine and cystatin C estimate of GFR was developed in 2012 and considers age, race, and sex.

Formulas are used to estimate GFR. The Cockcroft and Gault creatinine-based formula is commonly used and considers age, body weight, and plasma creatinine ($P_{cr}$) values: The National Kidney Foundation recommends the Modification of Diet in Renal Disease (MDRD) equation. The Chronic Kidney Disease Epidemiology Collaboration (2009 CKD-EPI) equation has been developed as a more precise estimate of GFR than the MDRD and considers age, sex, and race. In 2012, cystatin C and combined creatinine and cystatin C equations were developed. Calculators for estimates of GFR using these formulas are readily available on the Internet (see example at http://touchcalc.com/ip_epi_gfr/ip_ckd_epi). Normal GFR values are 90 to 120 ml/min.

### Plasma Creatinine Concentration

A chronic decline in the GFR over weeks or months is reflected in the plasma creatinine ($P_{cr}$) concentration (normal value = 0.7 to 1.2 mg/dl). The $P_{cr}$ concentration has a stable value when the GFR is stable, because creatinine has a constant rate of production as a product of muscle metabolism. The amount filtered is approximately equal to the amount excreted. When the GFR declines, the $P_{cr}$ increases proportionately. Thus the GFR and $P_{cr}$ are inversely related. If the GFR were to decrease by 50%, the filtration and excretion of creatinine would be reduced by 50% and creatinine would accumulate in plasma to twice the normal value. Therefore, elevated $P_{cr}$ values represent decreasing GFR. In the new steady state, however, the total amount of creatinine excreted in the urine would remain the same because of the proportionate decrease in GFR and increase in $P_{cr}$.

The application of this principle is simple and useful for monitoring progressive changes in renal function. The test is most valuable for monitoring the progress of chronic rather than acute renal disease because it takes 7 to 10 days for the plasma creatinine level to stabilize when GFR declines. Serial measures can be obtained over a long time and plotted as a curve of glomerular function. The $P_{cr}$ also becomes elevated during trauma or the breakdown of muscle tissue. In such instances, the value is then not useful for estimating GFR.

### Blood Urea Nitrogen

The concentration of urea nitrogen in the blood reflects glomerular filtration and urine-concentrating capacity. Because urea is filtered at the glomerulus, blood urea
nitrogen (BUN) levels increase as glomerular filtration drops. Because urea is reabsorbed by the blood through the permeable tubules, the BUN value rises in states of dehydration and with acute and chronic renal failure when passage of fluid through the tubules slows. BUN values also change as a result of altered protein intake and protein catabolism. The normal range for BUN level in the adult is 10 to 20 mg/dl of blood.

**Urinalysis**

*Urinalysis* is a noninvasive and relatively inexpensive diagnostic procedure. The best results are obtained from a fresh, cleanly voided specimen because decay permits changes in the composition of urine. Urinalysis includes evaluation of color, turbidity, protein, pH, specific gravity, sediment, and supernatant. Urine tests are listed in Table 29-3 and bladder function tests are listed in Table 29-4.

Pediatric Considerations

**Pediatrics & Renal Function**

Glomerular filtration rate in infants does not reach adult levels until 1 to 2 years of age, and newborns have a decreased ability to efficiently remove excess water and solutes. Their shorter loops of Henle also decrease concentrating ability and produce a more dilute urine than that produced by adults. Risks for metabolic acidosis are increased during the first few months of life while the mechanisms for excreting acid and retaining bicarbonate are maturing. These normal developmental processes result in a narrow safety margin for fluid and electrolyte balance when there is any disturbance such as diarrhea, infection, fever, fasting for diagnostic tests, improper feeding, fluid replacement, or drug administration. Newborns diurese 2 to 3 days after birth, which is reflected by a decrease in total body water and body weight. An increased risk of toxicity accompanies drug administration. Low birth weight infants have a delay in achieving full renal function and may not have full GFR until 8 years of age. They also are at greater risk for low nephron numbers and chronic kidney disease as adults.

Geriatric Considerations

Aging & Renal Function

• Structural changes commonly occur in the kidney with aging, including loss of renal mass, arterial sclerosis, an increased number of sclerotic glomeruli, loss of tubules, and interstitial fibrosis. These changes contribute to a slow decline in GFR and a reduction in creatinine clearance in most individuals, but it generally is not significant enough to lead to severe loss of renal function. As the number of nephrons decreases and degenerative changes occur, nephrons are less able to concentrate urine and less able to tolerate dehydration, excessive water loads, or electrolyte imbalances, particularly with physiologic stress. Up to 45% of people older than 70 years of age have chronic kidney disease.

• The presence of comorbid conditions, such as hypertension and diabetes mellitus, accelerates the decline of renal function. Obesity does not accelerate a decline in GFR.

• Response to acid-base changes and reabsorption of glucose may be delayed.

• Drugs eliminated by the kidney can accumulate in the plasma, causing toxic reactions; GFR and drug dosage should be carefully evaluated.

• Decreased thirst sensation and diminished water intake may alter water balance.

• Impairment in renal blood flow, hormonal regulatory systems, and metabolism of medications may alter sodium and water balance.

• Older donor kidneys show decreased regenerative capacity.

Did You Understand?

Structures of the Renal System

1. The kidneys are paired structures lying bilaterally between the twelfth thoracic and third lumbar vertebrae and behind the peritoneum of the abdominal cavity.

2. The kidney is composed of an outer cortex and an inner medulla.

3. The calyces receive urine from the distal tubules and join to form the renal pelvis, which is continuous with the upper end of the ureter.

4. The nephron is the urine-forming unit of the kidney and is composed of the glomerulus, proximal convoluted tubule, hairpin loops of Henle, distal tubule, and collecting duct.

5. The glomerulus contains loops of capillaries supported by mesangial cells. The capillary walls serve as a filtration membrane for the formation of the primary urine.

6. The proximal tubule is lined with microvilli to increase surface area and enhance reabsorption of water, solutes, and electrolytes.

7. The hairpin loops of Henle transport solutes and water, contributing to the hypertonic state of the medulla, and are important for the concentration and dilution of urine.

8. The distal convoluted tubule adjusts acid-base balance by excreting acid into the urine and forming new bicarbonate ions. It reabsorbs water with the influence of ADH and reabsorbs sodium and excretes potassium with the influence of aldosterone.

9. The ureters extend from the renal pelvis to the posterior wall of the bladder. Urine flows through the ureters and into the bladder by means of peristaltic contraction of the ureteral muscles.

10. The bladder is a bag composed of the detrusor and trigone muscles and innervated by parasympathetic fibers. When accumulation of urine reaches 250 to 300 ml, mechanoreceptors, which respond to stretching of tissue, stimulate the micturition reflex.
Renal Blood Flow

1. Renal blood flows at about 1000 to 1200 ml/min, or 20% to 25% of the cardiac output.

2. Blood flow through the glomerular capillaries is maintained at a constant rate in spite of a wide range of arterial pressures by autoregulation of the glomerular capillaries.

3. The glomerular filtration rate (GFR) is the filtration of plasma per unit of time and is directly related to the perfusion pressure of renal blood flow.

4. Renin is an enzyme secreted from the juxtaglomerular apparatus in response to decreased blood pressure and causes the generation of angiotensin II, a potent vasoconstrictor. The renin-angiotensin-aldosterone system is thus a regulator of renal blood flow.

Kidney Function

1. The major function of the nephron is urine formation, which involves the processes of glomerular filtration, tubular reabsorption, and tubular secretion and excretion.

2. Glomerular filtration is favored by capillary hydrostatic pressure and opposed by oncotic pressure in the capillary and hydrostatic pressure in Bowman capsule. The balance of favoring and opposing filtration forces is known as net filtration pressure (NFP).

3. The GFR is approximately 120 ml/min, and 99% of the filtrate is reabsorbed.

4. The proximal convoluted tubule reabsorbs about 60% to 70% of the filtered sodium and water and 90% of other electrolytes.

5. Because most molecules are reabsorbed by active transport, the carrier mechanism can become saturated at a point known as the transport maximum ($T_m$). Molecules not reabsorbed are excreted with the urine.

6. The concentration or specific gravity of the final urine is a function of the level of antidiuretic hormone (ADH). This hormone stimulates the distal tubules and
collecting ducts to reabsorb water. The countercurrent exchange system of the long loops of Henle and their accompanying capillaries establishes a concentration gradient within the renal medulla to facilitate the reabsorption of water from the collecting duct.

7. The kidney secretes or activates a number of hormones having systemic effects, including vitamin D, erythropoietin, and the natriuretic hormone urodilatin.

**Tests of Renal Function**

1. Creatinine, a substance produced by muscle, is measured in both plasma and urine to calculate a commonly used clinical measurement of GFR.

2. Plasma creatinine concentration, cystatin C level, and blood urea nitrogen (BUN) level are estimates of glomerular function. BUN value also is an indicator of hydration status.

3. Formulas for estimating GFR can be helpful clinical indicators of renal function.

4. Urinalysis involves evaluation of color, turbidity, protein, pH, specific gravity, sediment, and supernatant. Presence of bacteria, red blood cells, white blood cells, casts, or crystals in the urine sediment may indicate a renal or bladder disorder.

**PEDIATRIC CONSIDERATIONS: Pediatrics & Renal Function**

1. Compared with adults, infants and children have more dilute urine because of higher blood flow and shorter loops of Henle.

2. Children are more affected than adults by fluid imbalances resulting from diarrhea, infection, or improper feeding because of their limited ability to quickly regulate changes in pH or osmotic pressure.

**GERIATRIC CONSIDERATIONS: Aging & Renal Function**

1. Older adults have a decreased ability to concentrate urine and are less able to tolerate dehydration or water loads because they have fewer nephrons.
2. Responses to acid-base changes and reabsorption of glucose are delayed in older adults.

3. In older adults, drugs eliminated by the kidney can accumulate in the plasma, causing toxic reactions.

Renal and urinary function can be affected by a variety of disorders. The most common type of urinary dysfunction is infection of the bladder. Stones, tumors, or inflammation also can obstruct the urinary tract. Renal function can be impaired by disorders of the kidney itself or by systemic diseases and may ultimately result in acute kidney injury or chronic kidney disease. Because the kidney filters the blood, it is directly linked to every other organ system. Renal failure, whether acute or chronic, is therefore a life-threatening condition.
Urinary Tract Obstruction

Urinary tract obstruction is an interference with the flow of urine at any site along the urinary tract (Figure 30-1). An obstruction may be anatomic or functional. The obstruction impedes flow proximal to the blockage, dilates structures distal to the obstruction, increases the risk for infection, and compromises renal function. Anatomic changes in the urinary system caused by obstruction are referred to as obstructive uropathy. The severity of an obstructive uropathy is determined by (1) the location of the obstructive lesion, (2) the involvement of ureters and kidneys, (3) the severity (completeness) of the blockage, (4) the duration of the blockage, and (5) the nature of the obstructive lesion.\textsuperscript{1,2} Obstructions may be relieved or partially alleviated by correction of the obstruction, although permanent impairments occur if a complete or partial obstruction persists over a period of weeks to months or longer.
Upper Urinary Tract Obstruction

Common causes of upper urinary tract obstruction include stricture or congenital compression of a calyx at the ureteropelvic-ureterovesical junction (e.g., stones [calculi], or vesicoureteral reflux) (see Chapter 31); compression from an aberrant vessel, tumor, or abdominal inflammation and scarring (retroperitoneal fibrosis); or ureteral blockage from stones or a malignancy of the renal pelvis or ureter.

Obstruction of the upper urinary tract causes dilation of the ureter, renal pelvis, calyces, and renal parenchyma proximal to the site of urinary blockage resulting
from a “backing up” of urine. The increased pressure is transmitted to the glomerulus, which decreases filtration. Dilation of the ureter is referred to as **hydroureter** (accumulation of urine in the ureter), and dilation of the renal pelvis and calyces proximal to a blockage is referred to as **hydronephrosis** or **ureterohydronephrosis** (dilation of both the ureter and the pelvicaliceal system) (**Figure 30-2**). Dilation of the upper urinary tract is an early response to obstruction and includes smooth muscle hypertrophy and accumulation of urine above the level of blockage (urinary stasis). Unless the obstruction is relieved, the dilation leads to enlargement and **tubulointerstitial fibrosis** with deposition of excessive amounts of collagen and other proteins. These changes occur in the distal nephrons and affect renal function within approximately 7 days. By 14 days, obstruction has adversely affected both distal and proximal tubular aspects of the nephron units. Within 28 days, the glomeruli of the kidney have been damaged and the renal cortex and medulla are reduced in size (thinned). Tubular damage initially decreases the kidney's ability to concentrate urine, causing an increase in urine volume despite a decrease in glomerular filtration rate (GFR). The affected kidney is unable to conserve sodium, bicarbonate, and water or to excrete hydrogen or potassium, leading to metabolic acidosis and dehydration. The magnitude of this damage, and the kidney's ability to recover normal regulatory function, is affected by the severity and duration of the obstruction. With complete obstruction and compression of the renal vasculature, damage to the renal tubules occurs in a matter of hours, and irreversible damage occurs within 4 weeks. Nevertheless, even in the face of a complete obstruction, the human kidney may recover at least partial function provided the blockage is removed within 56 to 69 days. This recovery requires a period of approximately 4 months. Partial obstruction, in the absence of renal infection, leads to subtler but ultimately permanent impairments including loss of the kidney's ability to concentrate urine, reabsorb bicarbonate, excrete ammonia, or regulate metabolic acid-base balance.
The body is able to partially counteract the negative consequences of unilateral obstruction by a process called **compensatory hypertrophy** and **hyperfunction**.\(^4\) Compensatory response is the result of two growth processes: obligatory growth occurs under the influence of somatomedins, and compensatory growth occurs under the influence of still unidentified hormone(s). These processes cause the unobstructed kidney to increase the size of individual glomeruli and tubules but not the total number of functioning nephrons. The ability of the body to engage in compensatory hypertrophy and hyperfunction diminishes with age, and the process is reversible when relief of obstruction results in recovery of function by the obstructed kidney.

Relief of bilateral, partial urinary tract obstruction or complete obstruction of one kidney is usually followed by a brief period of diuresis (commonly called **postobstructive diuresis**).\(^5\) Postobstructive diuresis is a physiologic response and is typically mild, representing a restoration of fluid and electrolyte imbalance caused by the obstructive uropathy. Occasionally, relief of obstruction will cause rapid excretion of large volumes of water, sodium, or other electrolytes, resulting in a urine output of 10 L/day or more. Rapid postobstructive diuresis causes dehydration and fluid and electrolyte imbalances that must be promptly corrected. Risk factors for severe postobstructive diuresis include chronic, bilateral obstruction; impairment of one or both kidneys' ability to concentrate urine or
reabsorb sodium (*acquired nephrogenic diabetes insipidus*); hypertension; edema and weight gain; congestive heart failure; and uremic encephalopathy.

**Kidney Stones**

**Calculi**, or **urinary stones**, are masses of crystals, protein, or other substances that are a common cause of urinary tract obstruction in adults. Calculi can be located in the kidneys, ureters, and urinary bladder. The prevalence of stones in the United States is approximately 7% in women and 10% in men and has increased in the past 20 years. The recurrence rate is approximately 30% to 50% within 5 years. Most renal stones are unilateral. The risk of urinary calculi formation is influenced by a number of factors, including age, sex, race, geographic location, seasonal factors, fluid intake, diet, and occupation. Most persons develop their first stone before age 50 years. Geographic location influences the risk of stone formation because of indirect factors, including average temperature, humidity, and rainfall, and their influence on fluid intake and dietary patterns. Persons who regularly consume an adequate volume of water and those who are physically active are at reduced risk when compared with persons who are inactive or consume lower volumes of water.

Urinary calculi can be classified according to the primary minerals (salts) that make up the stones. The most common stone types include calcium oxalate or phosphate (70% to 80%), struvite (magnesium-ammonium-phosphate) (15%), and uric acid (7%). Cystine stones are rare (<1%).

**Pathophysiology**

Calculus formation is complex and related to (1) supersaturation of one or more salts in the urine, (2) precipitation of the salts from a liquid to a solid state, (3) growth through crystallization or agglomeration (sometimes called *aggregation*), and (4) the presence or absence of stone inhibitors (e.g., uromodulin [Tamm-Horsfall protein]). *Supersaturation* is the presence of a higher concentration of a salt within a fluid (in this case, the urine) than the volume is able to dissolve to maintain equilibrium.

Human urine contains many ions capable of *precipitating* from solution and forming a variety of salts. The salts form crystals that are retained and grow into stones. *Crystallization* is the process by which crystals grow from a small *nidus* or nucleus to larger stones in the presence of supersaturated urine. Although supersaturation is essential for free stone formation, the urine need not remain continuously supersaturated for a calculus to grow once its nidus has precipitated from solution. Intermittent periods of supersaturation after the ingestion of a meal or during times of dehydration from limited oral intake or secondary to continued
use of diuretics are sufficient for stone growth in many individuals. In addition, the standard tubules and papillae have many surfaces that may attract a crystalline nidus (Randall plaque) and add biologic material (matrix) forming a stone.\textsuperscript{10} Matrix is an organic material (i.e., mucoprotein) in which the components of a kidney stone are embedded.

The temperature and pH of the urine also influence the risk of precipitation and calculus formation, and pH is most important. An alkaline urinary pH (pH >7.0) significantly increases the risk of calcium phosphate stone formation, whereas acidic urine (pH <5.0) increases the risk of uric acid stone formation. Cystine and xanthine also precipitate more readily in acidic urine.

\textit{Stone} or \textit{crystal growth inhibiting substances}, such as potassium citrate, Tamm-Horsfall protein, pyrophosphate, and magnesium, are capable of crystal growth inhibition, thereby reducing the risk of calcium phosphate or calcium oxalate precipitation in the urine and preventing subsequent stone formation.

The size of a stone determines the likelihood that it will pass through the urinary tract and be excreted through micturition.\textsuperscript{11} Stones smaller than 5 mm have about a 50\% chance of spontaneous (painful) passage, whereas stones that are 1 cm have almost no chance of spontaneous passage.

Retention of \textit{crystal particles} occurs primarily at the papillary collecting ducts. Although most crystals are flushed from the tract through antegrade urine flow, urinary stasis (i.e., from benign prostatic hyperplasia, neurogenic bladder), anatomic abnormalities (strictures), or inflamed epithelium within the urinary tract may prevent prompt flushing of crystals from the system, thus increasing the risk of calculus formation.

\textbf{Calcium stones} account for 70\% to 80\% of all stones requiring treatment. Calcium oxalate accounts for about 80\% of these stones and calcium phosphate about 15\%. Most individuals have \textit{idiopathic calcium urolithiasis (ICU)}, a condition whose exact etiology has not yet been defined. Stones can form freely in supersaturated urine or detach from interstitial sites within the tubules (Randall plaque formation) near the tip of the renal papillae. Hypercalciuria, hyperoxaluria, hyperuricosuria, hypocitraturia, mild renal tubular acidosis, or crystal growth inhibitor deficiencies and alkaline urine are associated with calcium stones. Hypercalciuria is attributable to intestinal hyperabsorption of dietary calcium and decreased renal calcium reabsorption. Hyperparathyroidism and bone demineralization associated with prolonged immobilization are also known to cause hypercalciuria. Although oxalate in the diet influences the risk of calcium stones, primary hyperoxaluria is a rare, inherited disorder.

\textbf{Struvite stones} primarily contain magnesium-ammonium-phosphate as well as varying levels of matrix. Matrix forms in an alkaline urine and during infection
with a urease-producing bacterial pathogen, such as a *Proteus, Klebsiella*, or *Pseudomonas*. Struvite calculi may grow quite large and branch into a staghorn configuration (**staghorn calculus**) that approximates the pelvicaliceal collecting system.

**Uric acid stones** occur in persons who excrete excessive uric acid in the urine, such as those with gouty arthritis. Uric acid is primarily a product of biosynthesis of endogenous purines and is secondarily affected by consumption of purines (e.g., meat and beer) in the diet. A consistently acidic urine (pH <5.0) greatly increases this risk. Cystine and xanthine are amino acids that precipitate more readily in acidic urine. *Cystinuria* and *xanthinuria* are both genetic disorders of amino acid metabolism, and excess of these amino acids in urine can cause **cystinuric**, or **xanthine, stone** formation in the presence of a low urine pH of 5.5 or less.

**Clinical manifestations**

**Renal colic**, described as moderate to severe pain often originating in the flank and radiating to the groin, usually indicates obstruction of the renal pelvis or proximal ureter. Colic that radiates to the lateral flank or lower abdomen typically indicates obstruction in the midureter, and bothersome lower urinary tract symptoms (urgency, frequent voiding, urge incontinence) indicate obstruction of the lower ureter or ureterovesical junction. The pain can be severe and incapacitating and may be accompanied by nausea and vomiting. Gross or microscopic hematuria may be present.

**Evaluation and treatment**

The evaluation and diagnosis of urinary calculi is based on presenting symptoms and history combined with a focused physical assessment. Imaging studies determine the location of the calculi, the severity of obstruction, and associated obstructive uropathy. The history queries dietary habits, the age of the first stone episode, stone analysis, and presence of complicating factors including hyperparathyroidism or recent gastrointestinal or genitourinary surgery. Urinalysis (including pH) is obtained and a 24-hour urine is completed to identify calcium oxalate, calcium citrate, and other significant constituents. In addition, every effort is made to retrieve and analyze calculi that are passed spontaneously or retrieved through aggressive intervention. To diagnose and manage underlying metabolic disorders, additional tests are completed for those with suspected hyperparathyroidism (elevated serum calcium levels) or cystine or uric acid (high purine diet) stones.

The goals of treatment are to manage acute pain, promote stone passage, reduce the size of stones already formed, and prevent new stone formation. The
components of treatment include (1) managing pain, (2) reducing the concentration of stone-forming substances by increasing urine flow rate with high fluid intake, (3) adjusting the pH of the urine (e.g., make it more alkaline with potassium citrate administration), (4) decreasing the amount of stone-forming substances in the urine by decreasing dietary intake or endogenous production or by altering urine pH, and (5) removing stones using percutaneous nephrolithotomy, ureteroscopy, or ultrasonic or laser lithotripsy to fragment stones for excretion in the urine. Prevention of recurrent stones includes increasing fluid intake to generate 2.5 L of urine per day, avoiding intake of colas and other soft drinks acidified with phosphoric acid, avoiding dietary oxalate (e.g., chocolate, beets, nuts, rhubarb, spinach, strawberries, tea, wheat bran), eating less animal protein, limiting sodium intake, and, for calcium stone prevention, maintaining a dietary calcium intake of 1000 to 1200 mg/day. Potassium citrate may be used to raise urinary pH.\textsuperscript{13,14}

**Lower Urinary Tract Obstruction**

Obstructive disorders of the lower urinary tract (LUT) are primarily related to storage of urine in the bladder or emptying of urine through the bladder outlet. The causes of obstruction include both neurogenic and anatomic alterations or, in some instances, a combination of both. Incontinence is a common symptom and types of incontinence are reviewed in Table 30-1.

**TABLE 30-1**

**Types of Incontinence**

<table>
<thead>
<tr>
<th>Type</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Urge incontinence (most common in older adults)</td>
<td>Involuntary loss of urine associated with abrupt and strong desire to void (urgency); often associated with involuntary contractions of detrusor; when associated with neurologic disorder, this is called detrusor hyperreflexia; when no neurologic disorder exists, this is called detrusor instability; may be associated with decreased bladder wall compliance</td>
</tr>
<tr>
<td>Stress incontinence (most common in women &lt;60 years and men who have had prostate surgery)</td>
<td>Involuntary loss of urine during coughing, sneezing, laughing, or other physical activity associated with increased abdominal pressure</td>
</tr>
<tr>
<td>Overflow incontinence</td>
<td>Involuntary loss of urine with overdistention of bladder; associated with neurologic lesions below S1, polyneuropathies, and urethral obstruction (e.g., enlarged prostate)</td>
</tr>
<tr>
<td>Mixed incontinence (most common in older women)</td>
<td>Combination of both stress and urge incontinence</td>
</tr>
<tr>
<td>Functional incontinence</td>
<td>Involuntary loss of urine attributable to dementia or immobility</td>
</tr>
</tbody>
</table>

**Neurogenic Bladder**
**Neurogenic bladder** is a general term for bladder dysfunction caused by neurologic disorders (Table 30-2). The types of dysfunction are related to the sites in the nervous system controlling sensory and motor bladder function. Lesions developing in upper motor neurons of the brain and spinal cord result in **dyssynergia** (loss of coordinated neuromuscular contraction) and overactive or hyperreflexive bladder function. Lesions in the sacral area of the spinal cord or peripheral nerves result in underactive, hypotonic, or atonic (flaccid) bladder function, often with loss of bladder sensation.

</table>

LMN, Lower motor neuron; UMN, upper motor neuron.

Neurologic disorders that develop above the pontine micturition center result in **detrusor hyperreflexia (overactivity)**, also known as an uninhibited or reflex bladder. This is an upper motor neuron disorder in which the bladder empties automatically when it becomes full and the external sphincter functions normally. Because the pontine micturition center remains intact, there is coordination between detrusor muscle contraction and relaxation of the urethral sphincter. Stroke, traumatic brain injury, dementia, and brain tumors are examples of disorders that result in detrusor hyperreflexia. Symptoms include urine leakage and incontinence.

Neurologic lesions that occur below the pontine micturition center but above the sacral micturition center (between C2 and S1) are also upper motor neuron lesions and result in **detrusor hyperreflexia with vesicosphincter dyssynergia**. There is loss of pontine coordination of detrusor muscle contraction and external sphincter relaxation, so both the bladder and the sphincter are contracting at the same time, causing a functional obstruction of the bladder outlet.\(^{15}\) Spinal cord injury, multiple sclerosis, Guillain-Barré syndrome, and vertebral disk problems are causes of this disorder. There is diminished bladder relaxation during storage with small urine volumes and high intravesicular (inside the bladder) pressures. The result is an overactive bladder syndrome with symptoms of frequency, urgency, urge incontinence, and increased risk for urinary tract infection.

Lesions involving the sacral micturition center (below S1; may also be termed
cauda equina syndrome) or peripheral nerve lesions result in detrusor areflexia (acontractile detrusor), a lower motor neuron disorder. The result is an acontractile detrusor or atonic bladder with retention of urine and distention. If the sensory innervation of the bladder is intact, the full bladder will be sensed but the detrusor may not contract. This is an underactive bladder syndrome and may have symptoms of stress and overflow incontinence. Myelodysplasia, multiple sclerosis, tabes dorsalis, and peripheral polyneuropathies are associated with this disorder.

**Overactive Bladder Syndrome**

Overactive bladder syndrome (OAB) is a syndrome of detrusor overactivity characterized by urgency with involuntary detrusor contractions during the bladder filling phase that may be spontaneous or provoked. There is coordination between the contracting bladder and the external sphincter, but the detrusor is too weak to empty the bladder, resulting in urinary retention with overflow or stress incontinence. Overactive bladder is defined by the International Continence Society as a symptom syndrome of urgency, with or without urge incontinence and usually associated with frequency and nocturia. Overactive bladder syndrome affects millions of adults and children. Adults are often reluctant to discuss this syndrome with their healthcare provider.

**Anatomic Obstructions to Urine Flow**

Anatomic causes of resistance to urine flow include urethral stricture, prostatic enlargement in men, pelvic organ prolapse in women, and tumor compression. Symptoms of obstruction are more common in men and include (1) frequent daytime voiding (urination more than every 2 hours while awake); (2) nocturia (awakening more than once each night to urinate for adults younger than 65 years of age or more than twice for older adults); (3) poor force of stream; (4) intermittency of urinary stream; (5) bothersome urinary urgency, often combined with hesitancy; and (6) feelings of incomplete bladder emptying despite micturition.

A urethral stricture is a narrowing of its lumen and occurs when infection, injury, or surgical manipulation produces a scar that reduces the caliber of the urethra. The vast majority of urethral strictures occur in men; they are rare in women. The severity of obstruction is influenced by its location within the urethra, its length, and the minimum caliber of urethral lumen within the stricture. Specifically, proximal urethral strictures cause more severe obstruction than do strictures of the distal urethra, longer strictures tend to be more obstructive, and the magnitude of blockage is inversely proportional to the urethral caliber.

Prostate enlargement is caused by acute inflammation, benign prostatic
hyperplasia, or prostate cancer (see Chapter 33). Each of these disorders can cause encroachment on the urethra with obstruction to urine flow and the symptoms summarized previously.

Severe **pelvic organ prolapse** (see Chapter 33) in a woman causes bladder outlet obstruction when a cystocele (the downward protrusion/herniation of the bladder into the vagina) descends below the level of the urethral outlet. A cystocele reaching or protruding beyond the vaginal introitus creates the greatest risk for obstruction, particularly if the bladder neck has been surgically repaired without simultaneous repair of the cystocele. In men the bladder may rarely herniate into the scrotum, causing a similar type of obstruction.

**Partial obstruction of the bladder outlet or urethra** initially causes an increase in the force of detrusor contraction. If the blockage persists, afferent nerves within the bladder wall are adversely affected, leading to urinary urgency and, in some cases, overactive detrusor contractions (a myogenic cause of overactive bladder). When obstruction persists, there is an increased deposition of collagen within the smooth muscle bundles of the detrusor muscle (**trabeculation**), possibly in an attempt to increase the force of its contraction strength. Ultimately, the bladder wall loses its ability to stretch and accommodate urine, a condition called **low bladder wall compliance**, and the detrusor loses its ability to contract efficiently. Low bladder wall compliance chronically elevates intravesicular pressure, greatly increasing the likelihood of hydroureter, hydronephrosis, and impaired renal function.

**Evaluation and treatment**

Although the history and physical examination are critical to the evaluation of lower urinary tract disorders, it must be remembered that no symptom or cluster of symptoms has been identified that accurately differentiates the various causes of these disorders. For example, symptoms such as urgency, urge incontinence, frequent urination, and nocturia may develop because of overactive bladder or either increased or decreased bladder outlet resistance. Reduced resistance is associated with the symptom of stress incontinence (incontinence with coughing or sneezing) and symptoms of increased resistance are similar to bladder outlet obstruction, including poor force of urinary stream, hesitancy, and feelings of incomplete bladder emptying.

Various diagnostic tests assist with evaluation. The **postvoid urine** is measured by catheterization within 5 to 15 minutes of urination or through a bladder ultrasound machine that measures bladder height and width to provide an approximation of urine within the vesicle. This measurement may be combined with **uroflowmetry**, a graphic representation of the force of the urinary stream expressed as milliliters
voided per second. A *cystometric test* uses a catheter and manometer to evaluate bladder urine volume and pressure in relation to involuntary bladder contraction (the leak point pressure) and the urge to void. Each of these measurements assesses the lower urinary tract's efficiency in evacuating urine through micturition but neither differentiates poor detrusor contraction strength from obstruction as a cause of urinary retention. Instead, *multichannel urodynamic testing* is used to identify obstruction, quantify its severity, and measure detrusor contraction strength (Figure 30-3). *Video-urodynamic recordings* can also demonstrate overactive bladder and detrusor sphincter dyssynergia. An evaluation of renal function, including functional imaging studies and measurement of serum creatinine level, is completed particularly when obstruction is severe and associated with elevated residuals or urinary tract infection.
Because the bladder neck consists of circular smooth muscle with adrenergic innervation, OAB and detrusor sphincter dyssynergia may be managed by α-adrenergic blocking (antimuscarinic) medications. In intractable cases, botulinum toxin A injections or surgery is recommended. Detrusor sphincter dyssynergia may be managed by intermittent catheterization in combination with higher dose antimuscarinic drugs to prevent overactive detrusor contractions and associated dyssynergia while ensuring regular, complete bladder evacuation by catheterization. Alternatively, men with dyssynergia may be managed by condom catheter containment, supplemented by an α-adrenergic-blocking drug or transurethral sphincterotomy (surgical incision of the striated sphincter) to relieve obstruction. Low bladder wall compliance may be managed by antimuscarinic drugs and intermittent catheterization; however, more severe cases may require augmentation enterocystoplasty (enlargement of the low compliant bladder wall using a detubularized piece of small bowel), urinary diversion, or long-term indwelling catheterization. Untreated OAB impairs health and quality of life, causes depression, leads to social isolation, and causes significant economic burden. In the elderly, OAB may cause risk for falls and urinary tract infection.

Prostate enlargement is managed by treating the underlying cause of the prostate enlargement with medication or surgery. Urinary retention may require transient placement of a suprapubic catheter. Urethral stricture is treated with urethral dilation accomplished by using a steel instrument shaped like a catheter (urethral sound) or a series of incrementally increasing catheter-like tubes (filiforms and followers). Long, dense strictures typically require surgical repair to prevent recurrence.

**Tumors**

**Renal Tumors**

Renal tumors are estimated at 61,560 (3.7%) of new cancer cases and 14,080 deaths for 2015. There are a number of different types of kidney tumors. **Renal adenomas** (benign tumors) are uncommon but are increasing in number. The tumors are encapsulated and are usually located near the cortex of the kidney. Because the tumors can become malignant, they are usually surgically removed. **Renal cell adenocarcinoma (RCC)** is the most common renal neoplasm (85% of all renal neoplasms) and represents about 2% of cancer deaths. **Renal transitional cell**
carcinoma (RTCC) is rare and primarily arises in the renal parenchyma and renal pelvis. Renal cell carcinoma usually occurs in men (two times more often than in women) between 50 and 60 years of age. Risk factors include cigarette smoking, obesity, and uncontrolled hypertension. With surgical resection 5-year survival is about 90% for stage I (encapsulated) cancer.\textsuperscript{22}

**Pathogenesis**

Renal cell carcinomas are adenocarcinomas that usually arise from tubular epithelium commonly in the renal cortex. The etiology is unknown. They are classified according to cell type and extent of metastasis. *Clear cell tumors*, the most common, present a better prognosis than granular cell or spindle tumors. Confinement within the renal capsule, together with treatment, is associated with a better survival rate. The tumors usually occur unilaterally (Figure 30-4). About 25% of individuals with RCC present with metastasis.\textsuperscript{23}

![Renal Cell Carcinoma](image.png)

**Clinical manifestations**

The classic clinical manifestations of renal tumors are hematuria, dull and aching flank pain, palpable flank mass, and weight loss, but all of these symptoms occur in fewer than 10% of cases. Further, they represent an advanced stage of disease, whereas earlier stages are often silent (painless hematuria). The most common sites of distant metastasis are the lung, lymph nodes, liver, bone, thyroid gland, and
central nervous system.

**Evaluation and treatment**

Diagnosis is based on the clinical symptoms, plain x-ray films of the abdomen, intravenous pyelography, renal angiography, computed tomography (CT) or positron emission tomography using $^{124}$I-girentuximab, and a radiolabeled monoclonal antibody that binds to clear cell cancer cells. The TNM classification is used to stage renal cell carcinoma. Staging systems using molecular tumor markers are rapidly improving. Treatment for localized disease is surgical removal of the affected kidney (radical nephrectomy) or partial nephrectomy for smaller tumors, with combined use of chemotherapeutic agents. Radiofrequency ablation also may be used for early stage tumors when surgery is not an option. Metastatic disease is treated with immunotherapy (i.e., bevacizumab [angiogenesis inhibitor such as sunitinib or sorafenib], T-cell activators, interferon-alpha, and interleukin-2) and target therapies including vascular endothelial growth factor (VEGF) or the mammalian target of rapamycin (mTOR) pathways, or both. Cell-based vaccines are showing promise. Survival is related to tumor grade, tumor cell type, and extent of metastasis.

**Bladder Tumors**

Bladder tumors are the fifth most common malignancy and represent about 1% of all malignant tumors with 70,530 new cases each year and 14,680 deaths. The development of bladder cancer is most common in men older than 60 years. *Transitional cell (urothelial) carcinoma* is the most common bladder malignancy and tumors are usually superficial. More advanced tumors are muscle invasive. Less common forms are squamous cell and adenocarcinoma (cells that produce mucus).

**Pathogenesis**

The risk of primary bladder cancer is greater among people who smoke or are exposed to metabolites of aniline dyes, high levels of arsenic in drinking water, heavy consumption of phenacetin, or have uroepithelial Schistosomiasis infection. Bladder cancer results from a genetic alteration in normal bladder epithelium. Metastasis is usually to lymph nodes, liver, bones, or lungs. The TNM classification is used for staging bladder carcinoma. Secondary bladder cancer develops by invasion of cancer from bordering organs, such as cervical carcinoma in women or prostatic carcinoma in men.

**Clinical manifestations**
Gross painless hematuria is the archetypal clinical manifestation of bladder cancer. Episodes of hematuria tend to recur, and they are often accompanied by bothersome lower urinary tract symptoms including daytime voiding frequency, nocturia, urgency, and urge urinary incontinence, particularly for carcinoma in situ. Flank pain may occur if tumor growth obstructs one or both ureterovesical junctions.

**Evaluation and treatment**

Cystoscopy with tissue biopsy confirms the diagnosis of bladder cancer. Urine cytologic study (pathologic analysis of sloughed cells within the urine) is used for screening-high risk individuals. Use of biologic markers for bladder cancer diagnosis and treatment prognosis are under investigation. Transurethral resection or laser ablation, combined with intravesical chemotherapy or biologic therapy, is effective for superficial tumors. Radical cystectomy with urinary diversion and adjuvant chemotherapy is required for locally invasive tumors.

**Quick Check 30-1**

1. List two typical complications of urinary tract obstruction, and briefly describe them.

2. How do kidney stones form?

3. Which population group is at greatest risk for bladder tumors?
Urinary Tract Infection

Causes of Urinary Tract Infection

A urinary tract infection (UTI) is an inflammation of the urinary epithelium usually caused by bacteria from gut flora. A UTI can occur anywhere along the urinary tract including the urethra, prostate, bladder, ureter, or kidney. At risk are premature newborns; prepubertal children; sexually active and pregnant women; women treated with antibiotics that disrupt vaginal flora; spermicide users; estrogen-deficient postmenopausal women; individuals with indwelling catheters; and persons with diabetes mellitus, neurogenic bladder, or urinary tract obstruction. Cystitis is more common in women because of the shorter urethra and the closeness of the urethra to the anus (increasing the possibility of bacterial contamination). Up to 50% of women may have a lower UTI at some time in their life. Generally, UTIs are mild and without complications, and they occur in individuals with a normal urinary tract; these infections are termed uncomplicated UTIs. A complicated UTI develops when there is an abnormality in the urinary system or a health problem that compromises host defenses, such as human immunodeficiency virus (HIV), renal transplant, diabetes, or spinal cord injury. UTI may occur alone or in association with pyelonephritis, prostatitis, or kidney stones. Up to 40% of cases of septic shock are caused by urosepsis. Factors associated with UTI are summarized in Figure 30-5.
Several factors normally combine to protect against UTIs. Most bacteria are washed out of the urethra during micturition. The low pH and high osmolality of urea, the presence of Tamm-Horsfall protein or uromodulin (secreted by renal tubular cells in the distal loop of Henle), and secretions from the uroepithelium provide a bactericidal effect. The ureterovesical junction closes during bladder contraction, preventing reflux of urine to the ureters and kidneys. Both the longer urethra and the presence of prostatic secretions decrease the risk of infection in men. A UTI occurs when a pathogen circumvents or overwhelms the host's defense mechanisms and rapidly reproduces.
Types of Urinary Tract Infection

Acute Cystitis

Acute cystitis is an inflammation of the bladder and is the most common site of UTI. The morphologic appearance of the bladder through cystoscopy describes different types of cystitis. With mild inflammation, the mucosa is hyperemic (red). More advanced cases may show diffuse hemorrhage (termed hemorrhagic cystitis), pus formation, or suppurative exudates (termed suppurative cystitis) on the epithelial surface of the bladder. Prolonged infection may lead to sloughing of the bladder mucosa with ulcer formation (termed ulcerative cystitis). The most severe infections may cause necrosis of the bladder wall (termed gangrenous cystitis).

Pathophysiology

The most common infecting microorganisms are uropathic strains of Escherichia coli and the second most common is Staphylococcus saprophyticus. Less common microorganisms include Klebsiella, Proteus, Pseudomonas, fungi, viruses, parasites, or tubercular bacilli. Schistosomiasis is the most common cause of parasitic invasion of the urinary tract on a global basis; it infects more than 200 million people and has a strong association with bladder cancer.

Bacterial contamination of the normally sterile urine usually occurs by retrograde movement of gram-negative bacilli into the urethra and bladder and then to the ureter and kidney. Uropathic strains of E. coli have type-1 fimbriae that bind to latex catheters and receptors on the uroepithelium. They resist flushing during normal micturition. These strains also have P fimbriae (pyelonephritis-associated fimbriae) that bind to the uroepithelium of individuals with P blood group antigen and readily ascend the urinary tract (see Figure 30-5). Some women may be genetically susceptible to certain strains of E. coli attachment. Hematogenous infections are uncommon and often preceded by septicemia. Infection initiates an inflammatory response and the symptoms of cystitis. The inflammatory edema in the bladder wall stimulates discharge of stretch receptors initiating symptoms of bladder fullness with small volumes of urine and producing the urgency and frequency of urination associated with cystitis.

Clinical manifestations

Many individuals with bacteriuria are asymptomatic, and the elderly have the highest risk. Clinical manifestations of cystitis are related to the inflammatory response and usually include frequency, urgency, dysuria (painful urination), and suprapubic and low back pain. Hematuria, cloudy urine, and flank pain are more serious symptoms. Approximately 10% of individuals with bacteriuria have no
symptoms, and 30% of individuals with symptoms are abacteriuric. Elderly persons with cystitis may be asymptomatic or demonstrate confusion or vague abdominal discomfort. The elderly with recurrent UTIs and other concurrent illness have a higher risk of mortality.\textsuperscript{37}

**Evaluation and treatment**

Infections in symptomatic individuals are diagnosed by urine culture of specific microorganisms with counts of 10,000/ml or more from freshly voided urine. Urine dipstick testing that is positive for leukocyte esterase or nitrite reductase can be used for the diagnosis of uncomplicated UTI. Risk factors, such as urinary tract obstruction, should be identified and treated. Evidence of bacteria from urine culture and antibiotic sensitivity warrants treatment with a microorganism-specific antibiotic. Acute uncomplicated cystitis in nonpregnant women can be diagnosed without an office visit or urine culture. If a urine culture and sensitivity are ordered, the urine specimen must be obtained before the initiation of any antibiotic therapy; 3 to 7 days of treatment is most common.\textsuperscript{38} Complicated UTI requires 7 to 14 days of treatment. From 20% to 25% of women have relapsing infection within 7 to 10 days requiring prolonged antibiotic treatment. Follow-up urine cultures should be obtained 1 week after initiation of treatment and at monthly intervals for 3 months. Clinical symptoms are frequently relieved, but bacteriuria may still be present. Repeat cultures should be obtained every 3 to 4 months until 1 year after treatment for evaluation and treatment of recurrent infection.\textsuperscript{39} (see *Health Alert: Urinary Tract Infection and Antibiotic Resistance*).
the mainstay of treatment. These bacteria and other gram-negative species produce β-lactamases and carbapenemases, causing resistance to penicillins, cephalosporins, and carbapenems (used for complicated UTI). TMP-SMX and fluoroquinolone have a high rate of resistance. Multidrug resistant extended-spectrum β-lactamase (ESBL) producing Escherichia coli are occurring with no known risk factors. First-time uncomplicated UTI can be treated empirically with a 3-day regimen. Complicated infection requires individualized assessment of risk factors for drug resistance and drug tolerability and includes history, physical examination, urine culture and sensitivity, and possible radiologic evaluation. Asymptomatic bacteriuria only requires treatment in exceptional cases. Awareness of drug resistance and knowledgeable prescribing are essential to prevent inappropriate use of antibiotics. New drugs are being discovered that overcome bacterial resistance, and old drugs in new combinations are being tested.

**Painful Bladder Syndrome/Interstitial Cystitis**

**Painful bladder syndrome/interstitial cystitis (PBS/IC)** is a condition that includes **nonbacterial infectious cystitis** (viral, mycobacterial, chlamydial, fungal), **noninfectious cystitis** (radiation, chemical, autoimmune, hypersensitivity), and interstitial cystitis. It occurs most commonly in women ages 20 to 30 years who have symptoms of cystitis, such as frequency, urgency, dysuria, and nocturia, but with negative urine cultures and no other known etiology. Nonbacterial infectious cystitis is most common among those who are immunocompromised. Noninfectious cystitis is associated with radiation or chemotherapy treatment for pelvic and urogenital cancers.

The cause of PBS/IC is unknown. An autoimmune reaction may be responsible for the inflammatory response, which includes mast cell activation, altered uroepithelial permeability, and increased sensory nerve sensitivity. Inflammation and fibrosis of the bladder wall are accompanied by the presence of hemorrhagic ulcers (Hunner ulcers), and bladder volume may decrease as a result of fibrosis. Alteration of the bladder uroepithelial proteoglycan layer makes it more susceptible to penetration by bacteria. Characteristic symptoms of PBS/IC include bladder fullness, urinary frequency (including nocturia), small urine volume, and chronic pelvic pain with symptoms lasting longer than 9 months. Diagnosis of PBS/IC
requires the exclusion of other diagnoses, and extensive evaluations are completed. No single treatment is effective. Oral and intravesical therapies, sacral nerve stimulation, and onabotulinumtoxinA (Botox) are used for symptom relief. Surgery is used in refractory cases.\textsuperscript{40,41}

**Acute Pyelonephritis**

*Pyelonephritis* is an infection of one or both upper urinary tracts (ureter, renal pelvis, and interstitium). Common causes are summarized in Table 30-3. Urinary obstruction and reflux of urine from the bladder (vesicoureteral reflux) are the most common underlying risk factors. One or both kidneys may be involved. Most cases occur in women.

</tbody>
</table>

**Pathophysiology**

Microorganisms usually associated with acute pyelonephritis include *E. coli*, *Proteus*, or *Pseudomonas*. The latter two microorganisms are more commonly associated with infections after urethral instrumentation or urinary tract surgery. These microorganisms also split urea into ammonia, making alkaline urine that increases the risk of stone formation. The infection is probably spread by ascending uropathic microorganisms along the ureters, but dissemination also may occur by way of the bloodstream. The inflammatory process is usually focal and irregular, primarily affecting the pelvis, calyces, and medulla. The infection causes medullary infiltration of white blood cells with renal inflammation, renal edema, and purulent urine. In severe infections, localized abscesses may form in the medulla and extend to the cortex. Primarily affected are the tubules; the glomeruli usually are spared. Necrosis of renal papillae can develop. After the acute phase, healing occurs with fibrosis and atrophy of affected tubules. The number of bacteria decreases until the urine again becomes sterile. Acute pyelonephritis rarely causes renal failure.\textsuperscript{42}
Clinical manifestations
The onset of symptoms is usually acute, with fever, chills, and flank or groin pain. Symptoms characteristic of a UTI, including frequency, dysuria, and costovertebral tenderness, may precede systemic signs and symptoms. Older adults may have nonspecific symptoms, such as low-grade fever and malaise.

Evaluation and treatment
Differentiating symptoms of cystitis from those of pyelonephritis by clinical assessment alone is difficult. The specific diagnosis is established by urine culture, urinalysis, and clinical signs and symptoms. White blood cell casts indicate pyelonephritis, but they are not always present in the urine. Complicated pyelonephritis requires blood cultures and urinary tract imaging. Uncomplicated acute pyelonephritis responds well to 2 to 3 weeks of microorganism-specific antibiotic therapy. Follow-up urine cultures are obtained at 1 and 4 weeks after treatment if symptoms recur. Antibiotic-resistant microorganisms or reinfection may occur in cases of urinary tract obstruction or reflux. Intravenous pyelography and voiding cystourethrography identify surgically correctable lesions.

Chronic Pyelonephritis
Chronic pyelonephritis is a persistent or recurrent infection of the kidney leading to scarring of one or both kidneys. The specific cause of chronic pyelonephritis is difficult to determine. Recurrent infections from acute pyelonephritis may be associated with chronic pyelonephritis. Generally, chronic pyelonephritis is more likely to occur in individuals who have renal infections associated with some type of obstructive pathologic condition, such as renal stones and vesicoureteral reflux.

Pathophysiology
Chronic urinary tract obstruction prevents elimination of bacteria and starts a process of progressive inflammation, alterations of the renal pelvis and calyces, destruction of the tubules, atrophy or dilation and diffuse scarring, and, finally, impaired urine-concentrating ability, leading to chronic kidney failure. The lesions of chronic pyelonephritis are sometimes termed chronic interstitial nephritis because the inflammation and fibrosis are located in the interstitial spaces between the tubules.

Clinical manifestations
The early symptoms of chronic pyelonephritis are often minimal and may include hypertension, frequency, dysuria, and flank pain. Progression can lead to kidney
failure, particularly in the presence of obstructive uropathy or diabetes mellitus.

**Evaluation and treatment**

Urinalysis, intravenous pyelography, and ultrasound are used diagnostically. Treatment is related to the underlying cause. Obstruction must be relieved. Antibiotics may be given, with prolonged antibiotic therapy for recurrent infection.

Glomerular Disorders

Glomerulonephritis

**Acute glomerulonephritis** is an inflammation of the glomerulus caused by *primary glomerular injury*, including immunologic responses, ischemia, free radicals, drugs, toxins, vascular disorders, and infection. *Secondary glomerular injury* is a consequence of systemic diseases, including diabetes mellitus, hypertension, bacterial toxins, systemic lupus erythematosus, congestive heart failure, and human immunodeficiency virus (HIV) related kidney disease.

**Pathophysiology**

Immune mechanisms are a major cause of injury for primary and secondary causes of glomerulonephritis (*Figure 30-6*). The injury damages the glomerular capillary filtration membrane, including the endothelium, basement membrane, and epithelium (podocytes). The most common types of immune injury are (1) deposition of circulating antigen-antibody immune complexes into the glomerulus (type III hypersensitivity) and (2) reaction of antibodies in situ against planted antigens within the glomerulus (type II hypersensitivity, cytotoxic) (see *Chapter 8*). Nonimmune glomerular injury is related to ischemia, metabolic disorders (e.g., diabetes mellitus), toxin exposure, drugs, vascular disorders (e.g., vasculitis), and infection with direct injury to glomerular cells. Different causes of injury may result in more than one type of glomerular lesion; thus lesions are not necessarily disease specific (*Table 30-4*).

</tbody>
</table>

Immune injury is caused by activation of biochemical mediators of inflammation (i.e., complement and cytokines from leukocytes) and begins after the antigen-antibody complexes have deposited or formed in the glomerular capillary wall or mesangium. Complement is deposited with the antibodies, and activation can cause cell lysis or serve as a chemotactic stimulus for attraction of neutrophils, monocytes, and T lymphocytes. These phagocytes, along with activated platelets, further the inflammatory reaction by releasing mediators that injure the glomerular filtration membrane, including epithelial cells, glomerular basement membrane, and endothelial cells (podocytes and filtration slits). The injury increases glomerular membrane permeability and reduces glomerular membrane surface area. The GFR decreases, resulting in increased serum creatinine levels. There also may be swelling and proliferation of mesangial cells and expansion of the extracellular matrix in the Bowman space, contributing to crescent formation (deposition of substances in the Bowman space, forming the shape of a crescent moon). The result is decreased glomerular blood flow, decreased driving hydrostatic pressure, decreased GFR, and hypoxic injury.

Loss of negative electrical charge across the glomerular filtration membrane and increase in filtration pore size enhance movement of proteins into the urine. Proteins are normally repelled because they also have a negative charge. Red blood cells also escape if pore size is large enough. Proteinuria or hematuria, or both, develops. The severity of glomerular damage and decline in glomerular function is related to the size, number, and location (focal or diffuse) of cells injured, duration of exposure, and type of antigen-antibody complexes.

**Clinical manifestations**

The onset of glomerulonephritis may be sudden or insidious and significant loss of nephron function can occur before symptoms develop. Acute glomerulonephritis may be silent, mild, moderate, or severe in symptom presentation. Severe or
progressive glomerular disease causes oliguria (urine output of 30 ml/hour or less), hypertension, and renal failure. Focal lesions tend to produce less severe clinical symptoms. Salt and water are reabsorbed, contributing to fluid volume expansion, edema, and hypertension.

Two major symptoms distinctive of more severe glomerulonephritis (i.e., associated with rapidly progressive glomerulonephritis) are (1) hematuria with red blood cell casts and (2) proteinuria exceeding 3 to 5 g/day with albumin (macroalbuminuria) as the major protein. Different types of acute glomerulonephritis may be associated with different patterns of urinary sediment and nephrotic or nephritic syndrome (see p. 759).

**Evaluation and treatment**

The diagnosis of glomerular disease is confirmed by the progressive development of clinical manifestations and laboratory findings of abnormal urinalysis with proteinuria, red blood cells, white blood cells, and casts. Microscopic evaluation from renal biopsy provides a specific determination of renal injury and type of pathologic condition. Patterns of antigen-antibody complex deposition within the glomerular capillary filtration membrane have been established using light, electron, and immunofluorescent microscopy for different disease processes. The findings with light microscopy provide information about the distribution and extent of immune response injury (Table 30-5). Electron microscopy differentiates morphologic changes within the glomerular capillary wall. Staining with fluorescein identifies different antibodies (i.e., immunoglobulin G [IgG] or immunoglobulin A [IgA]) and their configurations when viewed under ultraviolet (black) light with a microscope.

</tr>
</tbody>
</table>
Reduced GFR during glomerulonephritis is evidenced by elevated plasma urea, cystatin C, and creatinine concentrations, or by reduced creatinine clearance (see Chapter 29). Edema, caused by excessive sodium and water retention, may require the use of diuretics or dialysis.

Management principles for treating glomerulonephritis are related to treating the primary disease, preventing or minimizing immune responses, and correcting accompanying problems, such as edema, hypertension, hypoalbuminemia, and hyperlipidemia. Specific treatment regimens are necessary for particular types of glomerulonephritis. Antibiotic therapy is essential for the management of underlying infections that may be contributing to ongoing antigen-antibody responses. Corticosteroids decrease antibody synthesis and suppress inflammatory responses. Cytotoxic agents (e.g., cyclophosphamide) may be used to suppress the immune response in corticosteroid-resistant cases. Anticoagulants may be useful for controlling fibrin crescent formation in rapidly progressive glomerulonephritis.

### Types of Glomerulonephritis

The classification of glomerulonephritis can be described according to cause, pathologic lesions, disease progression (acute, rapidly progressive, chronic), or clinical presentation (nephrotic syndrome, nephritic syndrome, acute or chronic renal failure). In nearly all types of glomerulonephritis, the epithelial or podocyte layer of the glomerular capillary membrane is disturbed with loss of negative charges and changes in membrane permeability; the mesangial matrix may be expanded or the basement membrane thickened. Features of the patterns of glomerular injury are summarized in Table 30-6. Many types of glomerular injury occur most often in children or young adults, including acute postinfectious glomerulonephritis and minimal change nephropathy (lipoid nephrosis). Details of these diseases are presented in Chapter 31.

</tbody>
</table>

Ab, Antibody; GBM, glomerular basement membrane; GFR, glomerular filtration rate; IgA, immunoglobulin A.

Complications of diabetic nephropathy and systemic lupus erythematosus can affect the entire nephron and glomerular injury is significant. Different patterns of injury develop over the course of these diseases. Diabetic nephropathy develops from metabolic and vascular complications (see Chapter 19). Changes in the glomerulus are characterized by progressive thickening and fibrosis of the glomerular basement membrane, and nodular expansion of the mesangial matrix with albuminuria, podocyte loss, tubular epithelial cell atrophy, and progression to chronic renal failure (Figure 30-7). Diabetic nephropathy is the most common cause of chronic kidney disease and end-stage renal failure. Glomerular structure and function can return to normal after pancreatic transplantation and years of normoglycemia. 46 Lupus nephritis is caused by the formation of autoantibodies against double-stranded DNA with glomerular deposition of the immune complexes.
and alteration in B cell and T cell subsets. There is complement activation and a cascade of inflammatory events resulting in damage to the glomerular membrane with mesangial expansion.\textsuperscript{47}

\textbf{Chronic Glomerulonephritis}

\textit{Chronic glomerulonephritis} encompasses several glomerular diseases with a progressive course leading to chronic kidney failure. There may be no history of kidney disease before the diagnosis. Hypercholesterolemia and proteinuria have been associated with progressive glomerular and tubular injury. The proposed mechanism is related to those observed in glomerulosclerosis and interstitial injury, such as hyperfiltration and inflammatory processes.\textsuperscript{48} The primary cause may be difficult to establish because advanced pathologic changes may obscure specific disease characteristics (see Figure 30-7). Diabetes mellitus and lupus erythematosus
are examples of secondary causes of chronic glomerular injury. Renal insufficiency usually begins to develop after 10 to 20 years, followed by nephrotic syndrome and an accelerated progression to end-stage renal failure. Symptom patterns vary depending on the underlying cause. The specific pathologic condition is identified by renal biopsy and is best performed in early stages of chronic kidney disease to identify specific treatment options. Use of steroids and immunosuppressive agents can prolong remissions and preserve renal function. Dialysis or kidney transplantation ultimately may be needed.

Nephrotic and Nephritic Syndromes

Nephrotic syndrome is the excretion of 3.5 g or more of protein in the urine per day and is characteristic of glomerular injury. It occurs when filtration of proteins exceeds tubular reabsorption. Primary causes of nephrotic syndrome include minimal change nephropathy (lipoid nephrosis) (see Chapter 31), membranous glomerulonephritis, and focal segmental glomerulosclerosis. Secondary forms of nephrotic syndrome occur in systemic diseases, including diabetes mellitus (see Chapter 19), amyloidosis, systemic lupus erythematosus, and Henoch-Schönlein purpura (see Chapter 31). Nephrotic syndrome also is associated with certain drugs (e.g., nonsteroidal anti-inflammatory drugs), infections, malignancies, and vascular disorders. When present as a secondary complication with renal diseases, nephrotic syndrome often signifies a more serious prognosis. Nephrotic syndrome is more common in children than adults (see Chapter 31).

Nephritic syndrome is hematuria and red blood cell casts in the urine. Proteinuria is usually less severe than in nephrotic syndrome. It occurs primarily with infection-related glomerulonephritis and rapidly progressive crescentic glomerulonephritis.

Pathophysiology

In nephrotic syndrome, disturbances in the glomerular basement membrane and podocyte injury lead to increased permeability to protein and loss of electrical negative charge. Loss of plasma proteins, particularly albumin and some immunoglobulins, occurs across the injured glomerular filtration membrane. Loss of plasma proteins decreases plasma oncotic pressure, resulting in edema. The predominant cause of nephrotic syndrome is minimal change nephropathy, which is common in children (see Chapter 31). Hypoalbuminemia results from urinary loss of albumin combined with a diminished synthesis of replacement albumin by the liver. Albumin is lost in the greatest quantity because of its high plasma concentration and low molecular weight. Decreased dietary intake of protein from
anorexia or malnutrition or accompanying liver disease may also contribute to lower levels of plasma albumin. Loss of albumin stimulates lipoprotein synthesis by the liver and hyperlipidemia and can promote progression of glomerular disease. Loss of immunoglobulins may increase susceptibility to infections. Sodium retention is common.\textsuperscript{52}

In nephritic syndrome, hematuria (usually microscopic) is present and red blood cell casts are present in the urine in addition to proteinuria, which is not severe. It is caused by increased permeability of the glomerular filtration membrane with pore sizes large enough to allow the passage of red blood cells and protein. Nephritic syndrome is associated with postinfectious glomerulonephritis, rapidly progressive (crescentic) glomerulonephritis, IgA nephropathy, lupus nephritis, and diabetic nephropathy. The pathophysiology is related to immune injury of the glomerulus as previously described. Hypertension and uremia occur in advanced stages of disease.

**Clinical manifestations**

Many clinical manifestations of nephrotic and nephritic syndrome are related to loss of serum proteins and associated sodium retention (Table 30-7). They include edema, hypoproteinemia, proteinuria, hyperlipidemia, lipiduria, vitamin D deficiency, and hypothyroidism.\textsuperscript{53} Vitamin D deficiency is related to loss of serum transport proteins and decreased vitamin D activation by the kidney. Hypothyroidism can result from urinary loss of thyroid-binding protein and thyroxine. Alterations in coagulation factors can cause hypercoagulability and may lead to thromboembolic events.\textsuperscript{54}

<td>Sloughing of tubular cells containing fat (oval fat bodies); free fat from hyperlipidemia</td>
<td>Fat droplets that may float in urine</td>
</tr>
</tbody>
</table>

**Evaluation and treatment**

Nephrotic syndrome is diagnosed when the protein level in a 24-hour urine collection is greater than 3.5 g. Serum albumin level decreases (to less than 3 g/dl), and concentrations of serum cholesterol, phospholipids, and triglycerides increase.
Fat bodies may be present in the urine. Nephrotic syndrome is commonly treated by consuming a moderate protein restriction (i.e., 0.8 g/kg body weight/day), low-fat, salt-restricted diet, and by prescribing diuretics. Diuretics are used to control hypertension and eliminate fluid. Care must be taken to observe for hypovolemia and hypokalemia or potassium toxicity in the presence of renal insufficiency. Spironolactone may be combined with loop diuretics to suppress aldosterone activity to conserve potassium. Heparinoids are used for prophylactic anticoagulation. Glucocorticoids are used to control immune-mediated disease or may be combined with immunosuppressive drugs. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) lower urine protein excretion.\[^{55}\]

The evaluation and treatment of nephritic syndrome are similar to those described for nephrotic syndrome. The course of glomerulonephritis is usually more severe with nephritic syndrome. High-dose corticosteroids and cyclophosphamide represent the standard therapy for rapidly progressive crescentic glomerulonephritis. The addition of plasma exchange (plasmapheresis) also may be helpful.\[^{56}\]

2. What immune mechanisms are operative in glomerulonephritis?

3. Why is edema present in individuals with nephrotic syndrome?
Acute Kidney Injury

Classification of Kidney Dysfunction

Kidney injury may be acute and rapidly progressive (within hours), and the process may be reversible. Kidney failure also can be chronic, progressing to end-stage kidney failure over a period of months or years. The terms renal insufficiency, renal failure, uremia, and azotemia are associated with decreasing renal function but are not specific in relation to the cause of kidney disease. They are often used synonymously, although with some distinctions. Generally, renal insufficiency refers to a decline in renal function to about 25% of normal or a GFR of 25 to 30 ml/minute. Levels of serum creatinine and urea are mildly elevated. The term acute kidney injury is preferred to the term acute renal failure because it captures the diverse nature of this syndrome, ranging from minimal or subtle changes in renal function to complete renal failure requiring renal replacement therapy. Renal failure refers to significant loss of renal function. When less than 10% of renal function remains, this is termed end-stage kidney disease (ESKD). Specific criteria for acute renal dysfunction are discussed in the next section. Uremia (uremic syndrome) is a syndrome of renal failure and includes elevated blood urea and creatinine levels accompanied by fatigue, anorexia, nausea, vomiting, pruritus, and neurologic changes. Uremia represents numerous consequences related to renal failure, including retention of toxic wastes, deficiency states, electrolyte disorders, and immune activation promoting a proinflammatory state. Azotemia is characterized by increased blood urea nitrogen levels (normal is 8 to 20 mg/dl) and frequently increased serum creatinine levels (normal is 0.7 to 1.4 mg/dl). Renal insufficiency or renal failure causes azotemia. Both azotemia and uremia indicate an accumulation of nitrogenous waste products in the blood, a common characteristic that explains the overlap in definitions of terms.

Acute Kidney Injury

Acute kidney injury (AKI) is a sudden decline in kidney function with a decrease in glomerular filtration and urine output with accumulation of nitrogenous waste products in the blood as demonstrated by an elevation in plasma creatinine and blood urea nitrogen levels. Classification criteria have been developed to guide the diagnosis of kidney injury and are described by the acronym RIFLE (R = risk, I = injury, F = failure, L = loss, and E = end-stage kidney disease [ESKD]), representing three levels of renal dysfunction of increasing severity (Table 30-8). A similar set of criteria have been published by the Acute Kidney Injury Network and Kidney
Disease Improving Global Outcomes.\textsuperscript{57}

### Pathophysiology

AKI results from ischemic injury related to extracellular volume depletion and decreased renal blood flow, toxic injury from chemicals, or sepsis-induced injury. The injury initiates an inflammatory response, vascular responses, and cell death. Alterations in renal function may be minimal or severe.\textsuperscript{58} Acute kidney injury can be classified as prerenal (renal hypoperfusion), intrarenal (disorders involving renal parenchymal or interstitial tissue), or postrenal (urinary tract obstructive disorders) (Table 30-9 and Figure 30-8).

</tr>
</tbody>
</table>
Prerenal acute kidney injury is the most common reason for AKI and is caused by inadequate kidney perfusion. Poor perfusion can result from hypotension, hypovolemia associated with hemorrhage or fluid loss (e.g., burns), sepsis, inadequate cardiac output (e.g., myocardial infarct [heart attack]), or renal vasoconstriction (e.g., caused by nonsteroidal anti-inflammatory drugs [NSAIDs] or radiocontrast agents) or renal artery stenosis. The GFR declines because of the decrease in filtration pressure. Failure to restore blood volume or blood pressure and oxygen delivery can cause ischemic cell injury and acute tubular necrosis or acute interstitial necrosis, a more severe form of AKI. Reperfusion injury with cell death also can occur.\(^5^9\) (see Figure 4-11). AKI can occur during chronic renal failure if a sudden stress is imposed on already marginally functioning kidneys.

Intrarenal (intrinsic) acute kidney injury can result from ischemic acute tubular necrosis (ATN) related to prerenal AKI, nephrotoxic ATN (e.g., exposure to radiocontrast media), acute glomerulonephritis, vascular disease (malignant hypertension, disseminated intravascular coagulation, and renal vasculitis), allograft rejection, or interstitial disease (drug allergy, infection, tumor growth). ATN caused by ischemia occurs most often after surgery (40% to 50% of cases) but also is associated with sepsis, obstetric complications, and severe hemorrhagic trauma or severe burns. Hypotension associated with hypovolemia produces ischemia and the inflammatory response, generating toxic oxygen free radicals that cause cellular swelling, injury, and necrosis. Intrarenal microcirculatory
vasoconstriction occurs in response to injury and inflammation. Ischemic necrosis tends to be patchy and may be distributed along any part of the nephron. Sepsis-related tubular injury can occur in the absence of hypoperfusion and may be related to inflammation and changes in microcirculation and mitochondrial function.\textsuperscript{60}

Nephrotoxic ATN can be produced by radiocontrast media and numerous antibiotics, particularly the aminoglycosides (neomycin, gentamicin, tobramycin) because these drugs accumulate in the renal cortex. Other substances, such as excessive myoglobin (oxygen-transporting substance from muscles released with crush injuries), carbon tetrachloride, heavy metals (mercury, arsenic), or methoxyflurane anesthetic, and bacterial toxins may promote renal failure. Dehydration, advanced age, concurrent renal insufficiency, and diabetes mellitus tend to enhance nephrotoxicity. Necrosis caused by nephrotoxins is usually uniform and limited to the proximal tubules.

**Postrenal acute kidney injury** is rare and usually occurs with urinary tract obstruction that affects the kidneys bilaterally (e.g., bladder outlet obstruction, prostatic hypertrophy, bilateral ureteral obstruction), tumors, or neurogenic bladder. A pattern of several hours of anuria with flank pain followed by polyuria is a characteristic finding. The obstruction causes an increase in intraluminal pressure upstream from the site of obstruction with a gradual decrease in GFR. This type of renal failure can occur after diagnostic catheterization of the ureters, a procedure that may cause edema of the tubular lumen.

**Oliguria** (<400 ml/24 hours) can occur in AKI, and three mechanisms have been proposed to account for the decrease in urine output.\textsuperscript{61} All three mechanisms probably contribute to oliguria in varying combinations and degrees throughout the course of the disease (see Figure 30-8). These mechanisms are as follows:

1. **Alterations in renal blood flow.** Efferent arteriolar vasoconstriction may be produced by intrarenal release of angiotensin II or there may be redistribution of blood flow from the cortex to the medulla. Autoregulation of blood flow may be impaired, resulting in decreased GFR. Changes in glomerular permeability and decreased GFR also may result from ischemia.

2. **Tubular obstruction.** Necrosis of the tubules causes sloughing of cells, cast formation, or ischemic edema that results in tubular obstruction, which in turn causes a retrograde increase in pressure and reduces the GFR. Renal failure can occur within 24 hours.

3. **Tubular backleak.** Glomerular filtration remains normal, but tubular reabsorption of filtrate is accelerated as a result of permeability caused by ischemia and
increased tubular pressure from obstruction.

**Clinical manifestations**

The clinical progression of AKI with recovery of renal function occurs in three overlapping phases: initiation phase, maintenance phase, and recovery phase. The *initiation phase* is the phase of reduced perfusion or toxicity in which kidney injury is evolving. Prevention of injury is possible during this phase. The *maintenance* or *oliguric phase* is the period of established kidney injury and dysfunction after the initiating event has been resolved, and may last from weeks to months. Urine output is lowest during this phase and serum creatinine and blood urea nitrogen (BUN) levels both increase. The *recovery* or *polyuric phase* is the interval when glomerular function returns but the regenerating tubules cannot concentrate the filtrate. Diuresis is common during this phase, with a decline in serum creatinine and urea concentrations and an increase in creatinine clearance.

Oliguria begins within 1 day after a hypotensive event and lasts 1 to 3 weeks, but may regress in several hours or extend for several weeks, depending on the duration of ischemia or the severity of injury or obstruction. Anuria (urine output less than 50 ml/day) is uncommon in ATN, involves both kidneys, and suggests bilateral renal artery occlusion, obstructive uropathy, or acute cortical necrosis. Renal failure can present with nonoliguric renal failure and represents less severe injury, particularly with intrinsic kidney injury associated with nephrotoxins. The urine output may vary in volume, but the BUN and plasma creatinine concentrations increase (plasma creatinine concentration is inversely proportional to the GFR). Other manifestations include hyperkalemia, hyperphosphatemia, and metabolic acidosis from decreased urine excretion. Edema and congestive heart failure can be associated with fluid retention.

As renal function improves, increase in urine volume (diuresis) is progressive. The tubules are still damaged early in the recovery phase but are recovering function. Polyuria can result in excessive loss of sodium, potassium, and water. Fluid and electrolyte balance must be carefully monitored and excessive urinary losses replaced.

Serial measurements of plasma creatinine concentration provide an index of renal function during the *recovery phase*. Return to normal status may take from 3 to 12 months, and some individuals do not have full recovery of a normal GFR or tubular function.

**Evaluation and treatment**

The diagnosis of AKI is related to the cause of the disease. A history of surgery, trauma, or cardiovascular disorders is common, and exposure to nephrotoxins,
obstructive uropathies (e.g., an enlarged prostate), or infection must be considered. The diagnostic challenge is to differentiate prerenal AKI from intrarenal AKI, and some evidence is available from urinalysis and measurement of plasma creatinine and BUN levels (Table 30-10). However, more than 50% of glomerular filtration must be lost before there is elevation of serum creatinine level. Cystatin C, a serum protein freely filtered at the glomerulus, can serve as a measure of GFR. Biomarkers are being developed to assess the extent of kidney injury before elevation of serum creatinine level. Prevention of AKI is the most important therapeutic approach and involves avoidance of hypotension, hypovolemia, and nephrotoxicity.

The primary goal of therapy is to maintain the individual's life until renal function has recovered. Management principles directly related to physiologic alterations generally include (1) correcting fluid and electrolyte disturbances, particularly hyperkalemia; (2) managing blood pressure; (3) preventing and treating infections; (4) maintaining nutrition; and (5) remembering that certain drugs or their metabolites are not excreted and can be toxic. Renal replacement therapy (hemodialysis or peritoneal dialysis) may be indicated for uncontrollable hyperkalemia, acidosis, or severe fluid overload.
Chronic Kidney Disease

**Chronic kidney disease (CKD)** is the progressive loss of renal function associated with systemic diseases, such as diabetes mellitus (most significant risk factor), hypertension, or systemic lupus erythematosus, or with intrinsic kidney diseases, such as acute kidney injury, chronic glomerulonephritis, chronic pyelonephritis, obstructive uropathies, or vascular disorders. Acute kidney injury can progress to CKD. The National Kidney Foundation defines kidney damage as a glomerular filtration rate (GFR) <60 ml/min/1.73 m$^2$ for 3 months or more, irrespective of cause. **Chronic kidney disease** is the preferred terminology and refers to declining glomerular filtration rate (GFR). The terms **renal insufficiency** and **chronic renal failure** are still often used to describe declining renal function, but they do not have the specificity of the stages based on GFR recommended by the National Kidney Foundation (Table 30-11). CKD decreases GFR and tubular functions with changes manifested throughout all organ systems (Table 30-12 and Figure 30-9).65

Pathophysiology

The kidneys have a remarkable ability to adapt to loss of nephron mass. Symptomatic changes result from increased levels of creatinine, urea, and potassium. Alterations in salt and water balance usually do not become apparent until renal function declines to less than 25% of normal when adaptive renal reserves have been exhausted.

Different theories have been proposed to account for the adaptation to loss of renal function. The intact nephron hypothesis proposes that loss of nephron mass with progressive kidney damage causes the surviving nephrons to sustain normal kidney function. These nephrons are capable of a compensatory hypertrophy and expansion or hyperfunction in their rates of filtration, reabsorption, and secretion and can maintain a constant rate of excretion in the presence of overall declining...
The intact nephron hypothesis explains adaptive changes in solute and water regulation that occur with advancing renal failure. Although the urine of an individual with chronic kidney disease may contain abnormal amounts of protein and red and white blood cells or casts, the major end products of excretion are similar to those of normally functioning kidneys until the advanced stages of renal failure, when there is a significant reduction of functioning nephrons.

With severe or repeated injury, epithelial cells have an impaired proliferative response resulting in interstitial capillary loss and fibroblast proliferation. The progressive process of glomerulosclerosis and tubulointerstitial fibrosis contributes to chronic kidney disease and end-stage kidney disease. The particular location of kidney damage also influences loss of kidney function. For example, tubular interstitial diseases damage primarily the tubular or medullary parts of the nephron, producing problems such as renal tubular acidosis, salt wasting, and difficulty diluting or concentrating the urine. When the damage is primarily vascular or glomerular, proteinuria, hematuria, and nephrotic syndrome are more prominent. A summary of factors involved in the progression of chronic kidney disease is outlined in Table 30-13 and Figure 30-10.

**TABLE 30-13**
Factors Representing Progression of Chronic Kidney Failure

<table>
<thead>
<tr>
<th>Factor</th>
<th>Characteristics</th>
</tr>
</thead>
<tbody>
<tr>
<td>Proteinuria</td>
<td>Glomerular hyperfiltration of protein contributes to tubular interstitial injury by accumulating in interstitial space and promoting inflammation and progressive fibrosis.</td>
</tr>
<tr>
<td>Creatinine and urea clearance</td>
<td>In chronic renal failure, the GFR falls and the plasma creatinine concentration increases by a reciprocal amount; because there is no regulatory adjustment for creatinine, plasma levels continue to rise and serve as an index of changing glomerular function.</td>
</tr>
<tr>
<td>Sodium and water balance</td>
<td>In chronic renal failure, sodium load delivered to nephrons exceeds normal, so excretion must increase; thus less is reabsorbed. Obligatory loss occurs, leading to sodium deficits and volume depletion. As GFR is reduced, ability to concentrate and dilute urine diminishes.</td>
</tr>
<tr>
<td>Phosphate and calcium balance</td>
<td>Changes in acid-base balance affect phosphate and calcium balance. Major disorders associated with chronic renal failure are reduced renal phosphate excretion, decreased renal synthesis of 1,25-dihydroxy-vitamin D₃, and hypocalcemia. Hypocalcemia leads to secondary hyperparathyroidism, GFR falls, and progressive hyperphosphatemia, hypocalcemia, and dissolution of bone result.</td>
</tr>
<tr>
<td>Hematocrit</td>
<td>Because of anemia that accompanies chronic renal failure, lethargy, dizziness, and low hematocrit are common.</td>
</tr>
<tr>
<td>Potassium balance</td>
<td>In chronic renal failure, tubular secretion of potassium increases until oliguria develops. Use of potassium-sparing diuretics also may precipitate elevated serum potassium levels. As disease progresses, total body potassium levels can rise to life-threatening levels and dialysis is required.</td>
</tr>
<tr>
<td>Acid-base balance</td>
<td>In early renal insufficiency, acid excretion and bicarbonate reabsorption are increased to maintain normal pH. Metabolic acidosis begins when GFR reaches 30% to 40%. Metabolic acidosis and hyperkalemia may be severe enough to require dialysis when end-stage renal failure develops.</td>
</tr>
<tr>
<td>Dyslipidemia</td>
<td>Chronic hyperlipidemia may induce glomerular and tubulointerstitial injury, contributing to progression of chronic renal disease.</td>
</tr>
</tbody>
</table>

GFR, Glomerular filtration rate.
Two factors that have consistently been recognized to advance renal disease are proteinuria and angiotensin II activity. Glomerular hyperfiltration and increased glomerular capillary permeability and loss of negative charge lead to proteinuria. Proteinuria contributes to tubulointerstitial injury by accumulating in the interstitial space of the nephron tubules and activating complement proteins and other mediators and cells, such as macrophages, that promote inflammation and progressive fibrosis. Angiotensin II (from activation of the renin-angiotensin-aldosterone system [RAAS]) promotes glomerular hypertension and hyperfiltration caused by efferent arteriolar vasoconstriction and also promotes systemic hypertension. The chronically high intraglomerular pressure increases glomerular
capillary permeability, contributing to proteinuria. Angiotensin II also may promote the activity of inflammatory cells and growth factors that participate in tubulointerstitial fibrosis and scarring.\textsuperscript{70}

**Clinical manifestations**

The clinical manifestations of chronic kidney disease include uremia and azotemia (see p. 760) with many systemic effects.\textsuperscript{71} The many systemic manifestations associated with chronic kidney disease are discussed in the following sections and summarized in Table 30-12 and Figure 30-9.

**Creatinine and Urea Clearance**

*Creatinine* is constantly released from muscle and excreted primarily by glomerular filtration. In chronic kidney disease (CKD), as glomerular filtration rate (GFR) declines, the plasma creatinine level increases by a reciprocal amount to maintain a constant rate of excretion. As GFR continues to decline, plasma creatinine concentration increases. The clearance of *urea* follows a similar pattern, but urea is both filtered and reabsorbed and its level varies with the state of hydration; therefore urea concentration is not a good index of GFR. However, as the GFR decreases, plasma urea concentration also increases.

**Fluid and Electrolyte Balance**

Fluid and electrolyte and acid-base balance is significantly disturbed with chronic kidney disease. When the GFR decreases to 25%, there is an adaptive loss of 20 to 40 mEq of *sodium* per day with osmotic loss of water. Dietary intake must be maintained to prevent sodium deficits and volume depletion. As GFR continues to decline, there also is loss of tubular function to dilute and concentrate the urine and urine specific gravity becomes fixed at about 1.010. Ultimately the kidney loses its ability to regulate sodium and water balance. Both sodium and water are retained, contributing to edema, proteinuria, and hypertension.

In early kidney failure, tubular secretion of *potassium* is maintained and larger amounts of potassium are lost through the bowel. With the onset of oliguria, total body potassium concentration can increase to life-threatening levels and must be controlled by dialysis.

*Metabolic acidosis* develops when the GFR decreases to less than 20% to 25% of normal. The causes of acidosis are primarily related to decreased hydrogen ion elimination and decreased bicarbonate reabsorption. With end-stage kidney disease, metabolic acidosis may be severe enough to require alkali therapy and dialysis.\textsuperscript{72}
Calcium, Phosphate, and Bone

Bone and skeletal changes develop with alterations in calcium and phosphate metabolism. These changes begin when the GFR decreases to 25% or less. Hypocalcemia is accelerated by impaired renal synthesis of 1,25-dihydroxy-vitamin D₃ (calcitriol) with decreased intestinal absorption of calcium. Renal phosphate excretion also decreases and the increased serum phosphate binds calcium, further contributing to hypocalcemia. Acidosis also contributes to a negative calcium balance. Decreased serum calcium level stimulates parathyroid hormone secretion with mobilization of calcium from bone. The combined effect of hyperparathyroidism related to elevated phosphate levels and vitamin D deficiency can result in renal osteodystrophies (i.e., osteoporosis, osteomalacia, and osteitis fibrosa) with increased risk for fractures.⁷³

Protein, Carbohydrate, and Fat Metabolism

Protein, carbohydrate, and fat metabolism are altered in CKD. Proteinuria, metabolic acidosis, inflammation, and a catabolic state contribute to a negative nitrogen balance. Levels of serum proteins diminish, including albumin, complement, and transferrin, and there is loss of muscle mass. Insulin resistance and glucose intolerance are common and may be related to proinflammatory cytokines, and alterations in adipokines (high leptin and low adiponectin levels) that interfere with insulin action.⁷⁴ Dyslipidemia is common among individuals with CKD. There is a high ratio of low-density lipoprotein (LDL) to high-density lipoprotein (HDL), a high level of triglycerides, and an accumulation of LDL particles with accelerated atherosclerosis and vascular calcification. Uremia causes a deficiency in lipoprotein lipase and a decreased level of hepatic triglyceride lipase. Decreased lipolytic activity results in a reduction in HDL level. The concentration of apolipoprotein B is also elevated, thereby accelerating atherogenesis.⁷⁵

Cardiovascular System

Cardiovascular disease is a major cause of morbidity and mortality in CKD. Proinflammatory cytokines, oxidative stress, metabolic derangements, and uremic toxins are significant contributors. Hypertension is the result of excess sodium and fluid volume and arteriosclerosis. Endothelial cell dysfunction and calcium deposits lead to a loss of vessel elasticity and vascular calcification. Elevated renin concentration also stimulates the secretion of aldosterone, increasing sodium
reabsorption. **Dyslipidemia** promotes atheromatous plaque formation. The resulting vascular disease increases the risk for *ischemic heart disease, left ventricular hypertrophy, congestive heart failure, stroke, and peripheral vascular disease* in individuals with uremia. Declining erythropoietin production causes anemia, thereby increasing demands for cardiac output and adding to the cardiac workload. *Pericarditis* can develop from inflammation caused by the presence of uremic toxins. Accumulation of fluid in the pericardial space can compromise ventricular filling and cardiac output. Fluid overload and hypertension can promote congestive heart failure (cardiorenal syndrome).

**Pulmonary System**

Pulmonary complications are associated with fluid overload, congestive heart failure, and dyspnea. Pulmonary edema develops and metabolic acidosis can cause Kussmaul respirations. Pulmonary hypertension can develop because of left ventricular dysfunction or uremic-associated vascular changes.

**Hematologic System**

Hematologic alterations include *normochromic-normocytic anemia, impaired platelet function, and hypercoagulability*. Inadequate production of erythropoietin decreases red blood cell production and uremia decreases red blood cell life span. Lethargy, dizziness, and low hematocrit values are common findings. Defective platelet aggregation, decreased platelet numbers, and altered vascular endothelium promote an increased bleeding tendency, increased risk for bruising, epistaxis, gastrointestinal bleeding, or cerebrovascular hemorrhage. Alterations in thrombin and other clotting factors contribute to hypercoagulability; thus control of coagulation is essential during dialysis.

**Immune System**

Immune system dysregulation develops with the uremia of CRF. Chemotaxis, phagocytosis, antibody production, and cell-mediated immune responses are suppressed. Malnutrition, metabolic acidosis, and hyperglycemia may amplify immunosuppression. Release of inflammatory cytokines results in systemic inflammation. Failure of antioxidant systems also promotes inflammation. There are deficient responses to vaccination, increased risk for infection, and virus-associated cancers (e.g., human papillomavirus, hepatitis B and C viruses, Epstein-Barr virus).
Neurologic System

Neurologic symptoms are common and progressive with CKD. Symptoms may include headache, pain, drowsiness, sleep disorders, impaired concentration, memory loss, and impaired judgment (known as uremic encephalopathy). In advanced stages of renal failure, symptoms may progress to seizures and coma. Neuromuscular irritation can cause hiccups, muscle cramps, and muscle twitching. Peripheral neuropathies associated with uremic toxins also can develop with impaired sensations, particularly in the lower limbs. Symptoms improve with hemodialysis.\(^7^9\)

Gastrointestinal System

Gastrointestinal complications are common in individuals with CKD. Uremic gastroenteritis can cause bleeding ulcer and significant blood loss. Nonspecific symptoms include anorexia, nausea, vomiting, constipation, or diarrhea. Uremic fetor is a form of bad breath caused by the breakdown of urea by salivary enzymes. Malnutrition is common.\(^8^0\)

Endocrine and Reproductive Systems

Endocrine and reproductive alterations develop with progression of CKD. Both males and females have a decrease in levels of circulating sex steroids. Males often experience a reduction in testosterone levels and may be impotent. Oligospermia and germinal cell dysplasia can result in infertility. Females have reduced estrogen levels, amenorrhea, and difficulty maintaining a pregnancy to term.\(^8^1\) A decrease in libido and fertility can occur in both genders.\(^8^2\)

Insulin resistance is common in uremia, and as CKD progresses the ability of the kidney to degrade insulin is reduced and the half-life of insulin is prolonged. Individuals with diabetes mellitus and CRF need to carefully manage their insulin dosages.\(^8^3\)

CRF also causes alterations in thyroid hormone metabolism, particularly hypothyroidism, known as nonthyroidal illness syndrome. Uremia delays the response of thyroid-stimulating hormone receptors and triiodothyronine (T\(_3\)) levels are often low.\(^8^4\)

Integumentary System

Skin changes are associated with other complications that develop with CKD.
Anemia can cause pallor and bleeding into the skin and results in hematomas and ecchymosis. Retained urochromes manifest as a sallow skin color. Hyperparathyroidism and uremic skin residues (known as uremic frost) are associated with inflammation, irritation, and pruritus with scratching, excoriation, and increased risk for infection. Half-and-half nails (half white and half red or brown) are common. Local bullous lesions and nephrogenic systemic fibrosis are less common.85

**Evaluation and treatment**

Early screening and evaluation of CKD is based on the risk factors, history, presenting signs and symptoms, and diagnostic testing. Elevated serum creatinine and serum urea nitrogen concentrations are consistent with chronic renal failure. Markers of kidney damage include measurement of urine protein level, particularly albumin, and examination of urine sediment. Ultrasound, CT scan, or plain x-ray films will show small kidney size. Renal biopsy confirms the diagnosis.

Management involves dietary restriction of protein, sodium, potassium, and phosphate, supplementation with vitamin D or vitamin D receptor activators, maintenance of sodium and fluid balance, restriction of potassium, promotion of adequate caloric intake, management of dyslipidemias, and use of erythropoietin as needed. Angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers are often used to control systemic hypertension, reduce proteinuria, provide renoprotection, and prevent progressive renal damage.86,87

End-stage renal failure related to diabetic nephropathy can be significantly reduced with glycemic control.83 End-stage renal failure is treated with conservative care, continuous renal replacement therapy, supportive therapy, and renal transplantation.88,89 Portable and wearable dialysis devices are in clinical trials.90

***Quick Check 30-4***

1. What mechanisms cause prerenal acute renal failure?

2. How does intrarenal acute renal failure differ from postrenal failure?

3. Briefly describe the causes of anemia, cardiovascular disease, and bone and neurologic changes associated with chronic renal failure.
Did You Understand?
Urinary Tract Obstruction

1. Obstruction can occur anywhere in the urinary tract, and it may be anatomic or functional, including renal stones, an enlarged prostate gland, urethral strictures, or neurogenic bladder. The most serious complications are hydronephrosis, hydroureter, ureterohydronephrosis, and infection caused by the accumulation of urine behind the obstruction.

2. Hypertrophy of the opposite kidney compensates for loss of function of the kidney with obstructive disease.

3. Relief of obstruction is usually followed by postobstructive diuresis and may cause fluid and electrolyte imbalance.

4. Persistent obstruction of the bladder outlet leads to residual urine volumes, low bladder wall compliance, and risk for vesicoureteral reflux and infection.

5. Kidney stones are caused by supersaturation of the urine with precipitation of stone-forming substances, changes in urine pH, or urinary tract infection.

6. The most common kidney stone is formed from calcium oxalate and most often causes obstruction by lodging in the ureter.

7. Obstructions of the bladder are a consequence of neurogenic or anatomic alteration of the bladder, or both.

8. A neurogenic bladder is caused by a neural lesion that interrupts innervation of the bladder.

9. Upper motor neuron lesions result in overactive or hyperreflexive bladder function.

10. Lower motor neuron lesions result in underactive, hypotonic, or atonic bladder function.

11. Underactive bladder (UAB) is a condition in which the duration or strength of contraction is inadequate to empty the bladder, resulting in distention and overflow incontinence.
12. Overactive bladder (OAB) syndrome is an uncontrollable or premature contraction of the bladder that results in urgency with or without incontinence, frequency, and nocturia.

13. Detrusor sphincter dyssynergia is failure of the urethrovesical junction smooth muscle to release urine during bladder contraction and causes a functional obstruction.

14. Other causes of lower urinary tract obstruction include prostatic enlargement, urethral stricture, and pelvic organ prolapse in women.

15. Partial obstruction of the bladder can result in overactive bladder contractions with urgency. There is deposition of collagen in the bladder wall over time, resulting in decreased bladder wall compliance and ineffective detrusor muscle contraction.

16. Renal cell carcinoma is the most common renal neoplasm and usually presents with hematuria. The larger neoplasms tend to metastasize to the lung, liver, and bone.

17. Bladder tumors are commonly composed of transitional cells with a papillary appearance and a high rate of recurrence.

**Urinary Tract Infection**

1. Urinary tract infections (UTIs) are commonly caused by the retrograde movement of bacteria into the urethra and bladder. UTIs are uncomplicated when the urinary system is normal or complicated when there is an abnormality.

2. Cystitis is an inflammation of the bladder commonly caused by bacteria and may be acute or chronic.

3. Painful bladder syndrome/interstitial cystitis includes nonbacterial infectious cystitis (viral, mycobacterial, chlamydial, fungal), noninfectious cystitis (i.e., radiation injury), and interstitial cystitis, which is related to autoimmune injury.

4. Pyelonephritis is an acute or chronic inflammation of the renal pelvis often related to obstructive uropathies and may cause abscess formation and scarring with an alteration in renal function.
Glomerular Disorders

1. Glomerular disorders are a group of related diseases of the glomerulus that can be caused by immune responses, toxins or drugs, vascular disorders, and other systemic diseases.

2. Acute glomerulonephritis commonly results from inflammatory damage to the glomerular filtration membrane as a consequence of immune reactions after a streptococcal infection.

3. Immune mechanisms in glomerulonephritis include the deposition of circulating antigen-antibody complexes often with complement components or the in situ formation of antibodies, or both, specific for the glomerular basement membrane.

4. Diabetic nephropathy is the most common cause of glomerular injury progressing to chronic kidney disease.

5. Chronic glomerulonephritis is related to a variety of diseases that cause deterioration of the glomerulus and a progressive loss of renal function.

6. Nephrotic syndrome is the excretion of at least 3.5 g of protein (primarily albumin) in the urine per day because of glomerular injury with increased capillary permeability and loss of membrane negative charge. Its principal signs are hypoproteinuria, hyperlipidemia, and edema. The liver cannot produce enough protein to adequately compensate for urinary loss.

7. Nephritic syndrome is characterized by hematuria and red blood cell casts with less severe proteinuria.

Acute Kidney Injury

1. Acute kidney injury is a sudden decline in kidney function with a decrease in GFR and urine output and with an elevation in plasma creatinine and blood urea nitrogen levels.

2. Prerenal acute kidney injury is caused by decreased renal perfusion with a decreased GFR, ischemia, and tubular necrosis.

3. Intrarenal acute kidney injury is associated with several systemic diseases but is
commonly related to acute tubular necrosis (ATN).

4. Postrenal kidney injury is associated with diseases that obstruct the flow of urine from the kidneys.

5. Oliguria is urine output that is less than 400 ml/24 hours.

**Chronic Kidney Disease**

1. Chronic kidney disease is the progressive loss of renal function. Plasma creatinine levels gradually become elevated as GFR declines; sodium is lost in the urine; potassium is retained; acidosis develops; calcium and phosphate metabolism are altered; and erythropoietin production is diminished. All organs systems are affected by CRF.

The incidence and type of renal and urinary tract disorders experienced by children vary with age and maturation. Newborn disorders may involve congenital malformations. During childhood, the kidney and genitourinary structures continue to develop, so renal dysfunction may be associated with mechanisms and manifestations that differ from those found in adults.
Structural Abnormalities

Congenital abnormalities of the kidney and urinary tract occur in about 1% to 2% of newborns. These abnormalities range from minor, nonpathologic, or easily correctable anomalies to those that are incompatible with life. For example, the kidneys may fail to ascend from the pelvis to the abdomen, causing ectopic kidneys—which usually function normally. The kidneys may fuse as they ascend, causing a single, U-shaped horseshoe kidney. Approximately one third of individuals with horseshoe kidneys are asymptomatic, with the most common problems being hydronephrosis, infection, stone formation, and, rarely, renal malignancies. Collectively, structural anomalies of the renal system account for approximately 45% of cases of renal failure in children in developed countries. Many are linked to gene defects. Certain structural anomalies are associated with urinary tract malformations, including:

- Low-set, malformed ears
- Sensorineural deafness
- Chromosomal disorders, including trisomy 13 (Patau syndrome) and trisomy 18 (Edward syndrome)
- Absent abdominal muscles (prune-belly syndrome)
- Anomalies of the spinal cord and lower and upper extremities
- Imperforate anus and Hirschsprung disease
- Optic nerve coloboma (hole)
- Nephroblastoma (Wilms tumor)
- Cystic disease of the liver

Hypospadias

Hypospadias is a congenital condition in which the urethral meatus is located on the ventral side or undersurface of the penis. The meatus can be located anywhere on the glans, on the penile shaft, at the base of the penis, at the penoscrotal junction, or in the perineum (Figure 31-1). This is the most common anomaly of the penis; it
occurs in about 1 in 300 infant boys. The cause of this condition is multifactorial and includes genetic, endocrine, and environmental factors. Advanced maternal age and low birth weight also have been implicated. **Chordee (penile torsion)** may accompany cases of hypospadias. In chordee, skin tethering and shortening of subcutaneous tissue cause the penis to bend or “bow ventrally” (Figure 31-2). Penile torsion is rotation of the penile shaft to either the right or the left. Partial absence of the foreskin and cryptorchidism (undescended testes; see Chapter 32) are associated with the anomaly.
The goals for corrective surgery on the child with hypospadias are (1) a straight penis when erect to facilitate intercourse as an adult, (2) a uniform urethra of adequate caliber to prevent spraying during urination, (3) a cosmetic appearance satisfactory to the individual, and (4) repair completed in as few procedures as possible. Surgery is most effective, psychologically as well as physically, when performed between 6 and 12 months of age.9

**Epispadias and Exstrophy of the Bladder**

**Epispadias** and extrophy of the bladder are the same congenital defect expressed to differing degrees. In male epispadias, the urethral opening is on the dorsal surface of the penis. In females, a cleft along the ventral urethra usually extends to the bladder neck. The incidence of epispadias is about 9.25 per 100,000 in-hospital live births.10 This is seen predominantly in males.

In boys, the urethral opening may be small and situated behind the glans (anterior epispadias), or a fissure may extend the entire length of the penis and into the bladder neck (posterior epispadias). Continence is determined in part by the location of the defect, with urinary incontinence rates of up to 75% in children with distal
Epispadias. Treatment is surgical reconstruction.

**Exstrophy of the bladder** is a rare, extensive congenital anomaly of herniation of the bladder through the abdominal wall. The bony part of the pelvis remains open (Figure 31-3), and the posterior portion of the bladder mucosa is exposed through the abdominal opening and appears bright red. The incidence of bladder extrophy in the United States is about 1.7 per 100,000 live births. Studies vary widely concerning male versus female prevalence.

Exstrophy of the bladder is caused by intrauterine failure of the abdominal wall and the mesoderm of the anterior bladder to fuse. The rectus muscles below the umbilicus are separated, and the pubic rami (bony projections of the pubic bone) are not joined. This causes a waddling gait when the child first learns to walk, but most children quickly learn to compensate. The clitoris in girls is divided into two parts with the urethra between each half. The penis in boys is epispadiac. Urine seeps onto the abdominal wall from the ureters, causing a constant odor of urine and excoriation of the surrounding skin. Because the exposed bladder mucosa becomes hyperemic and edematous, it bleeds easily and is painful.

The unrepaired extrophic bladder is prone to cancerous changes as soon as 1 year after birth. Ideally, the bladder and pubic defect should be closed before the infant is 72 hours old. Surgical reconstruction is usually performed within the first year either as a complete primary repair or as staged procedures. Staged procedures may include bladder augmentation, bladder neck reconstruction, and epispadias.

**FIGURE 31-3  Exstrophy of Bladder.** (Courtesy H. Gil Rushton, MD, Children’s National Medical Center, Washington, DC; from Hockenberry MJ, Wilson D: Wong’s nursing care of infants and children, ed 10, St Louis, 2015, Mosby.)
Objectives of management include preservation of renal function, attainment of urinary control, prevention of infection, and improvement of sexual function. Diagnosis is often made by prenatal ultrasound. 

Cloacal extrophy is the most rare and severe form of bladder extrophy. The intestine and spine may be involved, and reconstruction with restored urine and fecal control is difficult.

**Bladder Outlet Obstruction**

Congenital causes of bladder outlet obstruction are rare and include urethral valves and polyps. A **urethral valve** is a thin membrane of tissue that occludes the urethral lumen and obstructs urinary outflow in males. Most valves occur in the posterior urethra, although a few arise from the embryologically distinct anterior urethra. **Urethral polyps** are rare. The timing and presentation of these conditions depend on the degree of obstruction they cause. Severe obstruction may impair renal embryogenesis and lead to renal failure. Urethral valves or polyps are resected as soon as they are diagnosed.

**Ureteropelvic Junction Obstruction**

**Ureteropelvic junction (UPJ) obstruction** is a blockage of the tapered point where the renal pelvis transitions into the ureter. UPJ obstruction is the most common cause of hydronephrosis in neonates. An intrinsic malformation of smooth muscle or urothelial development produces obstruction in the majority of cases. Extrinsic compression abnormalities are less common. **Secondary ureteropelvic junction obstruction** is caused by kinking or secondary scarring in the presence of high-grade vesicoureteral reflux (see p. 775). There is an increased risk of vesicoureteral reflux in children with UPJ obstruction in the obstructed or contralateral kidney, or both; whether this represents a sequela of the embryonic defect leading to the UPJ defect is not known. Diagnosis of a UPJ obstruction can be made by ultrasound. Obstruction of the distal ureter (**ureterovesical junction obstruction**) causes dilation of the entire ureter, renal pelvis, and calyceal system. An **ureterocele** is a cystic dilation of the intravesical ureter. Open or endoscopic surgery to relieve an obstruction occurs if there is decline of renal drainage or function.

**Hypoplastic/Dysplastic Kidneys**

During embryologic development, the ureteric duct grows into the metanephric tissue, triggering the formation of the kidneys. If this growth does not occur, the
kidney is absent—a condition called **renal aplasia**. A **hypoplastic kidney** is small with a decreased number of nephrons. These conditions may be unilateral or bilateral; the occurrence may be incidental or familial. Bilateral hypoplastic kidneys are a common cause of chronic renal failure in children. Segmental hypoplasia—the **Ask-Upmark kidney**—may be congenital or secondary to vesicoureteral reflux. Systemic hypertension is a common presentation.

**Renal dysplasia** usually results from abnormal differentiation of the renal tissues; for example, primitive glomeruli and tubules, cysts, and nonrenal tissue (such as cartilage) are found in the dysplastic kidney. Dysplasia may be secondary to antenatal obstruction of the urinary tract from ureteroceles, posterior urethral valves, or prune-belly syndrome (congenital absence of abdominal muscles).

### Polycystic Kidney Disease

**Polycystic kidney disease (PKD)** is an autosomal dominant disease (PDK1 or PDK2 gene) occurring in 1 of 1000 live births, or an autosomal recessive (PKHD1 gene) inherited disorder with an incidence of 1 in 20,000 to 1 in 40,000. Affected kidneys have multiple cysts that interfere with renal function. Autosomal dominant PKD (ADPKD) usually presents in late childhood or adulthood with the development of cysts. Defects in the formation of epithelial cells and their cilia result in cyst formation in all parts of the nephron. Cysts in other organs, including the liver, pancreas, and ovaries, may occur. Hypertension, aortic and intracranial aneurysms, and heart valve defects may develop. Autosomal recessive PKD (ARPKD) is often first suspected on a prenatal ultrasound. Epithelial hyperplasia and fluid secretion result in collecting duct cysts. Hepatic disease and hypertension typically accompany PKD. Clinical trials for various potential treatment modalities are ongoing.

### Renal Agenesis

**Renal agenesis** (the absence of one or both kidneys) may be unilateral or bilateral, and may occur randomly or be hereditary. It may be an isolated entity or be associated with anomalies in other organs.

**Unilateral renal agenesis** occurs in approximately 1 in 1000 live births. Males are more often affected, and it is usually the left kidney that is absent. The single remaining kidney is often completely normal so that the child can expect a normal, healthy life. By the time the child is several years old, the volume of this kidney may approach twice the normal size to compensate for the absence of a second kidney. In some instances, however, the single kidney is abnormally formed and associated
with abnormalities of its collecting system. Because the child has a decreased number of nephrons, there is a risk of “hyperfiltration injury,” increasing the chance of developing proteinuria, hypertension, and chronic kidney disease. Extrarenal congenital abnormalities of the urogenital, skeletal, cardiac, and other systems may coexist.

_Bilateral renal agenesis_ is a rare disorder incompatible with extrauterine life. Approximately 75% of affected children are males. **Oligohydramnios** (low amount of amniotic fluid) resulting from inadequate fetal urine production leads to underdeveloped lungs and **Potter syndrome** (wide-set eyes, parrot-beak nose, low-set ears, and receding chin). Approximately 40% of affected infants are stillborn. Infants with this condition rarely live more than 24 hours because of pulmonary insufficiency. Renal agenesis can be detected prenatally by ultrasound.

†Quick Check 31-1

1. Describe hypospadias.

2. Why does bladder exstrophy occur?

Glomerular Disorders

Common glomerular disorders in children are glomerulonephritis, nephrotic syndrome, immunoglobulin A (IgA) nephropathy, and hemolytic uremic syndrome. Most glomerular diseases are acquired and immunologically mediated (see Chapter 30 and Figure 30-6, and Tables 29-5 and 29-7). The disease can be acute or chronic. The likelihood of developing renal failure depends on the specific condition.

Glomerulonephritis

Glomerulonephritis includes a number of renal disorders in which proliferation and inflammation of the glomeruli are secondary to an immune mechanism (the pathophysiology is described in Chapter 30). Chronic glomerulonephritis accounts for about 14% of the cases of renal failure in children in the United States\(^3\) and is the causative factor for 9% to 35% of end-stage renal disease in children worldwide.\(^24\)

Acute Poststreptococcal Glomerulonephritis

Acute poststreptococcal glomerulonephritis (APGN) is one of the most common immune complex–mediated renal diseases in children. It most commonly occurs after a throat or skin infection with a nephritogenic strain of group A \(\beta\)-hemolytic streptococci, although other bacteria and viruses also may be responsible.\(^25\) Occurrences have been observed after bacterial endocarditis, which may be associated with streptococcal or staphylococcal microorganisms, or after viral diseases, such as varicella-zoster virus and hepatitides B and C. Glomerulonephritis develops with the deposition of antigen-antibody complexes in the glomerulus. The antigen-antibody complex activates complement and the release of inflammatory mediators that damage endothelial and epithelial cells lying on the glomerular basement membrane. Damage to the glomerular basement membrane leads to hematuria and proteinuria.

Symptoms usually begin 1 to 2 weeks after an upper respiratory tract infection (more common during cold weather) and up to 6 weeks after skin infections such as impetigo (more common during warm weather).

The onset of symptoms is abrupt, varying with disease severity. The child typically has gross or microscopic hematuria, proteinuria, edema, and renal insufficiency. Oliguria may be present. Hypertension occurs because of increased vascular volume. Acute hypertension may cause headache, vomiting, somnolence, and other central nervous system manifestations. Cardiovascular symptoms are related to circulatory overload and are compounded by hypertension. These include dyspnea, tachypnea, and an enlarged, tender liver. The most severely affected
children develop acute renal failure with oliguria. As many as half of affected children are asymptomatic. The disease usually runs its course in 1 month, but urine abnormalities may be found for up to 1 year or longer after the onset. Prolonged proteinuria and abnormal glomerular filtration rate (GFR) indicate an unfavorable prognosis. More than 95% of affected children recover completely. Less than 1% of children develop end-stage renal disease. Treatment is supportive and symptom specific.

**Immunoglobulin A Nephropathy**

**Immunoglobulin A (IgA) nephropathy** is the most common form of glomerulonephritis worldwide and occurs more often in males. It is characterized by deposition primarily of immunoglobulin A and complement proteins in the mesangium of the glomerulus. Children with the disease have recurrent gross hematuria concurrent with a respiratory tract infection. Most continue to have microscopic hematuria between the attacks of gross hematuria and have a mild proteinuria as well. Treatment is supportive. Some children recover completely, whereas 20% or more will eventually require dialysis and transplantation. IgA nephropathy may recur following transplantation.

**Henoch-Schönlein purpura nephritis** is a particular form of IgA nephropathy that involves a systemic vasculitis. Symptoms vary widely. In addition to palpable purpura, children may experience abdominal pain, arthralgia, hematuria, and/or proteinuria. Complete recovery may occur, but some children progress to end-stage kidney disease.

**Nephrotic Syndrome**

Nephrotic syndrome is characterized by severe proteinuria, hypoalbuminemia, hyperlipidemia, and edema. The syndrome is more common in children than in adults. When no identifiable cause is found, the condition is *primary (idiopathic) nephrotic syndrome*. If it results from a systemic disease or other causes (e.g., drugs, toxins), it is called *secondary nephrotic syndrome*. Primary nephrotic syndrome is found predominantly in the preschool-age child, with a peak incidence of onset between 2 and 3 years of age. It is rare after 8 years of age. Boys are affected more often than girls. No prevalent racial or geographic distributions are evident. The incidence is approximately 3 per 100,000 children per year.

**Pathophysiology**

The most common causes of primary nephrotic syndrome in children are minimal
change nephropathy and focal segmental glomerulosclerosis. **Minimal change nephropathy (MCN) (lipoid nephrosis)** is characterized by fusion of the glomerular podocyte foot processes, which are seen by electron microscopy. The glomeruli appear normal by light microscopy. A systemic immune mechanism is a likely cause of the disease, but the true etiology is unknown. An unidentified circulating permeability factor released by T lymphocytes has been proposed.\(^{30}\) Loss of the electrical negative charge and increased permeability within the glomerular capillary wall lead to albuminuria. Hypoalbuminemia (causing decreased plasma oncotic pressure) and sodium retention contribute to edema.\(^{31}\) Hyperlipidemia leads to hyperlipiduria and primarily results from increased hepatic lipid synthesis and decreased plasma lipid catabolism.

In idiopathic **focal segmental glomerulosclerosis (FSGS)**, there is segmental loss of glomerular capillaries with proliferation of the mesangial matrix and adhesion of the capillaries to Bowman capsule.

**Clinical manifestations**

Onset of nephrotic syndrome can be insidious, with periorbital edema as the usual first sign. The edema is most noticeable in the morning and subsides during the day as fluid shifts to the abdomen, genitalia, and lower extremities. Parents may notice diminished, frothy, or foamy urine output; or when edema becomes pronounced with ascites, respiratory difficulty from pleural effusion or labial or scrotal swelling may occur. Edema of the intestinal mucosa may cause diarrhea, anorexia, and poor absorption. Edema often masks the malnutrition caused by malabsorption and protein loss. Pallor, with shiny skin and prominent veins, also is common. Blood pressure is usually normal. The child has an increased susceptibility to infection, especially pneumonia, peritonitis, cellulitis, and septicemia. Irritability, fatigue, and lethargy are common. **Congenital nephrotic syndrome (Finnish type)** is caused by an autosomal recessive mutation of the *NPHS1* gene that encodes an immunoglobulin-like protein, nephrin, at the podocyte slit membrane.\(^{32}\) Congenital nephrotic syndrome (Finnish type) presents with heavy proteinuria, hypoproteinemia, and edema in the first 3 months of life. These babies do not respond to steroid treatment and require albumin infusion and diuretics.\(^{33}\)

**Evaluation and treatment**

The diagnosis of nephrotic syndrome is evident from the findings of proteinuria, hyperlipidemia, and edema. Diagnostic testing, including kidney biopsy, may be required to determine whether the cause is an intrinsic renal disease or a consequence of systemic disease. Basic management of nephrotic syndrome includes administering glucocorticosteroids (prednisone); adhering to a low-
sodium, well-balanced diet; performing good skin care; and, if edema becomes problematic, prescribing diuretics (furosemide, metolazone). Immunosuppressive agents (i.e., cyclophosphamide) may be used with children who have frequent relapses or who are resistant to steroid therapy. Long-term outcomes depend on the underlying cause of the nephrotic syndrome. Children with minimal change disease tend to do very well, whereas those with other conditions may develop end-stage kidney disease.

**Hemolytic Uremic Syndrome**

**Hemolytic uremic syndrome (HUS)** is an acute disorder characterized by hemolytic anemia, thrombocytopenia, and acute renal failure. HUS is the most common cause of acute renal failure in children. The disease occurs most often in infants and children younger than 4 years of age but has been known to occur in adolescents and adults.

**Pathophysiology**

HUS has been associated with bacterial and viral agents, as well as endotoxins, especially that from *Escherichia coli* 0157:H7 and more recently *Escherichia coli* 0104:H4 (Shiga toxins).\(^{34}\) In HUS, the endothelial lining of the glomerular arterioles becomes swollen and occluded with platelets and fibrin clots. Narrowed vessels damage passing erythrocytes. These damaged red blood cells are removed by the spleen, causing acute hemolytic anemia. Fibrinolysis, the process of dissolution of a clot, acts on precipitated fibrin, causing the fibrin split products to appear in serum and urine. Platelet thrombi develop within damaged vessels, and platelet removal produces thrombocytopenia. Varying degrees of vascular occlusion cause altered renal perfusion and renal insufficiency or failure.\(^{35}\)

**Clinical manifestations**

A prodromal gastrointestinal illness (fever, vomiting, diarrhea) or, less frequently, an upper respiratory tract infection often precedes the onset of HUS by 1 to 2 weeks. After a symptom-free 1- to 5-day period, the sudden onset of pallor, bruising or purpura, irritability, and oliguria heralds the commencement of the disease. Slight fever, anorexia, vomiting, diarrhea (with the stool characteristically watery and blood stained), abdominal pain, mild jaundice, and circulatory overload are accompanying symptoms. Seizures and lethargy indicate central nervous system (CNS) involvement. Renal failure is apparent within the first days of onset. The renal failure causes metabolic acidosis, azotemia, hyperkalemia, and often hypertension.
Evaluation and treatment

Clinical evaluation includes history of preexisting illness, presenting symptoms, and urine and blood analysis. Management is supportive. When renal failure occurs, dialysis is indicated. Blood transfusions with packed red cells are needed to maintain reasonable hemoglobin levels. Seventy percent of children recover completely. Potential long-term sequelae include renal (hypertension, proteinuria, chronic kidney disease, and end-stage kidney disease) and nonrenal abnormalities (diabetes mellitus, neurologic manifestations). In cases unresponsive to treatment, splenectomy may be indicated.36
Nephroblastoma

Nephroblastoma (Wilms tumor) is a rare embryonal tumor of the kidney arising from undifferentiated mesoderm and represents 5% of childhood cancers in the United States. Approximately 500 children are diagnosed each year in the United States, most younger than 5 years of age. The peak incidence occurs between 2 and 3 years of age. Nephroblastoma is slightly more common in black children than in white children. Maternal preconception toxin exposure (e.g., pesticides) may be associated with increased risk in offspring.

Pathogenesis

Nephroblastoma has both sporadic and inherited origins. The sporadic form occurs in children with no known genetic predisposition. Inherited cases, which are relatively rare, are transmitted in an autosomal dominant fashion. Syndromic and nonsyndromic causes of nephroblastoma have been linked to mutation of several tumor-suppressor genes (i.e., WT1 and WT2 mutations). Eighteen percent of children who have nephroblastoma also have other congenital anomalies. The anomalies associated with nephroblastoma include aniridia (lack of an iris in the eye), hemihyperplasia (an asymmetry of the body), and genitourinary malformations (i.e., horseshoe kidneys, hypospadias, ureteral duplication, polycystic kidneys). Children with both congenital anomalies and nephroblastoma are more likely to have the inherited bilateral form of the disease.

Clinical manifestations

Most children with nephroblastoma present with an enlarging asymptomatic abdominal mass before the age of 5 years. Many tumors are actually discovered by the child's parent, who feels or notices an abdominal swelling, usually while dressing or bathing the child. The child appears healthy and thriving. Other presenting complaints include vague abdominal pain, hematuria, anemia, and fever. Hypertension may be present, often as a result of excessive renin secretion by the tumor.

Nephroblastoma may occur in any part of the kidney and varies greatly in size at the time of diagnosis. The tumor generally appears as a solitary mass surrounded by a smooth, fibrous external capsule and also may contain cystic or hemorrhagic areas. A pseudocapsule generally separates the tumor from the renal parenchyma.

Evaluation and treatment

On physical examination, the tumor feels firm, nontender, and smooth, and is generally confined to one side of the abdomen. If the tumor is palpable past the
midline of the abdomen, it may be large or may be arising from a horseshoe or ectopic kidney. Once an abdominal mass is detected, diagnostic imaging demonstrates a solid intrarenal mass.

Diagnosis is based on surgical biopsy. Imaging studies are used to evaluate the presence or absence of metastasis. The most common sites of metastasis are regional lymph nodes and the lungs, and less commonly the liver, brain, and bone. Several staging systems for nephroblastoma have been developed and serve as guides to treatment. The most widely accepted system was developed by the National Wilms Tumor Study Group (Table 31-1). Primary treatment is usually surgical exploration and resection or chemotherapy and then surgical resection. Radiation therapy may be used for children with higher stages of disease and metastases. Survival is greater than 90% for localized disease and up to 80% for higher stages, although congestive heart failure, renal failure, and hypertension occur more frequently in long-term survivors than in the general population.

Quick Check 31-2

1. What is the cause of proteinuria?

2. What is Wilms tumor and what cellular components are involved?

*Staging system of the National Wilms Tumor Study Group.
Urinary tract infections (UTIs) are rare in newborns, and children with congenital renal abnormalities and noncircumcised males are at increased risk. UTIs in children are most common in 7- to 11-year-old girls as a result of perineal bacteria, especially E. coli, ascending the urethra. Susceptibility, bacterial virulence, and, perhaps, genetics affect the severity of the disease. An abnormal urinary tract (presence of reflux, obstruction, stasis, or stones) is particularly susceptible to infection. Sexually active female adolescents are at increased risk to have a UTI.

Cystitis, or infection of the bladder, results in mucosal inflammation and congestion. This causes detrusor muscle hyperactivity and a resulting decrease in bladder capacity, resulting in urgency and frequency. It may also cause distortion of the ureterovesical (UV) junction leading to transient reflux of infected urine up the ureters, causing acute or chronic pyelonephritis.

Differentiating whether an infection is in the bladder or in the kidneys is difficult based on symptoms alone. Infants may be asymptomatic or develop fever, lethargy, abdominal pain, vomiting, diarrhea, or asymptomatic jaundice. Children may present with fever of undetermined origin, frequency, urgency, dysuria, enuresis or incontinence in a previously dry child, flank or back pain, and sometimes hematuria. Acute pyelonephritis usually causes chills, high fever, and flank or abdominal pain, along with enlarged kidney(s) caused by inflammatory edema. Chronic pyelonephritis may be asymptomatic.

Diagnosis of UTIs is by urine culture. Dipstick analyses for nitrite, leukocyte esterase, and blood may be used as a screening tool. Any positive or strong suspicion of a UTI, including unexplained jaundice in infants, requires urine culture. Diagnostic imaging may be necessary to rule out obstructions, renal scarring, or functional abnormalities. With treatment, UTI symptoms are usually relieved in 1 to 2 days, and the urine becomes sterile. A 2- to 4-day course of oral antibiotics is effective for uncomplicated UTI. Longer treatment may be required if the child has a history of recurrent UTIs or has congenital abnormalities of the urinary tract. If there is no improvement in 2 days, the child should be reevaluated (see Health Alert: Childhood Urinary Tract Infections).

Health Alert

Childhood Urinary Tract Infections
Childhood urinary tract infections (UTIs) are often seen in primary care settings and can cause significant longer term morbidity if not treated. Children younger than 2 years often have few, nonspecific signs of infection, including fever, irritability, poor feeding, failure to thrive, and diarrhea. Obtaining a proper urine sample and culture is vital because true infections require further examination. Antibiotic prophylaxis may be considered because of the link between vesicoureteral reflux (VUR), recurrent UTIs, and renal scarring and hypertension; however, this is a controversial issue because of the risk of antibiotic resistance. Current recommendations are to consider prophylaxis for children younger than 1 year of age with VUR and a history of febrile UTIs, and other children as indicated. Circumcision status is controversial; however, recent studies have shown a decreased rate of UTIs in circumcised boys. The position of the American Academy of Pediatrics is that scientific evidence shows medical benefits of neonatal circumcision, but data are insufficient to support routine neonatal circumcision. Abnormalities in bowel and bladder function must be addressed because they can impact the development of UTIs and affect the resolution of VUR. Surgical management of VUR is considered based on failure of medical management to prevent recurrent infections, VUR grade, and degree of renal scarring.

**Vesicoureteral Reflux**

**Vesicoureteral reflux (VUR)** is the retrograde flow of urine from the bladder into the kidney or ureters, or both. This allows infected urine from the bladder to reach the kidneys. Vesicoureteral reflux occurs more often in girls by a ratio of 10:1 and is uncommon in blacks. The actual incidence is unknown because VUR is often undiagnosed. An estimated 30% to 40% of children younger than 5 years who develop a UTI have VUR. Siblings of those affected have about a 27% to 51% chance of having reflux, and children with parents who had childhood reflux have almost a 70% chance of reflux. Although reflux is considered abnormal at any age, the shortness of the submucosal tunnel of the ureter during infancy and childhood renders the antireflux mechanism relatively inefficient and delicate. Thus reflux is seen commonly in association with infections during early childhood but rarely in older children and adults.

**Pathophysiology**
The normal distal ureter enters the bladder through the detrusor muscle and passes through a submucosal tunnel before opening into the bladder lumen via the ureteral orifice. As the bladder fills with urine the ureter is compressed within the bladder wall, preventing reflux. Primary VUR results from a congenital abnormally short submucosal tunnel and ureter that permits reflux by the rising pressure of the filling bladder (Figure 31-4). Urine sweeps up into the ureter and then flows back into the empty bladder. The reflux perpetuates infection by preventing complete emptying of the bladder and providing a reservoir for infection. With bladder filling, the maximal intravesical pressure can be transmitted up the ureter to the renal pelvis and calyces. The combination of reflux and infection is an important cause of pyelonephritis. Renal parenchymal injury, scarring, hypertension, and chronic renal insufficiency can occur many years later, making early diagnosis and treatment important. Secondary reflux develops in association with acquired conditions (e.g., neurogenic bladder dysfunction, ureteral obstruction, voiding disorders, or surgery on the ureterovesical [UV] junction). Reflux may be unilateral or bilateral, and is graded using the International Reflux Grading System\(^4\) (Figure 31-5):

**Grade I:** reflux into a nondilated distal ureter

**Grade II:** reflux into the upper collecting system without dilation

**Grade III:** reflux into a dilated ureter or blunting of calyceal fornices

**Grade IV:** reflux into a grossly dilated ureter and calyces

**Grade V:** massive reflux with urethral dilation and tortuosity and effacement of the calyceal details
Clinical manifestations

Children with reflux may be asymptomatic or have recurrent urinary tract
infections, unexplained fevers, poor growth and development, irritability, and feeding problems. The family history may reveal VUR or urinary tract infections.

**Evaluation and treatment**

In addition to the history of recurrent urinary tract infection and other symptoms, a voiding cystourethrogram is the primary diagnostic procedure. Most children with VUR respond to nonoperative management aimed at prevention and treatment of infection. Spontaneous remission of grades I, II, and III reflux may occur in 50% to 80% of children younger than 5 years. Approximately 20% of grades IV and V will resolve. Recurrent infection may require endoscopic, open, laparoscopic, and robotic procedures to stop the refluxing ureter.
Urinary Incontinence

Urinary incontinence refers to the involuntary passage of urine by a child who is beyond the age when voluntary bladder control should have been acquired. Bladder control is accomplished by most children before the age of 5 years, although this is largely influenced by cultural beliefs and parental toilet training practices.

Types of Incontinence

Wetness that occurs during the day is called **daytime incontinence**. Nighttime wetting is called **enuresis**. **Primary incontinence** (enuresis) means the child has never been continent, whereas **secondary incontinence** (enuresis) means the child has been continent for at least 6 months before wetting recurs. A child may have daytime incontinence, enuresis, or a combination of both. (Types of incontinence and clinical manifestations are defined in Table 31-2.)

The incidence of incontinence (enuresis) is difficult to determine because it is not a problem parents often discuss. Enuresis occurs in as many as 10% of 7-year-old males and resolves at a rate of 15% per year. Daytime incontinence occurs in up to 9% of early school age children.\(^{52}\)

Pathogenesis

A combination of factors is likely to be responsible for incontinence or enuresis. Organic causes account for a minority of cases and include UTIs; neurologic disturbances; congenital defects of the meatus, urethra, or bladder neck; and allergies. Disorders that increase the normal output of urine, such as diabetes mellitus and diabetes insipidus, or disorders that impair the concentrating ability of the kidney, such as chronic renal failure or sickle cell disease, should be considered...
during evaluation. Other conditions that may be associated with incontinence include perinatal anoxia, CNS trauma, seizures, attention-deficit/hyperactivity disorder, developmental delay, imperforate anus, bladder trauma or surgery, obesity, and occult spinal dysraphism. Altered sleep arousal or obstructive sleep apnea may be associated with enuresis. Stressful psychologic situations, such as a new sibling, may cause incontinence or enuresis to develop. Constipation is frequently present in children with urinary incontinence. Incontinence or enuresis in which no structural or neurologic abnormality is identified is common in children.

Genetic factors contribute to some types of incontinence. At least four gene loci associated with enuresis have been identified. Enuresis occurs with high frequency among parents, siblings, and other near relatives of symptomatic children. There is a high concordance rate in monozygotic twins with enuresis.

**Evaluation and treatment**

Diagnostic evaluation of childhood incontinence includes a thorough history, voiding diary, physical examination, and urinalysis. Urodynamic flow studies or imaging may be required based on the history and physical findings. Therapeutic management of incontinence or enuresis begins with education. If the child and family understand the probably etiology of the child's condition, they are better able to choose and participate in therapies that are most likely to succeed. Treatment of daytime incontinence includes behavioral therapy, including timed voiding; fluid management; treatment of constipation, urinary tract infections, and other coexisting conditions if present; and medication (anticholinergic or alpha-blocker medications). Enuresis treatment also may include enuresis alarms or other medications (e.g., desmopressin acetate).

---

**Quick Check 31-3**

1. How does the cause of urinary tract infections (UTIs) in newborns differ from that in older children?

2. How does vesicoureteral reflux occur?

3. What organic causes are operative in enuresis?
Did You Understand?

**Structural Abnormalities**

1. Congenital renal disorders affect about 10% to 15% of the population. These disorders range in severity from minor conditions that need no treatment to those incompatible with life.

2. Hypospadias is a congenital condition in which the urethral meatus can be located anywhere on the ventral surface of the glans, the penile shaft, the midline of the scrotum, or the perineum.

3. Exstrophy of the bladder is a congenital malformation in which the pubic bones are separated, the lower portion of the abdominal wall and anterior wall of the bladder are missing, and the posterior wall of the bladder is everted through the opening.

4. Urethral valves and polyps are congenital formations of tissue that block the urethra.

5. Ureteropelvic junction obstruction is blockage where the renal pelvis joins the ureter and is often caused by smooth muscle or urothelial malformation or by scarring that leads to hydronephrosis.

6. A dysplastic kidney is the result of abnormal differentiation of renal tissues. A hypoplastic kidney is small with a decreased number of nephrons.

7. Polycystic kidney disease is a cystic genetic disorder resulting in multiple, bilateral renal cysts.

8. Renal agenesis is the failure of a kidney to grow or develop. The condition may be unilateral or bilateral and may occur as an isolated entity or in association with other disorders.

**Glomerular Disorders**

1. Glomerulonephritis is an inflammation of the glomeruli characterized by hematuria, edema, and hypertension. The cause is unknown but is often immune mediated. Glomerulonephritis may follow infections, especially those of the upper
respiratory tract caused by strains of group A β-hemolytic streptococcus. Increases in glomerular capillary permeability lead to hematuria and proteinuria.

2. IgA nephropathy occurs with deposition of IgA in the glomerulus, causing glomerular injury with gross hematuria.

3. **Nephrotic syndrome** is a term used to describe a symptom complex characterized by proteinuria, hypoproteinemia, hyperlipidemia, and edema. Metabolic, biochemical, or physiochemical disturbances in the glomerular basement membrane may lead to increased permeability to protein.

4. Hemolytic uremic syndrome is an acute disorder characterized by hemolytic anemia, acute renal failure, and thrombocytopenia.

**Nephroblastoma**

1. Nephroblastoma (Wilms tumor) is an embryonal tumor of the kidney that usually presents between birth and 5 years of age. Survival is high following treatment by surgery, a combination of drugs, and, sometimes, radiation therapy.

**Bladder Disorders**

1. Urinary tract infections can result from general sepsis in the newborn but are caused by bacteria ascending the urethra in older children. The bladder alone is infected in cystitis. The infection ascends to one or both kidneys in pyelonephritis. Urinary tract anomalies may require surgical correction to prevent frequent recurrent infections.

2. Vesicoureteral reflux is the retrograde flow of bladder urine into the kidney or ureter, or both, increasing the risk for pyelonephritis. It can be unilateral or bilateral; primary or secondary.

**Urinary Incontinence**

1. Urinary incontinence is the involuntary passage of urine. It may occur during the day (incontinence) or at night (enuresis), or both. Maturational delay, UTIs, constipation, and many other factors may contribute.

  Aging and the Female Reproductive System, 797
The male and female reproductive systems have several anatomic and physiologic features in common. Most obvious is their major function—reproduction—through which a 23-chromosome female gamete, the ovum, and a 23-chromosome male gamete, the spermatozoon (sperm cell), unite to form a 46-chromosome zygote that is capable of developing into a new individual. The male reproductive system produces sperm that can be transferred to the female reproductive tract. The female reproductive system produces the ovum (pl., ova), and if the ovum is fertilized it is then called the embryo and developing fetus. These functions are determined not only by anatomic structures but also by complex hormonal and neurologic factors.¹²
Development of the Reproductive Systems

The structure and function of both male and female reproductive systems depend on steroid hormones called **sex hormones** and their precursors. Cholesterol is the precursor for steroid hormones, including the sex hormones. Other hormones support reproduction. The actions of both sex and reproductive hormones are summarized in **Table 32-1**. Sex hormones, like all hormones, act on target tissues by binding with cellular receptors (see **Chapter 18**). Hormonal effects on the reproductive systems begin during embryonic development and continue in varying degrees throughout life.

---

Sexual Differentiation in Utero
Initially, in embryonic development, the reproductive structures of male and female embryos are homologous (the same) or undifferentiated. They consist of one pair of primary sex organs, or gonads, and two pairs of ducts—the mesonephric ducts (wolffian ducts) and the paramesonephric ducts (müllerian ducts) (Figure 32-1). The müllerian ducts are the precursor of the internal female sex organs (oviducts, uterus, cervix, and upper vagina). Müllerian ducts are initially formed regardless of genotypic sex and require no SRY signaling for development. SRY signaling is required in males to cause regression of the müllerian ducts, which in turn prevents the development of the female reproductive tract. The wolffian ducts are the precursor of male internal sex organs (secrete testosterone and promote development of the male sex organs).
The first sign of development of reproductive organs (male or female) occurs during the fifth week of gestation. Between 6 and 7 weeks' gestation, the male embryo will differentiate under the influence of testes-determining factor (TDF), a protein expressed by a gene in the sex-determining region on the Y chromosome (SRY). When the SRY gene is expressed, male gonadal development prevails. TDF stimulates the male gonads to develop into the two testes, and by 8 weeks' gestation testosterone secretion begins. Müllerian inhibitory hormone (MIF), secreted by Sertoli cells in the testes, promotes degeneration of the müllerian ducts. Without MIF, the müllerian ducts would develop and the wolffian ducts would degenerate with loss of male sex organ development. By 9 months' gestation, the male gonads (testes) have descended into the scrotum. The testes produce sperm after puberty.
Female gonadal development occurs in the absence of SRY expression and with the expression of other genes.\textsuperscript{3} The presence of estrogen and the absence of testosterone and MIF cause a loss in the wolffian system, and at 6 to 8 weeks' gestation the two female gonads develop into ovaries, which will produce ova. In females, the mesonephric ducts deteriorate and the upper ends of paramesonephric ducts become the fallopian tubules, whereas the lower ends join to become the uterus, cervix, and upper two thirds of the vagina (see Figure 32-1). The fallopian tubes will carry ova from the ovaries to the uterus during a woman's reproductive years. Lack of testosterone and the presence of estrogen promote the development of external genitalia (lower end of vagina, labia, and clitoris).

Like the internal reproductive structures, the external structures develop from homologous embryonic tissues. During the first 7 to 8 weeks' gestation, both male and female embryos develop an elevated structure called the genital tubercle (Figure 32-2). Testosterone is necessary for the genital tubercle to differentiate into external male genitalia; otherwise, female genitalia develop, which may occur even in the absence of ovaries, possibly because of the presence of placental estrogens.
Anterior pituitary development begins between the fourth and fifth weeks of fetal life, and the vascular connection between the hypothalamus and the pituitary is established by the twelfth week. **Gonadotropin-releasing hormone (GnRH)** is produced in the hypothalamus by 10 weeks' gestation and controls the production of two gonadotropins, **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)**, by the anterior pituitary gland. In the female fetus, high levels of FSH and LH are excreted. FSH and LH stimulate the production of estrogen and progesterone by the ovary. The production of FSH and LH increases until about 28 weeks' gestation, when the production of estrogen and progesterone by the ovaries and placenta is high enough to result in the decline of gonadotropin production. Production of primitive female gametes (ova) occurs solely during fetal life. From puberty to menopause, one female gamete matures per menstrual cycle. Production of the male gametes (sperm) begins at puberty; after that, millions are produced daily, usually for life.

By the end of pregnancy, a sensitive negative feedback system, which includes the **gonadostat** (also known as the **gonadotropin-releasing hormone pulse generator**), is operative in the human fetus. The gonadostat responds to high levels of placental estrogens by releasing low levels of GnRH. Soon after birth, steroid hormone levels drop because of the loss of maternal placental hormones. Hypothalamic pulsatile GnRH is secreted and gonadotropins LH and FSH are released; their levels peak at 3 to 6 months for boys and at 12 to 18 months for girls and then fall steadily. The gonadotropins will be suppressed until the onset of puberty.

**Puberty and Reproductive Maturation**

**Puberty** is the onset of sexual maturation and differs from adolescence. Adolescence is the stage of human development between childhood and adulthood and includes social, psychologic, and biologic changes. In girls, puberty begins at about age 8 to 9 years with thelarche (breast development). In boys, it begins later—at about age 11 years and occurs earlier with increased weight and body mass index. Genetics, environment, ethnicity, general health, and nutrition can influence the timing of puberty. There is an association between obesity and earlier puberty in girls perhaps from higher estrogen levels related to leptin, gonadotropin, and estrogen secretion. Girls who have low body fat and reduced body weight and perform intense exercise may experience delayed maturation.

Reproductive maturation involves the hypothalamic-pituitary-gonadal axis, the
central nervous system, and the endocrine system (Figure 32-3). There is a sequential series of hormonal events that promote sexual maturation as puberty approaches. About 1 year before puberty in girls, nocturnal pulses of gonadotropin secretion (i.e., LH and FSH) and an increased response in the pituitary to GnRH occur. This, in turn, stimulates gonadal maturation (gonadarche) with estradiol secretion in girls and testosterone secretion in boys. Estradiol causes development of the breasts (thelarche), maturation of the reproductive organs (vagina, uterus, ovaries), and deposition of fat in the female's hips. Estrogen and increased production of growth factors cause rapid skeletal growth in both boys and girls. Testosterone causes growth of the testes, scrotum, and penis. A positive feedback loop is created with gonadotropins stimulating the gonads to produce more sex hormones. The most important hormonal effects occur in the gonads. In males, the testes begin to produce mature sperm that are capable of fertilizing an ovum. Male puberty is complete with the first ejaculation that contains mature sperm. In females, the ovaries begin to release mature ova. Female puberty is complete at the time of the first ovulatory menstrual period; however, this can take up to 1 to 2 years after menarche. Adrenarche is the increased production of adrenal androgens (dehydroepiandrosterone and androstenedione, which are converted to testosterone and estrogen) before puberty, which occurs in both sexes and is manifested by growth of axillary and pubic hair and activation of sweat and sebaceous glands. Puberty is complete when an individual is capable of reproduction.

Quick Check 32-1

1. When do sex hormones first exhibit an effect on sexual development?

2. Why are sex hormones necessary for reproduction?
FIGURE 32-3  Hormonal Stimulation of the Gonads. The hypothalamic-pituitary-gonadal axis.
The Female Reproductive System

The function of the female reproductive system is to produce mature ova; if fertilization occurs, the female reproductive system provides protection and nourishment of the fetus until it is expelled at birth. The most important internal reproductive organs in females are the ovaries, fallopian tubes, uterus, and vagina. The external genitalia protect body openings and play an important role in sexual functioning.

External Genitalia

Figure 32-4 shows the external female genitalia, known collectively as the vulva, or pudendum. The major structures are as follows:

Mons pubis: Fatty layer of tissue over pubic symphysis (joint formed by union of the pubic bones). During puberty it becomes covered with pubic hair, and sebaceous and sweat glands become more active. Estrogen causes fat to be deposited under the skin, gives the mons pubis a moundlike shape, and protects the pubic symphysis during sexual intercourse.

Labia majora (sing., labium majus): Two folds of skin arising at the mons pubis and extending back to the fourchette, forming a cleft. During puberty the amount of fatty tissue increases, pubic hair grows on lateral surfaces, and sebaceous glands on hairless medial surfaces secrete lubricants. This structure is highly sensitive to temperature, touch, pressure, and pain; it is homologous to the male scrotum; and it protects the inner structures of the vulva.

Labia minora (sing., labium minus): Two smaller, thinner, asymmetric folds of skin within the labia majora that form the clitoral hood (prepuce) and frenulum, then split to enclose the vestibule, and converge near the anus to form the fourchette. The labia minora are hairless, pink, and moist; they are well supplied by nerves, blood vessels, and sebaceous glands that secrete bactericidal fluid with a distinctive odor that lubricates and waterproofs vulvar skin. The labia swell with blood during sexual arousal.

Clitoris: Richly innervated erectile organ between the labia minora. It is a small, cylindric structure having a visible glans and a shaft that lies beneath the skin; the clitoris is homologous to the penis. It secretes smegma, which has a unique odor that may be sexually arousing to the male. Like the penis, the clitoris is a major site of sexual stimulation and orgasm. With sexual arousal, erectile tissue fills
with blood, causing the clitoris to enlarge slightly.

**Vestibule:** An area protected by the labia minora that contains the external opening of the vagina, called the *introitus* or vaginal orifice. A thin, perforated membrane, the *hymen*, may cover the introitus. The vestibule also contains the opening of the urethra, or *urinary meatus* (orifice). These structures are lubricated by two pairs of glands: Skene glands and Bartholin glands. The ducts of the *Skene glands* (also called the *lesser vestibular* or *paraurethral glands*) open on both sides of the urinary meatus. The ducts of the *Bartholin glands* (*greater vestibular* or *vulvovaginal glands*) open on either side of the introitus. In response to sexual stimulation, Bartholin glands secrete mucus that lubricates the inner labial surfaces, as well as enhances the viability and motility of sperm. Skene glands help lubricate the urinary meatus and the vestibule. Secretions from both sets of glands facilitate coitus. In response to sexual excitement, the highly vascular tissue just beneath the vestibule also fills with blood and becomes engorged.

**Perineum:** An area with less hair, skin, and subcutaneous tissue lying between the vaginal orifice and anus. Unlike the rest of the vulva, this area has little subcutaneous fat so the skin is close to the underlying muscles. The perineum covers the muscular *perineal body*, a fibrous structure that consists of elastic fibers and connective tissue and serves as the common attachment for the bulbocavernosus, external anal sphincter, and levator ani muscles. The perineum varies in length from 2 to 5 cm or more and has elastic properties. The length of the perineum and the elasticity of the perineal body influence tissue resistance and injury during childbirth.
Internal Genitalia

Vagina

The **vagina** is an elastic, fibromuscular canal that is 9 to 10 cm long in a reproductive-age female. It extends up and back from the introitus to the lower portion of the uterus. As Figure 32-5 shows, the vagina lies between the urethra (and part of the bladder) and the rectum. Mucosal secretions from the upper genital organs, menstrual fluids, and products of conception leave the body through the vagina, which also receives the penis during coitus. During sexual excitement, the vagina lengthens and widens and the anterior third becomes congested with blood.
The vaginal wall is composed of four layers:

1. Mucous membrane lining of squamous epithelial cells that thickens and thins in response to hormones, particularly estrogen. The squamous epithelial membrane is continuous with the membrane that covers the lower part of the uterus. In women of reproductive age, the mucosal layer is arranged in transverse wrinkles, or folds, called rugae (sing., ruga) that permit stretching during coitus and childbirth.

2. Fibrous connective tissue containing numerous blood and lymphatic vessels.

4. Connective tissue and a rich network of blood vessels

The upper part of the vagina surrounds the cervix, the lower end of the uterus (see Figure 32-5). The recessed space around the cervix is called the fornix of the vagina. The posterior fornix is “deeper” than the anterior fornix because of the angle at which the cervix meets the vaginal canal. In most women this angle is about 90 degrees. A pouch called the cul-de-sac separates the posterior fornix and the rectum.

Its elasticity and relatively sparse nerve supply enhance the vagina's function as the birth canal. During sexual arousal, the vaginal wall becomes engorged with blood, like the labia minora and clitoris. Engorgement pushes some fluid to the surface of the mucosa, enhancing lubrication. The vaginal wall does not contain mucus-secreting glands; rather, secretions drain into the vagina from the endocervical glands or from the Bartholin and Skene glands of the vestibule.

Two factors help to maintain the self-cleansing action of the vagina and to defend it from infection, particularly during the reproductive years. They are (1) an acid-base balance that discourages the proliferation of most pathogenic bacteria and (2) the thickness of the vaginal epithelium. Before puberty, vaginal pH is about 7.0 (neutral) and the vaginal epithelium is thin. At puberty, the pH becomes more acidic (4.0 to 5.0) and the squamous epithelial lining thickens. These changes are maintained until menopause (cessation of menstruation), when the pH rises again to more alkaline levels and the epithelium thins. Therefore protection from infection is greatest during the years when a woman is most likely to be sexually active. Both defense factors are greatest when estrogen levels are high and the vagina contains a normal population of *Lactobacillus acidophilus*, a harmless resident bacterium that helps to maintain pH at acidic levels. Any condition that causes vaginal pH to rise—such as douching or use of vaginal sprays or deodorants, the presence of low estrogen levels, or destruction of *L. acidophilus* by antibiotics—lowers vaginal defenses against infection.

**Uterus**

The uterus is a hollow, pear-shaped organ whose lower end opens into the vagina. It anchors and protects a fertilized ovum, provides an optimal environment while the ovum develops, and pushes the fetus out at birth. In addition, the uterus plays an important role in sexual response and conception. During sexual excitement, the opening of the lower uterus (the cervix) dilates slightly. At the same time, the uterus increases in size and moves upward and backward, creating a tenting effect in the midvagina that results in the cervix “sitting” in a pool of semen. During orgasm, rhythmic contractions facilitate movement of sperm through the cervical os while
also enhancing physical pleasure.

At puberty, the uterus attains its adult size and proportions and descends from the abdomen to the lower pelvis, between the bladder and the rectum (see Figure 32-5). The uterus of a mature, nonpregnant female is approximately 7 to 9 cm long and 6.5 cm wide, with muscular walls 3.5 cm thick, and enlarges about 1 cm in all dimensions after pregnancy. It is loosely held in position by ligaments, peritoneal tissue folds, and the pressure of adjacent organs, especially the urinary bladder, sigmoid colon, and rectum. In most women, the uterus is tipped forward (anteverted) so that it rests on the urinary bladder; however, it may be tipped backward (retroverted). Various degrees of flexion are normal (Figure 32-6).

The uterus has two major parts: the body, or corpus, and the cervix (Figure 32-7). The top of the corpus, above the insertion of the fallopian tubes, is called the fundus. The diameter of the uterine cavity is widest at the fundus and narrowest at the isthmus, just above the cervix (see Figure 32-5). The cervix, or “neck of the uterus,” extends from the isthmus to the vagina. The passageway between the upper opening (the internal os) and the lower opening (the external os) of the cervix is
called the **endocervical canal** (see Figure 32-7). The entire uterus, like the upper vagina, is innervated exclusively by motor and sensory fibers of the autonomic nervous system.

The uterine wall is composed of three layers (see Figure 32-7). The **perimetrium** (*parietal peritoneum*) is the outer serous membrane that covers the uterus. The **myometrium** is the thick, muscular middle layer. It is thickest at the fundus, apparently to facilitate birth. The **endometrium**, or uterine lining, is composed of a functional layer (superficial compact layer and spongy middle layer) and a basal layer. The functional layer of the endometrium responds to the sex hormones estrogen and progesterone. Between puberty and menopause, this layer proliferates and is shed monthly. The basal layer, which is attached to the myometrium, regenerates the functional layer after shedding (menstruation).

The endocervical canal does not have an endometrial layer but is lined with columnar epithelial cells. It is continuous with the lining of the outer cervix and vagina, which are lined with squamous epithelial cells. The point where the two types of cells meet is called the **transformation zone**, or **squamous-columnar junction**. The transformation zone is vulnerable to the human papillomavirus,
which can lead to cervical dysplasia or carcinoma in situ (see Figure 33-16). Cells of the transformation zone are removed for examination during a Papanicolaou (Pap test) smear.\(^8\)

The cervix acts as a mechanical barrier to infectious microorganisms from the vagina. The external cervical os is a very small opening that contains thick, sticky mucus (the mucous “plug”) during the luteal phase of the menstrual cycle and throughout pregnancy. During ovulation, the mucus changes under the influence of estrogen and forms watery strands, or **spinnbarkeit mucus**, to facilitate the transport of sperm into the uterus. In addition, the downward flow of cervical secretions moves microorganisms away from the cervix and uterus. In women of reproductive age, the pH of these secretions is inhospitable to many bacteria. Further, mucosal secretions contain enzymes and antibodies (mostly immunoglobulin A [IgA]) of the secretory immune system. Uterine pathophysiologic disorders include infection, displacement of the uterus within the pelvis, benign growths (fibroids) of the uterine wall, hyperplasia of the endometrium, endometriosis, and cancer (see Chapter 33).

**Quick Check 32-2**

1. Name three functions of the uterus.

2. Where are the Bartholin glands located? What is their function?

3. What is the name of the cells in which cervical cancer is most likely to grow?

**Fallopian Tubes**

The two **fallopian tubes** (oviducts, **uterine tubes**) enter the uterus bilaterally just beneath the fundus (see Figure 32-7). They direct the ova from the spaces around the ovaries to the uterus. From the uterus, the fallopian tubes curve up and over the two ovaries. Each tube is 8 to 12 cm long and about 1 cm in diameter, except at its ovarian end, which resembles the bell of a trumpet and is fringed or fimbriated (**infundibulum**). The **fimbriae** (fringes) move, creating a current that draws the ovum into the infundibulum. Once the ovum enters the fallopian tube, cilia (hairlike structures) and peristalsis (muscle contractions) keep it moving toward the uterus.

The ampulla, or distal third, of the fallopian tube is the usual site of fertilization (see Figure 32-7). Sperm released into the vagina travel upward through the endocervical canal and uterine cavity and enter the fallopian tubes. If an ovum is present in either tube, fertilization can occur. Whether or not the ovum encounters
sperm, it continues to travel through the fallopian tube to the uterus. If fertilized, the ovum (then called a blastocyst) implants itself in the endometrial layer of the uterine wall. If not fertilized, the ovum fragments and leaves the uterus with menstrual fluids. Disorders that affect the fallopian tubes (e.g., congenital malformations, infection, and inflammation) block the path of both sperm and the ovum and may cause infertility or ectopic (tubal) pregnancy.

**Ovaries**

The ovaries, the female gonads, are the primary female reproductive organs (Figure 32-8). Their two main functions are secretion of female sex hormones and development and release of female gametes, or ova.

![Cross Section of Ovary and Development of an Ovarian Follicle](image)

The almond-shaped ovaries are located on both sides of the uterus and are suspended and supported by the mesovarium portions of the broad ligament,
ovarian ligaments, and suspensory ligaments (see Figure 32-7). The ovaries are smaller than their male homologs, the testes. In women of reproductive age, each ovary is about 3 to 5 cm long, 2.5 cm wide, and 2 cm thick and weighs 4 to 8 g. Size and weight vary slightly during each phase of the menstrual cycle (see pp. 788-790).

At birth, the cortex of each ovary contains approximately 1 to 2 million ova within primordial (immature) ovarian follicles. By puberty, the number ranges between 300,000 and 500,000, and some of the follicles and the ova within them begin to mature. Between puberty and menopause, the ovarian cortex always contains follicles and ova in various stages of development (primary and secondary follicles). Once every menstrual cycle (about every 28 days), one of the follicles reaches maturation and discharges its ovum through the ovary's outer covering, the germinal epithelium. During the reproductive years, 400 to 500 ovarian follicles mature completely and release an ovum (ovulation). The remaining follicles either fail to develop at all or degenerate without maturing completely and are known as atretic follicles (see Figure 32-8).

After release of the mature ovum (ovulation), the follicle develops into another structure, the corpus luteum (see Figure 32-8). If fertilization occurs, the corpus luteum enlarges and begins to secrete hormones that maintain and support pregnancy. If fertilization does not occur, the corpus luteum secretes these hormones for approximately 14 days and then degenerates, which triggers the maturation of another follicle. The ovarian cycle—the process of follicular maturation, ovulation, corpus luteum development, and corpus luteum degeneration—is continuous from puberty to menopause, except during pregnancy or hormonal contraceptive use. At menopause, this process ceases and the ovaries atrophy to the point that they cannot be felt during a pelvic examination.

Sex hormones are secreted by cells present within the ovarian cortex, including two types of cells in the ovarian follicle—theca cells (produce androgens that migrate to granulosa cells) and granulosa cells (convert androgens to estradiol)—and cells of the corpus luteum (secrete primarily progesterone, estrogen, and inhibin) (see Figure 32-8). These cells all contain receptors for the gonadotropins (LH, FSH) or for the sex hormones, which are discussed in the next section.

**Female Sex Hormones**

The sex hormones are all steroid hormones and are synthesized from cholesterol (see Chapter 18). Both male and female sex hormones are present in all adults. However, the female body contains low levels of testosterone and other androgens, and the male body contains low levels of estrogen. Individual effects of sex hormones depend on the amount and concentration in the blood.
Estrogens and Androgens

**Estrogen** is a generic term for any of three similar hormones derived from cholesterol: estradiol, estrone, and estriol. **Estradiol (E₂)** is the most potent and plentiful of the three and is principally produced (95%) by the ovaries (ovarian follicle and corpus luteum). Limited amounts are secreted by the cortices of the adrenal glands and the placenta during pregnancy. Androgens are converted to estrone in ovarian and adipose tissue; estriol is the peripheral metabolite of estrone and estradiol.

Estrogen has numerous biologic effects, many of which involve interactions with other hormones. It is needed for maturation of reproductive organs, development of secondary sex characteristics, growth, and maintenance of pregnancy, as well as the many nonreproductive effects of estrogen, including closure of long bones after the pubertal growth spurt (in both males and females), maintenance of bone and skin, and systemic organ function (see Table 32-1 and Box 32-1). After menopause, the ovaries dramatically reduce production of estradiol and secretion of estrone is markedly diminished (see Aging and the Female Reproductive System, p. 797). At this time, the majority of estradiol is derived from intracellular synthesis in peripheral tissues. Estradiol acts locally to meet physiologic needs according to cell type and is then inactivated without systemic effects.9

**Box 32-1**

**Summary of Nonreproductive Effects of Estrogen**

- Estrogens (including estrone, estradiol, estriol) function through estrogen receptors alpha and beta, have different roles in different cells and tissues, and have paracrine or intracrine function.

- Maintains bone density.

- Acts in liver to decrease cholesterol level, increase high-density lipoprotein (HDL) level, and decrease low-density lipoprotein (LDL) level (antiatherosclerotic); promotes fat deposition.

- Maintains nervous system (neurotrophic and neuroprotective); facilitates memory and cognition.
• Increases collagen content, dermal thickness, elasticity, water content, and healing ability of skin.

• Protects against chronic kidney disease in individuals without diabetes.

• Prevents vascular injury and early atheroma formation through endothelial mechanisms.

• Inhibits platelet adhesiveness.

• Can promote inflammation and have variable effects on immunity.

• Estrogen associated with pregnancy or use in contraceptive pills promotes clotting and increased risk of thromboembolism.

Although androgens are primarily male sex hormones produced in the testes, small amounts are produced in the adrenal cortex in both men and women, and in the ovaries in women. Some androgens (dehydroepiandrosterone and its metabolite androstenedione) are precursors of estrogens (estrone, estradiol) (see Table 32-1). At puberty, androgens contribute to the skeletal growth spurt and cause growth of pubic and axillary hair. Androgens also activate sebaceous glands, accounting for some cases of acne during puberty, and play a role in libido.

**Progesterone**

Luteinizing hormone (LH) from the anterior pituitary stimulates the corpus luteum to secrete progesterone, the second major female sex hormone. With estrogen, progesterone controls the ovarian menstrual cycle. LH surge occurs when there is a peak level of estrogen, about 24 to 36 hours before ovulation. LH promotes luteinization of the granulosa in the dominant follicle, resulting in progesterone production and the development of blood vessels and connective tissue. During the follicular phase, the ovary and adrenal glands each contribute approximately 50% of the progesterone production. Conversely, large amounts are cyclically secreted from the ovary while the corpus luteum is active for about 9 to 13 days after ovulation. The complementary and opposing effects of progesterone and estrogen are listed in Table 32-2. Progesterone secreted by the corpus luteum stimulates the thickened endometrium to become more complex in preparation for implantation of a blastocyte. If conception and implantation do occur, the corpus luteum persists and secretes progesterone (and estrogen) until the placenta is well established at approximately 8 to 10 weeks' gestation and undertakes progesterone production.

Progesterone is sometimes called the *hormone of pregnancy*. Progesterone's effects in pregnancy include (1) maintaining the thickened endometrium; (2) relaxing smooth muscle in the myometrium, which prevents premature contractions and helps the uterus to expand; (3) thickening (hypertrophy) the myometrium, which prepares it for the muscular work of labor; (4) promoting growth of lobules and alveoli in the breast in preparation for lactation, but preventing lactation until the fetus is born and then promoting lactation in collaboration with prolactin after birth\(^{10}\); (5) preventing additional maturation of ova by suppressing FSH and LH, thereby stopping the menstrual cycle; and (6) providing immune modulation, allowing tolerance against fetal antigens (the mother's immune system does not attack the fetus).\(^{11}\)

#### Quick Check 32-3

1. What hormones does the ovary produce?
2. Why is the ovary the most essential female reproductive organ?

### Menstrual (Ovarian) Cycle

In addition to pregnancy, the obvious manifestation of female reproductive functioning is menstrual bleeding (the menses), which starts with **menarche** (first menstruation) and ends with **menopause** (cessation of menstrual flow for 1 year). In the United States, the median age of first menstruation is about 12.14 years in black females, 12.25 years in Latina or Hispanic females, and 12.6 years in white females, with a range from 9 to 13.5 years.\(^{12}\) Menarche appears to be related to body weight, especially percentage of body fat (ratio of fat to lean tissue), which may trigger a
change in the metabolic rate and lead to hormonal changes associated with early menarche (age 11 years or younger). There is an increased sensitivity to leptin (a regulatory hormone of appetite and energy metabolism) during puberty and, in theory, the adolescent consumes more calories to meet the caloric needs of the pubertal growth spurt.

Cycles are anovulatory at first and may vary in length from 10 to 60 days or more. As adolescence proceeds, regular patterns of menstruation and ovulation are established at intervals ranging between 21 and 45 days. Menstruation continues to recur in a recognizable and characteristic pattern during adulthood, with the length of the menstrual cycle varying considerably among women. The commonly accepted cycle average is 28 (25 to 30) days, with rhythmic intervals of 21 to 35 days considered normal (see Figure 32-9). Approximately 2 to 8 years before menopause, cycles begin to lengthen again. Menstrual cyclicity and regular ovulation are dependent on (1) the activity of GnRH; (2) the initial pituitary secretion of the gonadotropin FSH; and (3) the estrogen (estradiol) positive feedback mechanism for preovulatory FSH and LH surge, oocyte maturation, corpus luteum formation, and progesterone production.

**Phases of the Menstrual Cycle**

The menstrual (ovarian) cycle (Figure 32-9) consists of two phases: the follicular/proliferative phase (postmenstrual) followed by the luteal/secretory phase (premenstrual).
During menstruation (menses), the functional layer of the endometrium disintegrates and is discharged through the vagina. Menstruation is followed by the follicular/proliferative phase. This phase is named for two simultaneous processes: maturation of an ovarian follicle and proliferation of the endometrium (see Figure 32-9). During this phase, GnRH and a balance between activin and inhibin levels from the granulosa cells contribute to the increase of FSH level, which stimulates a number of follicles. The pulsatile secretion of FSH from the anterior pituitary gland rescues a dominant ovarian follicle from apoptosis by days 5 to 7 of the cycle.
Together, estrogen and FSH increase the number of FSH receptors in the granulosa cells of the primary follicle, making them more sensitive to FSH. FSH and estrogen combine to induce production of LH receptors on the granulosa cells, thus promoting LH stimulation to combine with FSH stimulation and cause a more rapid secretion of follicular estrogen. As estrogen level increases, FSH level drops because of an increase in inhibin-B secreted by the granulosa cells in the dominant follicle. This drop in FSH concentration decreases the growth of less developed follicles (see Figure 32-8). Estrogen causes cells of the endometrium to proliferate and stimulates production of LH. A surge in the levels of both FSH and LH is required for final follicular growth and ovulation.

**Ovulation** is the release of an ovum from a mature follicle and marks the beginning of the **luteal/secretory phase** of the menstrual cycle. The ovarian follicle begins its transformation into a corpus luteum (see Figure 32-8), hence the name **luteal phase**. Pulsatile secretion of LH from the anterior pituitary stimulates the corpus luteum to secrete progesterone, which in turn initiates the secretory phase of endometrial development. Glands and blood vessels in the endometrium branch and curl throughout the functional layer, and the glands begin to secrete a thin, glycogen-containing fluid, hence the name **secretory phase**. If conception occurs, the nutrient-laden endometrium is ready for implantation. Human chorionic gonadotropin (hCG) is secreted 3 days after fertilization by the blastocyes and maintains the corpus luteum once implantation occurs at about day 6 or 7. hCG can be detected in maternal blood and urine 8 to 10 days after ovulation. The production of estrogen and progesterone will continue until the placenta can adequately maintain hormonal production. If conception and implantation do not occur, the corpus luteum degenerates and ceases its production of progesterone and estrogen. Without progesterone or estrogen to maintain it, the endometrium enters the ischemic (“blood-starved”) phase and disintegrates, hence the name **ischemic/menstrual phase**. Then menstruation occurs, marking the beginning of another cycle.

Ovulatory cycles appear to have a minimum length of 24 to 26.5 days: the ovarian follicle requires 10 to 12.5 days to develop, and the luteal phase appears fixed at 14 days (±3 days). Menstrual blood flow usually lasts 3 to 7 days but may last as long as 8 days or stop after 2 days and still be considered within normal limits. Bleeding is consistently scant to heavy and varies from 30 to 80 ml, with most blood loss occurring during the first 3 days of menses. Menstrual discharge consists of blood, mucus, and desquamated endometrial tissue and does not clot under normal circumstances. It is usually dark and produces a characteristic musty odor on oxidation. Environmental factors, such as severe emotional stress, illness, malnutrition, obesity, and seasonal variation, may affect the length of the menstrual...
Hormonal Controls

Hormonal control of the menstrual cycle depends on complex interactions among the hypothalamus, the anterior pituitary, and the ovaries (or hypothalamic-pituitary-ovarian [H-P-O] axis)\(^{20}\) (Table 32-3). Hormonal control is dependent on negative and positive ovarian feedback mechanisms. GnRH controls the gonadotropin production of FSH and LH, and the constant and pulsatile release of GnRH is critical to the timing of the menstrual cycle. GnRH is secreted by the hypothalamus into the hypophysial portal system and travels to the anterior pituitary, where it stimulates the secretion of FSH and LH. FSH and LH are released from the anterior pituitary in pulses that correspond to the secretion of GnRH.

</tbody>
</table>

FSH, Follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

During the early follicular phase, estrogen levels rise steadily and, through negative feedback, suppress FSH production and positively increase the production of LH. During the late follicular phase, the preovulatory rise in progesterone level facilitates a positive feedback loop whereby estrogen levels begin to increase, stimulating a surge of FSH and LH secretion from the anterior pituitary. The midcycle surge of LH and FSH induces ovulation. A nonsteroidal ovarian factor, gonadotropin surge-attenuating factor (GnSAF), may antagonize the effect of estrogen on the pituitary and regulate the surge of LH at midcycle.\(^{21}\) Rising estrogen and progesterone levels during the luteal phase may inhibit the anterior pituitary and thus reduce LH and FSH secretion. Just before menstruation, FSH and LH levels begin to increase slightly, probably because of declining estrogen and progesterone levels (see Figure 32-9).
A variety of growth factors and autocrine/paracrine peptides influence hormonal control and follicular response. During the early follicular stage, FSH stimulates FSH receptors, LH receptors and release of insulin-like growth factor 1 as well as the production of inhibin and activin in the ovary. Activin from granulosa cells stimulates the secretion of FSH, increases the pituitary response to GnRH, and increases FSH binding in the granulosa cells in the dominant follicle. FSH stimulates inhibin secretion from granulosa cells and it, in turn, suppresses FSH synthesis. Inhibin B is primarily secreted in the follicular phase of the cycle but sharply spikes when ovulation occurs. Inhibin A is secreted in the luteal phase and further suppresses FSH. Inhibin also restrains prolactin and growth hormone release, interferes with GnRH receptors, and promotes breakdown of intracellular gonadotropins. In summary, the balance between activin and inhibin regulates FSH secretion and follistatin inhibits activin and boosts inhibin activity. Inhibin and activin also regulate LH stimulation of androgen synthesis in theca cells. Research continues to advance understanding of the function and structural complexity of these polypeptides and their interaction with GnRH, gonadotropins, and sex hormones.

**Ovarian Cycle**

By stimulating follicles, gonadotropins initiate their growth and maturation. The most important hormonal event is a rise in FSH level. The decline in luteal phase estrogen, progesterone, and inhibin secretion allows FSH level to rise; concurrently there is a slight increase in LH levels (see Figure 32-9). FSH stimulates granulosa cell growth and initiates estrogen production in these cells. At this time, a group of ovarian follicles is recruited and begins to mature; the exact number depends on the remaining pool of inactive follicles. As the follicles mature, granulosa cells multiply, increasing estradiol secretion. Within a few days of the cycle, one follicle becomes dominant and the others atrophy. The mechanism for follicular recruitment or dominance is unknown. The dominant follicle begins to secrete progressively larger amounts of estrogen (estradiol), which exerts an increase in GnRH receptor concentration and an increase in pituitary sensitivity to GnRH, creating a positive feedback effect that causes a FSH and LH surge. Ovulation occurs 1 to 2 hours before the final progesterone surge, or about 12 to 36 hours after the onset of the FSH and LH surge. Progesterone, proteolytic enzymes, and prostaglandins trigger mechanisms controlling follicular rupture and release of the ovum. The FSH and LH surge also transforms the granulosa cells of the ovulatory follicle into the corpus luteum. The corpus luteum secretes both estrogen and progesterone in amounts that depend, in part, on adequate development of the
follicle before ovulation. Progesterone acts both centrally and locally within the ovary to suppress new follicular growth during the early to midluteal phases. If pregnancy does not occur, the corpus luteum persists for 11 to 14 days and then regresses and eventually disappears. An increase in pulse frequency of GnRH from a low level reactivates hormonal control of the menstrual cycle.

**Uterine Phases**

Uterine phases of the menstrual cycle—the follicular/proliferative phase, the luteal/secretory phase, and menstruation—involve the cyclic changes that occur in the endometrium controlled by estrogen and progesterone. Hormonal effects are influenced by the presence of receptors and numerous growth factors, peptides, and enzymes that act as intermediaries between the sex steroids and the endometrium. During the midfollicular/proliferative phase, increasing levels of estrogen contribute to endometrial repair and proliferation, thus increasing endometrial thickness (luteal phase). Once ovulation occurs and serum progesterone levels increase, the endometrial tissue develops secretory characteristics (secretory phase). If implantation of a fertilized ovum does not take place, endometrial tissue begins to break down approximately 11 days after ovulation (ischemic phase of menstruation; see Figure 32-9). Shedding of tissue (menstrual bleeding) begins about 14 days after ovulation.

Cervical mucus also undergoes cyclic changes. During the proliferative phase, the cervical mucus is thin and watery. Peak estrogen levels occur just before ovulation and maximally stimulate the cervical glands to produce mucus. Cervical mucus becomes abundant and more elastic (spinnbarkeit). Increasing estrogen levels apparently contribute to the development of tiny channels in cervical mucus, providing access for sperm into the interior of the uterus. Changes in the consistency of cervical mucus can be used to identify fertile intervals.24

**Vaginal Response**

The vaginal endothelium also responds to the cyclic hormonal changes of the menstrual cycle. Under the influence of estrogen, cells of the vaginal epithelium grow maximally during the follicular/proliferative phase. After ovulation, layers of keratinized cells overgrow the basal epithelium, a process known as **cornification**. Near the end of the luteal phase, leukocytes invade vaginal epithelium, removing the outer layers in a process termed **decornification**.

**Body Temperature**

Basal body temperature (BBT) undergoes characteristic biphasic changes during
menstrual cycles in which ovulation occurs. During the follicular phase, the BBT fluctuates around 98° F (37° C). During the luteal phase, the average temperature increases by 0.4° to 1.0° F (0.2° to 0.5° C). At the end of the luteal phase, 1 to 3 days before the onset of menstruation, BBT declines to follicular-phase levels. The shift in temperature is related to ovulation, corpus luteum formation, and increased serum progesterone levels. Progesterone probably acts on the thermoregulatory center of the hypothalamus to increase body temperature. Changes in BBT are used to document ovulatory cycles but when used alone are not the best method to predict the exact timing of ovulation.25

Quick Check 32-4

1. Why does menstruation occur?

2. What event is associated with the luteal/secretory phase of the menstrual cycle?
Structure and Function of the Breast

The breasts are modified sebaceous glands that lie on the ventral surface of the thorax, within the superficial fascia of the chest wall. They extend vertically from the second rib to the sixth or seventh intercostal space and laterally from the side of the sternum to the midaxillary line. Breast tissue also may extend into the axilla; this tissue is known as the tail of Spence.

Female Breast

The female breast is composed of 15 to 20 pyramid-shaped lobes that are separated and supported by Cooper ligaments (Figure 32-10). Each lobe contains 20 to 40 lobules (alveoli), which subdivide further into many functional units called acini (sing., acinus). Each acinus is lined with a layer of epithelial cells capable of secreting milk and a layer of subepithelial cells capable of contracting to squeeze milk from the acinus. Biochemical signaling and density within the extracellular matrix is essential for differentiation and function of the acini glandular epithelium. The acini empty into a network of lobular collecting ducts, which empty into interlobular collecting and ejecting ducts. Collagen fiber alignment is required for ductal elongation and organized branching. The ducts reach the skin through openings (pores) in the nipple. The lobes and lobules are surrounded and separated by muscle strands and fatty connective tissue. The amount of fatty connective tissue varies among individuals, depending on weight and genetic and endocrine factors, and contributes to the diversity of breast size and shape and the function of the mammary epithelium. Fat increases in the breast after menopause.
An extensive capillary network surrounds the acini and is supplied by the internal and lateral thoracic arteries and the intercostal arteries. Venous return follows arterial supply, with relatively rapid emptying into the superior vena cava. The breasts receive sensory innervation from branches of the second through sixth intercostal nerves and the cervical plexus. This accounts for the fact that breast pain may be referred to the chest, back, scapula, medial arm, and neck. Lymphatic drainage of the breast occurs largely through axillary nodes, but there may be predominance of superficial mammary routes with resultant asymmetry between a person's breasts\(^7\) (Figure 32-11).
The **nipple** is a pigmented cylindric structure usually located at the fourth or fifth intercostal space. On its surface lie multiple openings, one from each lobe. It measures 0.5 to 1.3 cm in diameter and is approximately 10 to 12 mm in height when erect. The **areola** is the pigmented circular area around the nipple. It may be 15 to 60 mm in diameter. A number of sebaceous glands, the **glands of Montgomery**, are located within the areola and aid in lubrication of the nipple during lactation. The nipple and areola contain smooth muscles, which receive motor innervation from the sympathetic nervous system. Sexual stimulation, breastfeeding, and exposure to cold cause the nipple to become erect.

The fetal and early postnatal development of breast tissue does not depend on hormones, although fetal breast tissue does become progressively responsive to hormonal stimulation. During childhood, breast growth is latent and growth of the nipple and areola keeps pace with body surface growth. At the onset of puberty in the female, estrogen secretion stimulates mammary growth. Breast development, or thelarche, is usually the first sign of puberty in the female. Full differentiation and development of breast tissue are mediated by several hormones, including estrogen, progesterone, prolactin, growth hormone, thyroid and parathyroid hormones, insulin, and cortisol.
During the reproductive years, the breast undergoes cyclic changes in response to changes in the levels of estrogen and progesterone associated with the menstrual cycle. Estrogen promotes development of the lobular ducts; progesterone stimulates development of cells lining the acini. Lactation (milk production) occurs after childbirth in response to increased levels of prolactin. Prolactin secretion, in turn, increases by continued breast-feeding. **Oxytocin**, another hormone released after delivery, controls milk ejection (let down) from acini cells. During the follicular/proliferative phase of the menstrual cycle, high estradiol levels increase the vascularity of breast tissue and stimulate proliferation of ductal and acinar tissue. This effect is sustained into the luteal/secretory phase of the cycle. During this phase, progesterone levels increase and contribute to the breast changes induced by estradiol. Specific effects of progesterone include dilation of the ducts and conversion of the acinar cells into secretory cells. Most women experience some degree of premenstrual breast fullness, tenderness, and increased breast nodularity. Breast volume may increase as much as 10 to 30 ml. Because the length of the menstrual cycle does not allow for complete regression of new cell growth, breast growth continues at a slow rate until approximately 35 years of age. Because of the cyclic changes that occur in breast tissue, breast examination should be conducted at the conclusion of or a few days after the menstrual cycle, when hormonal effects are minimal and breasts are at their smallest.

The function of the female breast is primarily to provide a source of nourishment for the newborn. Physiologically, breast milk is the most appropriate nourishment for newborns. Colostrum, produced in low quantities in the first few days postpartum, is rich in immunologic components, including secretory IgA, lactoferrin, leukocytes, and developmental factors, such as epidermal growth factor. The nutrient composition changes over time to meet the changing digestive capabilities and nutritional requirements of the infant. Secretory IgA and nonspecific antimicrobial factors, such as lysosomes and lactoferrin, protect the infant against infection. During lactation, high prolactin levels interfere with hypothalamic-pituitary hormones that stimulate ovulation. This mechanism suppresses the menstrual cycle and can prevent ovulation. In some parts of the world breast-feeding is the major means of contraception (lactational amenorrhea method). However, it is not absolute that ovulation will not occur and this method will not ensure that pregnancy will not occur. Breasts are also a source of pleasurable sexual sensation and in Western cultures have become a sexual symbol.

**Male Breast**

Until puberty, development of the male breast is similar to that of the female breast.
In the absence of sufficiently high levels of estrogen and progesterone, and with antagonistic effects of androgens, the male breast does not develop any further. The normal male breast consists mostly of fat with a small, underdeveloped nipple and a few ductlike structures in the subareolar area. The male breast may appear enlarged in obese men because of accumulation of fatty tissue. During puberty, some males experience benign gynecomastia (benign proliferation of male breast glandular tissue), a condition in which the breasts enlarge temporarily as a result of hormonal fluctuations, and should be differentiated from any underlying systemic disorders.\textsuperscript{32}

The Male Reproductive System

The external genitalia in men perform the major functions of reproduction. Sperm are produced in the male gonads and the testes, and delivered by the penis. The internal male genitalia consist of conducting tubes and fluid-producing glands, all of which aid in the transport of sperm from the testes to the urethral opening of the penis. The male reproductive and urinary structures are shown in Figure 32-12.

External Genitalia

Testes

The testes are the essential organs of male reproduction. Like the ovaries, the testes have two functions: (1) production of gametes (i.e., sperm) and (2) production of sex hormones (i.e., androgens and testosterone).

During embryonic and fetal life, the testes develop within the abdomen (see
Figure 32-1). About 3 months before birth, the testes start to descend toward the developing scrotum. About 1 month before birth, they enter twin passageways called **inguinal canals**. The inguinal canals are vaginal processes created by outpouchings of the peritoneum (lining of the abdominal cavity). The descent of a testis is shown in Figure 32-13. When descent is complete, the abdominal end of each vaginal process closes and the inguinal canal disappears. Failure of the testes to descend through the inguinal canal is known as cryptorchidism. The scrotal end of each vaginal process becomes the outer covering of the testis, the **tunica vaginalis**.
Figure 32-14 shows a sagittal section of a mature testis. The adult testis is oval and varies considerably in length (3 to 6 cm), width (2 to 3.5 cm), depth (3 to 4 cm), and weight (10 to 40 g). The testis is almost entirely surrounded by the tunica vaginalis, which separates the testis from the scrotal wall, and the tunica albuginea. Inward extensions of the tunica albuginea separate the testis into about 250 compartments, or lobules, each of which contains several tortuously coiled ducts called seminiferous tubules. Sperm are produced in these tubules.
production, termed spermatogenesis, is described on p. 796.) Tissue surrounding these ducts contains Leydig cells, which occur in clusters and produce androgens, chiefly testosterone.

The two ends of each seminiferous tubule join and leave the lobule through the tubulus rectus, which leads to the central portion of the testis, the rete testis. The sperm then move through the efferent tubules, or vasa efferentia, to the epididymis, where they mature.

The testes are innervated by adrenergic fibers whose sole function apparently is to regulate blood flow to the Leydig cells. Arterial blood from the internal spermatic and differential arteries flows over the surface of the testes before entering the parenchyma (functional tissues). Surface flow cools the blood to temperatures that promote spermatogenesis, approximately 1° to 7° C (33.8° to 44.6° F) below body core temperature. Additionally, the testes are suspended outside the pelvic cavity to facilitate cooling.

**Epididymis**

The epididymis (pl., epididymides) is a comma-shaped structure that curves over the posterior portion of each testis (see Figure 32-14). It consists of a single, densely
packed and markedly coiled duct measuring 5 to 7 cm in length (but about 6 meters in length when uncoiled). The epididymis has structural and physiologic functions. Its structural function is to conduct sperm from the efferent tubules to the vas deferens, whereas physiologic functions include sperm maturation, mobility, and fertility. When sperm enter the head of the epididymis, they are not fully mature or motile, nor can they fertilize an ovum. During the 12 days (or more) sperm take to travel the length of the epididymis, they receive nutrients and testosterone and their capacity for fertilization is enhanced. After traveling the length of the epididymis, sperm are stored in the epididymal tail and vas deferens. The vas deferens is a duct with muscular layers capable of powerful peristalsis that transports sperm toward the urethra. The vas deferens enters the pelvic cavity through the spermatic cord (see Figure 32-14).

Scrotum
The testes, epididymides, and spermatic cord are enclosed and protected by the scrotum, a skin-covered, fibromuscular sac homologous to the female labia majora (see Figure 32-2). The skin of the scrotum is thin and has rugae (wrinkles or folds), which enable it to enlarge or relax away from the body. At puberty the scrotal skin darkens, develops active sebaceous glands, and becomes sparsely covered with hair. Just under the skin lies a layer of connective tissue (fascia) and smooth muscle, the tunica dartos (see Figure 32-14). The tunica dartos also forms a septum that separates the two testes. Exposure to cold temperatures causes the tunica dartos to contract, pulling the testes close to the warm body. In warm temperatures, the tunica dartos relaxes, suspending the testes away from body heat. These mechanisms promote optimal temperatures for spermatogenesis. In addition, scrotal sensitivity to touch, pressure, temperature, and pain protects the testes from potential harm. During sexual excitement, the scrotal skin and tunica thicken, the scrotum tightens and lifts, and the spermatic cords shorten, partially elevating the testes toward the body. As excitement plateaus, the engorged testes increase 50% in size, rotate anteriorly, and flatten against the body, signaling impending ejaculation.

Penis
The penis has two main functions: delivery of sperm to the female vagina and elimination of urine. (Urine formation and excretion are discussed in Chapter 29.) Embryonically, the penis is homologous to the female clitoris (see Figure 32-2). Figure 32-15 shows a sagittal section of the adult penis and its anatomic relation to other urogenital structures. Externally, the penis consists of a shaft with a tip (the glans) that contains the opening of the urethra (see Figures 32-14 and 32-15). The
skin of the glans folds over the tip of the penis, forming the **prepuce**, or **foreskin**. The skin of the penis is continuous with that of the groin, scrotum, and inner thighs. It is hairless, movable, and darker than surrounding skin.

**FIGURE 32-15** Cross Section of the Penis. (From Thompson JM et al, editors: Mosby's clinical nursing, ed 5, St Louis, 2002, Mosby.)

Internally, the penis consists of the urethra and three compartments or sinusoids: two **corpora cavernosa** and the **corpus spongiosum** (see **Figure 32-15**) separated by Buck fascia. Like the testes, these compartments are enclosed by the fibrous tunica albuginea. The **urethra** passes through the corpus spongiosum and ends at a sagittal slit in the glans.

Penetration of the female vagina is made possible by the **erectile reflex**, a process in which erectile tissues within the corpora cavernosa and corpus spongiosum become engorged with blood. The erectile tissues consist of vascular spaces, or chambers, supplied with blood by arterioles (small arteries). Usually, the arterioles are constricted, so that not much blood flows through the erectile tissues. Sexual stimulation, however, causes the arterioles to dilate and fill with blood, expanding the erectile tissues and causing an erection. Erection apparently is maintained by compression or constriction of veins that drain the corpora cavernosa and corpus spongiosum. When sexual stimulation ceases or orgasm and ejaculation occur, these veins open, blood flows out of the arterioles, and the penis becomes flaccid (soft and pendulous). Erection is under the control of the autonomic nervous system but can be stimulated or inhibited by central nervous system input.

Erections begin in utero and continue throughout life, but ejaculation does not occur until sperm production begins at puberty. Growth of the penis and scrotal contents continues well past puberty, however, and may not be complete until the late
teens or early twenties. Penis size, when flaccid, varies considerably; with an erection, difference in penis size diminishes. Sexual excitement causes the corpora cavernosa to increase in length and width and become rigid; the penis becomes erect. Stimulation of the glans, which is endowed with copious sensitive nerve endings, provides maximum erotic sensation. With sexual arousal, skin color deepens, the glans doubles in size, and the urethral meatus dilates. Ejaculation occurs with frequent, strong contractions of the vas deferens, epididymis, seminal vesicles, prostate, urethra, and penis. Erection and ejaculation can occur independently of each other.\textsuperscript{35,36}

**Internal Genitalia**

Figure 32-12 shows the anatomy of the internal genitalia and their relation to other pelvic organs. The internal genitalia consist of ducts and glands, as follows:

*Ducts*—consist of two vasa deferentia, ejaculatory duct, and urethra; conduct sperm and glandular secretions from the testes to the urethral opening of the penis

*Glands*—consist of prostate gland, two seminal vesicles, and two Cowper (bulbourethral) glands; secrete fluids that serve as a vehicle for sperm transport and create nutritious alkaline medium that promotes sperm motility and survival

Together the sperm and the glandular fluids compose **semen**.

Sperm leave the epididymides and travel rapidly through the internal ducts (emission). Emission occurs just seconds before ejaculation, at the moment when sexual arousal peaks. It always leads to ejaculation.

Emission occurs as smooth muscle in the walls of the epididymides and vasa deferentia begins to contract rhythmically, pushing sperm and epididymal secretions through the vasa deferentia. Each vas deferens is a firm, elastic, fibromuscular tube that begins at the tail of the epididymis, enters the pelvic cavity within the spermatic cord, loops up and over the bladder, and ends in the prostate gland (Figure 32-16). Sperm are conducted by peristaltic contractions of smooth muscle in the walls of the vas deferens.
As sperm leave the ampulla (wide portion) of the vas deferens, the seminal vesicles secrete a nutritive, glucose-rich fluid into the ejaculate (semen). The **seminal vesicles** are glands about 4 to 6 cm long that lie behind the urinary bladder and in front of the rectum. The ducts of the seminal vesicles join the ampulla of the vas deferens to become the **ejaculatory duct**, which contracts rhythmically during emission and ejaculation. As seen in Figures 32-13 and 32-16, the ejaculatory duct joins the urethra, where both pass through the prostate gland. During emission and ejaculation, a sphincter (muscle surrounding a duct) closes, preventing urine from entering the prostatic urethra.

The **prostate gland** is about the size of a walnut, surrounds the urethra, and is composed of glandular alveoli and ducts embedded in fibromuscular tissue. Nerves required for penile erection travel along the posterolateral surface of the prostate. While semen moves through the prostatic portion of the urethra, the prostate gland contracts rhythmically and secretes prostatic fluid (a thin, milky substance with an alkaline pH that helps sperm to survive in the acidic environment of the female reproductive tract) into the mixture. In addition, substances in seminal and prostatic fluids help to mobilize sperm after ejaculation.

**Bulbourethral glands** (Cowper glands) are the last pair of glands to add fluid to the ejaculate; their ducts secrete mucus into the urethra near the base of the penis. Ejaculation occurs as semen reaches the base of the penis, where muscles
rhythmically contract and expel semen. Normally a man ejaculates between 2 and 6 ml of semen, containing 75 million to 400 million sperm. About 98% of the ejaculate consists of glandular fluids; 60% to 70% of the volume originates from the seminal vesicles and 20% from the prostate. Therefore the ejaculate of a man who has undergone a vasectomy (a surgical procedure for permanent male birth control) is reduced by only about 2%.

**Spermatogenesis**

Spermatogenesis begins at puberty and continues for life. In this respect, spermatogenesis differs markedly from oogenesis (production of primordial ova), which occurs during fetal life only. Spermatogenesis takes place within the seminiferous tubules of the testes (see Figures 32-14 and 32-17). The basement membrane of each seminiferous tubule is lined with diploid (46-chromosome) germ cells called spermatogonia (sing., spermatogonium). These cells undergo continuous mitotic division (division into two identical cells, see Chapter 1.) Some spermatogonia move away from the basement membrane and mature, becoming primary spermatocytes (Figure 32-17). These undergo meiosis, cell division that results in two haploid (23-chromosome) cells called secondary spermatocytes. (Meiosis is described and illustrated in Chapter 2.) The secondary spermatocytes also undergo meiosis, resulting in four spermatids. The spermatids differentiate into spermatozoa, or sperm, each of which contains 23 chromosomes (Figure 32-18).

**FIGURE 32-17  Seminiferous Tubule and Spermatogenesis.** Cross section of a seminiferous tubule showing the different cell types. Interstitial cells that produce testosterone are between the seminiferous tubules. Spermatids in the lumen become sperm by a process called spermiogenesis. The numbers in white represent the number of chromosomes. (From Applegate E: The anatomy and physiology learning system, ed 4, St Louis, 2011, Saunders.)
The development of spermatids into sperm depends on the presence of Sertoli cells (nondividing support cells) within the seminiferous tubules. Spermatids attach themselves to the Sertoli cells (see Figure 32-17), where they receive nutrients and hormonal signals necessary to develop into sperm.37

The process of spermatogenesis, from mitotic division of a spermatagonium to maturation of the spermatids, takes about 70 to 80 days. Mature sperm migrate from the seminiferous tubules to the epididymides, where their capacity for fertilization continues to develop. Although they are completely mature by the time they are ejaculated, the sperm do not become motile (capable of movement) until they are activated by biochemicals in semen and in the female reproductive tract (known as sperm capacitation).38

**Male Sex and Reproductive Hormones**

The male sex hormones are androgens. Testosterone, the primary male sex hormone, and other androgens are produced mainly by Leydig cells of the testes, but they are also produced by the adrenal glands (see Table 32-1 and discussion about adrenarche under Puberty and Reproductive Maturation, p. 780). In men, sex hormone production is relatively constant and does not occur in a cyclic pattern, as it does in women.

The physiologic actions of androgen are related to the growth and development of male tissues and organs.39 Androgens are responsible for the fetal differentiation and development of the male urogenital system and have some effects on the fetal brain. After birth, the Leydig cells become quiescent until activated by the gonadotropins during puberty. Then androgens cause the sex organs to grow and
secondary sex characteristics to develop.

Testosterone affects nervous and skeletal tissues, bone marrow, skin and hair, and sex organs. It has an anabolic effect on skeletal muscle tissue, thereby contributing to the difference in body weight and composition between men and women. Testosterone also stimulates growth of the musculature and cartilage of the larynx, causing a permanent deepening of the voice. Testosterone directly stimulates the bone marrow and indirectly stimulates renal erythropoietin production to achieve increased hemoglobin and hematocrit levels. Because sebaceous gland activity is stimulated by testosterone, acne may develop. Hair becomes coarser in texture, and facial, axillary, and pubic hair grows in male patterns. Later in life, testosterone causes baldness in genetically susceptible individuals. Testosterone is required for spermatogenesis and for secretion of fluid by the prostate gland, seminal vesicles, and Cowper glands. Testosterone is also associated with libido (sex drive). Other, less-understood effects of testosterone include alterations in fatty acid and cholesterol metabolism.

The regulation of androgen production and spermatogenesis is achieved by a complex feedback system involving the extrahypothalamic central nervous system, the hypothalamus, the anterior pituitary, the testes, and the androgen-sensitive end organs. These relationships are essentially the same in women (see Figure 32-3).

Quick Check 32-6

1. Which cells produce testosterone?

2. Why do sperm take 12 days to travel the length of the epididymis?

3. What is the purpose of prostatic secretion?
Aging & Reproductive Function

Aging and the Female Reproductive System

Menopause is a normal developmental and transitional event that is universally experienced by the average age of about 51 years with a range of 40 to 60 years. Genetics are associated with timing of menopause and menopause can occur 2 years sooner on average for smokers. Findings from studies of body mass index, physical activity, and race are inconsistent in relation to timing of menopause.\textsuperscript{40} Changes are caused primarily by declining ovarian function and a resulting decrease in ovarian hormone secretion. The primary changes of menopause are as follows\textsuperscript{41}:

\textit{Perimenopause:} This is the transitional period between reproductive and nonreproductive years and can last 1 to 8 years. About 5 to 10 years before menopause, approximately 90\% of women note mild to extreme variability in frequency and quality of menstrual flow. Symptoms usually begin with a shortening of the menstrual cycle, which correlates with a shorter follicular phase, followed by unpredictable or irregular ovulation and a lengthening of the menstrual cycle. The perimenopause varies between women and from cycle to cycle in the same woman.

\textit{Menopause:} Menopause is defined by the point that marks 12 consecutive months of amenorrhea. This means that it is determined retrospectively after a woman has not had a menstrual period for 1 year. It is characterized by loss of ovarian function, low estrogen and progesterone levels, and high FSH and LH levels (Figure 32-19).\textsuperscript{42} Early menopause is the 5 years after menopause onset. Late menopause follows and continues until death.\textsuperscript{43}
**Ovarian changes:** Around 37 to 38 years of age, women experience accelerated follicular loss, which ends when the supply of follicles is depleted at menopause. This accelerated loss is correlated with increased FSH stimulation, declining inhibin production, and slightly elevated estradiol levels (see Figure 32-19). The ovarian response to high FSH level recruits increasing numbers of follicles; these follicles only partially develop, with a net effect of irregular ovulation, lower progesterone levels, and depleted follicle reserve. The ovaries begin to decrease in size around age 30; this decrease accelerates after age 60.

**Uterine changes:** The increase in anovulatory cycles allows for proliferative growth of the endometrium. With this longer exposure to unopposed estrogen and greater thickness of the endometrium, 50% of perimenopausal women will experience dysfunctional uterine bleeding that is heavy and unpredictable. In the past, this has put women at high risk for hysterectomy. Newer treatment includes progesterone administration or endometrial ablation by laser or electrocautery. New methods of decreasing the function of the endometrial tissue are being developed.
Breast tissue changes: Breast tissue becomes involuted, fat deposits and connective tissue increase, and breasts are reduced in size and firmness.

Urogenital tract changes: The ovaries shrink; the uterus atrophies; and the vagina shortens, narrows, and loses some elasticity. Lubrication of the vagina diminishes and vaginal pH increases, creating higher incidence of vaginitis. The cervix atrophies; the cervical os shrinks; vaginal epithelium atrophies; labia major and minora become less prominent; some pubic hair is lost; urethral tone declines along with muscle tone throughout the pelvic area; urinary frequency or urgency, urinary tract infections, and incontinence may occur. Regular sexual activity and orgasm may diminish some of these changes. Sexually active women have less vaginal atrophy.

Skeletal changes: Bone mass is lost, leading to increased brittleness and porosity and possibly osteoporosis particularly in the lumbar spine and femoral neck (see Chapter 39).

Cardiac changes: The risk of coronary heart disease increases significantly with an increase in total and LDL-cholesterol and a decrease in HDL-cholesterol (see Chapter 24).

Systemic changes: Vasomotor flushes are characterized by a rise in skin temperature, dilation of peripheral blood vessels, increased blood flow in the hands, increased skin conductance, and transient increase in heart rate followed by a temperature drop and profuse perspiration over the area of flush distribution. This usually occurs in the face and neck and may radiate into the chest and other parts of the body. Dizziness, nausea, headaches, and palpitations may accompany the flush. These flushes can vary in frequency, intensity, and duration and are experienced for 1 to 15 years (mean 1 to 5 years) by up to 85% of perimenopausal to postmenopausal women. Flushes are believed to be caused by rapid decreases in estrogen levels; estrogen replacement therapy can ameliorate these symptoms. Rapid changes in estrogen levels also can increase emotional stress with unpredictable mood swings, depression and anxiety, weight gain, migraine headaches, and insomnia. Lower estrogen levels will decrease skin thickness and diminish skin elasticity, thereby causing increased skin dryness and wrinkling.

Menopause increases the risk of ovarian, breast, and uterine cancers. The risk is greater in women who began menstruating before age 12 or experience menopause after age 55. Women who menstruate longer than normal during a lifetime are
exposed to more estrogen and have more ovulations. A longer exposure to estrogen increases a woman's risk of uterine and breast cancers, and having more ovulations than normal increases a woman's risk of ovarian cancer.\textsuperscript{45,46}

Hormone therapy can be considered to relieve severe menopausal symptoms. However, risk and benefits of such therapy must be carefully evaluated. There is increased risk for serious disorders for some women including breast cancer, heart disease, and stroke. Risks vary depending on age, timing of menopause, health history, dosage, and route of delivery (oral vs. patch). Nonhormonal therapy also may be an option for symptom relief. An individualized management plan considering risks and benefits of available alternatives can improve quality of life.\textsuperscript{47,48}

\section*{Aging and the Male Reproductive System}

Men maintain reproductive capacity longer than women. No known discrete event, comparable to menopause, characterizes aging of the male reproductive system. Changes do occur, however, in testicular structure and function and sexual behavior.\textsuperscript{49} Emotional and physical changes associated with androgen deficiency in the aging male are known as \textbf{andropause}, but it occurs in only a small percentage of men.\textsuperscript{50} Contributing factors include decreased levels of testosterone, change in responsiveness of target tissues, decreased levels of sex hormone binding globulin, and changes in the hypothalamus and pituitary gland. Obesity also contributes to decreased testosterone production in aging men.\textsuperscript{51,52}

Male sexual behavior encompasses both sexual drive and erectile and ejaculatory capacity. Libido, or sexual drive, is a complex phenomenon that requires a baseline hormonal milieu and is significantly influenced by health status and environmental, social, and psychologic factors. However, in men older than 40 years of age, organic factors are involved in more than half of cases of male sexual dysfunction. Chronic disease and also vascular, endocrine, and neurologic disorders are common causes of organically-based dysfunction of sexual capability. Primary changes\textsuperscript{53} are summarized as follows:

\textit{Sexual drive (libido):} Influenced by changes in health status and testosterone levels.

\textit{Erectile/ejaculatory capacity:} Longer stimulation needed to achieve full erection, slower and less forceful ejaculation, less pelvic muscle involvement; decreased vasocongestive response; longer refractory time, up to 24 hours.

\textit{Testicular changes:} Decreased weight, atrophy, softening of testes; seminiferous
tubules thicken in basement membrane area, have germ cell arrest, decrease in spermatogenic activity, and collapse; then sclerosis and fibrosis cause complete obstruction; semen volume, sperm concentration, total sperm count, sperm motility, and number of motile sperm decrease; morphologic appearance of sperm changes. Fertility decreases.\textsuperscript{54}

_Hormonal changes:_ Hormone synthesis decreases and target tissues decline in responsiveness; testosterone levels decline as number of Leydig cells decreases; gonadotropin levels increase.

_Associated change:_ Functional deterioration of accessory sex organs occurs; loss of muscle mass, strength, and endurance and decrease in libido develop.

Did You Understand?

Development of the Reproductive Systems

1. Differentiation of female and male genitalia begins around 7 to 8 weeks of embryonic development when the gonads of genetically male embryos begin to secrete male sex hormones, primarily testosterone, under the influence of SRY gene expression and testosterone-determining factor (TDF). Female gonadal development occurs in the absence of SRY gene expression. Until that time, the primitive reproductive organs of males and females are homologous (the same).

2. The structure and function of both male and female reproductive systems depend on interactions among the central nervous system (hypothalamus), the endocrine system (anterior pituitary), the gonads (ovaries, testes), and the hypothalamic-pituitary-gonadal (H-P-G) axis. A set of complex neurologic and hormonal interactions accelerate at puberty and lead to sexual maturation and reproductive capability.

3. Production of primitive female gametes (ova) occurs solely during fetal life. From puberty to menopause, one female gamete matures per menstrual cycle. Production of the male gametes (sperm) begins at puberty; after that, millions are produced daily, usually for life.

4. Puberty is the onset of sexual maturation. Adolescence is a stage of human development between childhood and adulthood and includes social, psychologic, and biologic changes.

5. At puberty, extrahypothalamic factors cause the hypothalamus to secrete gonadotropin-releasing hormone (GnRH), which stimulates the anterior pituitary to secrete the gonadotropins follicle-stimulating hormone (FSH) and luteinizing hormone (LH) that stimulate the gonads (ovaries and testes) to secrete female (estrogen and progesterone) or male sex hormones (testosterone). Puberty is complete in females with the first ovulatory menstrual period and is complete in males with the first ejaculation that contains mature sperm.

The Female Reproductive System

1. The function of the female reproductive system is to produce mature ova and, when they are fertilized, to protect and nourish them through embryonic and fetal
life and expel them at birth.

2. The external female genitalia are the mons pubis, labia majora, labia minora, clitoris, vestibule (urinary and vaginal openings), Bartholin glands, and Skene glands. They protect body openings and may play a role in sexual functioning.

3. The internal female genitalia are the vagina, uterus, fallopian tubes, and ovaries. Although all these organs are needed for reproduction, the ovaries are the most essential because they produce the female gametes and female sex hormones.

4. The vagina is a fibromuscular canal that receives the penis during sexual intercourse and is the exit route for menstrual fluids and products of conception. The vagina leads from the introitus (its external opening) to the cervical portion of the uterus.

5. The uterus is the hollow, muscular organ in which a fertilized ovum develops until birth. The uterine walls have three layers: the endometrium (lining), myometrium (muscular layer), and perimetrium (outer covering, which is continuous with the pelvic peritoneum). The endometrium proliferates (thickens) and is shed in response to cyclic changes in levels of female sex hormones. The cervix is the narrow, lower portion of the uterus that opens into the vagina.

6. The two fallopian tubes extend from the uterus to the ovaries. Their function is to conduct ova from the spaces around the ovaries to the uterus. Fertilization normally occurs in the distal third of the fallopian tubes.

7. From puberty to menopause, the ovaries are the site of (1) ovum maturation and release and (2) production of female sex hormones (estrogen, progesterone) and androgens. The female sex hormones are involved in sexual differentiation and development, the menstrual cycle, pregnancy, and lactation. Although they are primarily male sex hormones, androgens in women are precursors of female sex hormones and contribute to the prepubertal growth spurt, pubic and axillary hair growth, and activation of sebaceous glands.

8. Estrogen (primarily estradiol) is produced by cells in the developing ovarian follicle (structure that encloses the ovum). Progesterone is produced by cells of the corpus luteum, the structure that develops from the ruptured ovarian follicle after ovulation (ovum release). Androgens are produced within the ovarian follicle, adrenal glands, and adipose tissue.
9. The average menstrual cycle lasts 27 to 30 days and consists of three phases, which are named for ovarian and endometrial changes: the follicular/proliferative phase, the luteal/secretory phase, and menstruation.

10. Ovarian events of the menstrual cycle are controlled by gonadotropins and follicular secretion of inhibin. High follicle-stimulating hormone (FSH) levels stimulate follicle and ovum maturation (follicular phase); then a surge of luteinizing hormone (LH) causes ovulation, which is followed by development of the corpus luteum (luteal phase).

11. Uterine (endometrial) phases of the menstrual cycle are caused by ovarian hormones. During the follicular phase of the ovarian cycle, estrogen produced by the follicle causes the endometrium to proliferate (proliferative phase). During the luteal phase, estrogen maintains the thickened endometrium, and progesterone causes it to develop blood vessels and secretory glands (secretory phase). During the ischemic/menstrual phase, the corpus luteum degenerates, production of both hormones drops sharply, and the “starved” endometrium degenerates and is shed, causing menstruation.

12. Cyclic changes in hormone levels also cause thinning and thickening of the vaginal epithelium, thinning and thickening of cervical secretions, and changes in basal body temperature.

Structure and Function of the Breast

1. Until puberty, the female and male breasts are similar, consisting of a small, underdeveloped nipple, some fatty and fibrous tissue, and a few ductlike structures under the areola. At puberty, however, a variety of hormones (estrogen, progesterone, prolactin, growth hormone, insulin, cortisol) cause the female breast to develop into a system of glands and ducts that is capable of producing and ejecting milk.

2. The basic functional unit of the female breast is the lobe, a system of ducts that branches from the nipple to milk-producing units called lobules. Each breast contains 15 to 20 lobes, which are separated and supported by Cooper ligaments. The lobules contain acini cells, which are convoluted spaces lined with epithelial cells. Contraction of the subepithelial cells of each acinus moves milk into the system of ducts that leads to the nipple.
3. Milk production occurs in response to prolactin, a hormone that is secreted in larger amounts after childbirth. Milk ejection is under the control of oxytocin, another hormone of pregnancy and lactation.

4. During the reproductive years, breast tissue undergoes cyclic changes in response to hormonal changes of the menstrual cycle. At menopause, the tissue involutes, fat deposits and connective tissue increase, and the breasts reduce in size and firmness.

5. The male breast does not develop because of the absence of sufficiently high levels of estrogen and progesterone, and antagonistic effects of androgens.

**The Male Reproductive System**

1. The function of the male reproductive system is to produce male gametes (sperm) and deliver them to the female reproductive tract.

2. The external male genitalia are the testes, epididymides, scrotum, and penis. The internal genitalia are the vas deferens, ejaculatory duct, prostatic and membranous sections of the urethra, seminal vesicles, prostate gland, and bulbourethral glands.

3. The testes (male gonads) are paired glands suspended within the scrotum. The testes have two functions: spermatogenesis (sperm production) and production of male sex hormones (androgens, chiefly testosterone).

4. The epididymis is a long, coiled tube arranged in a comma-shaped compartment that curves over the top and rear of the testis. The epididymis receives sperm from the testis and stores them while they develop further. Sperm travel the length of the epididymis and then are ejaculated into the vas deferens, which transports sperm to the urethra.

5. The scrotum is a skin-covered, fibromuscular sac that encloses the testes and epididymides, which are suspended within the scrotum by the spermatic cord. The scrotum keeps these organs at optimal temperatures for sperm survival (about 1° to 2° C lower than body temperature) by contracting in cold environments and relaxing in warm environments.

6. The penis is a cylindric organ consisting of three longitudinal compartments (two corpora cavernosa and one corpus spongiosum) and the urethra. The urethra runs through the corpus spongiosum. The corpora cavernosa and corpus spongiosum consist of erectile tissue. Externally the penis consists of a shaft and a tip, which is
called the *glans*.

7. The penis has two functions: delivery of sperm and elimination of urine.

8. Sexual intercourse is made possible by the erectile reflex, in which tactile or psychogenic stimulation of the parasympathetic nerves causes arterioles in the corpora cavernosa and corpus spongiosum to dilate and fill with blood, causing the penis to enlarge and become firm.

9. Emission, which occurs at the peak of sexual arousal, is the movement of semen from the epididymides to the penis. Ejaculation, which is a continuation of emission, is the pulsatile ejection of semen from the penis.

10. Spermatogenesis is a continuous process because spermatogonia, the primitive male gametes, undergo continuous mitosis within the seminiferous tubules of the testes. Some spermatogonia develop into primary spermatocytes, which divide meiotically into secondary spermatocytes and then spermatids. The spermatids develop into sperm with the help of nutrients and hormonal signals from Sertoli cells.

11. Production of the male sex hormones (androgens) is controlled by interactions among the hypothalamus, anterior pituitary, and gonads. The male hormones are produced steadily rather than cyclically, however.

### Aging & Reproductive Function

1. Perimenopause is the transitional period between reproductive and nonreproductive years in women.

2. Menopause, the point that marks 12 consecutive months of amenorrhea, includes atrophic changes in the ovaries, vagina, and breast; loss of bone mass; and increased risk of cardiovascular disease.

3. Andropause is androgen deficiency in the aging male and occurs in about 1 in 200 men. There is a decrease in testosterone production with testicular atrophy, decreased fertility, and some loss of muscle mass and strength.

Alterations of the reproductive system span a wide range of concerns—from delayed sexual development and suboptimal sexual performance to structural and functional abnormalities. Many common reproductive disorders carry potentially serious physiologic or psychologic consequences. For example, sexual or reproductive dysfunction, such as impotence or infertility, can dramatically affect self-concept, relationships, and overall quality of life. Conversely, organic and psychosocial problems, such as alcoholism, depression, situational stressors, chronic illness, and medications, can affect ovulation and menstruation, sexual performance, and fertility and may be risk factors for the development of some types of reproductive tract cancers. Diagnosis and treatment of reproductive system disorders, however, are often complicated by the stigma and symbolism associated with the reproductive organs and emotion-laden beliefs and behaviors related to reproductive health. Treatment or diagnosis for any problem may be delayed because of embarrassment, guilt, fear, or denial.
Abnormalities of the Female Reproductive Tract

Normal development of the female reproductive tract requires absence of testosterone during embryonic and fetal life (see Chapter 32). The resulting fusion of the two paramesonephric (müllerian) ducts produces the normal cervix and the uterus with an internal cavity. The distal portions of the paramesonephric ducts remain independent and form the two fallopian/uterine tubes. Alterations in the normal process include errors in cellular sensitivity to testosterone (androgen insensitivity) or failures of cell line migration resulting in changes in the structure of the reproductive organs.

Androgen insensitivity occurs in its most extreme form in about 1 in 20,000 people and is discussed briefly in this chapter because of the often-resulting female phenotype despite a male genotype. Androgen insensitivity syndrome (AIS) is a disorder of hormone resistance characterized by a female phenotype in an individual with an XY karyotype or male genotype, and with testes producing age-appropriate normal concentrations of androgens. To date, more than 1000 mutations have been reported in the androgen receptor (AR) with most of these being associated with androgen insensitivity syndrome. Children with complete androgen insensitivity may have testes palpable within the labia majora, but are often not diagnosed until puberty. Breast development may be normal but pubic and axillary hair is often sparse and menarche does not occur because of the absence of a cervix, uterus, and ovaries. A short vagina that ends blindly also may be present. Milder forms of androgen insensitivity (also a common cause of male infertility) are much more common and have less dramatic phenotypic manifestations with many having normal male genitalia.

Other abnormalities of the uterus, cervix, and fallopian/uterine tubes have multifactorial origins, often the result of an interaction between genetic predisposition and environmental factors. Such interactions result in müllerian duct abnormalities. Some medications, chemicals, and toxins have been implicated as a direct cause of uterine abnormalities.

About 5% of the general female population has some sort of uterine abnormality but the rate is much higher in populations of women who have experienced infertility or miscarriage. Most uterine abnormalities stem from abnormal cell migration in the müllerian ducts during key moments in fetal development (Figure 33-1). Uterine abnormalities are rarely diagnosed until the woman has trouble becoming pregnant or carrying a baby to term because the uterus is capable of menstruation but may have difficulty supporting a growing fetus.
malformations are usually diagnosed by ultrasound during pregnancy or with magnetic resonance imaging (MRI). Their prognosis depends on the severity of the malformation and the location and size of the placenta and fetus. Some abnormalities can be surgically corrected to improve the outcome of subsequent pregnancies. Abnormalities of the lower genital tract also can result in women having two vaginas or a vaginal septum (a thin membrane dividing the vaginal vault). For most women this does not create functional problems but can be surgically corrected if needed.
Alterations of Sexual Maturation

The process of sexual maturation, or puberty, is marked by the development of secondary sex characteristics, rapid growth, and, ultimately, the ability to reproduce. A variety of congenital and endocrine disorders can disrupt the timing of puberty. These disorders may cause puberty to occur too late (delayed puberty) or too early (precocious puberty). Both types involve an inappropriate onset of sex hormone production by the gonads.

The age of puberty is multifactorial, involving genetic and environmental components. The study of epigenetics and the regulation of puberty is only beginning. Girls of African descent and Hispanic/Latina girls begin puberty up to 1 year sooner than their non-African and non-Latina counterparts. Obesity decreases the age at onset of puberty by about 6 months. Although many factors are associated with obesity, much research is being done on leptin-responsive pathways in the regulation of eating behaviors and the onset of puberty, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). A recent genetic study found pubertal onset in girls is strongly influenced by genetic variation affecting follicle-stimulating hormone (FSH). FSH stimulates ovarian follicle maturation and estradiol synthesis, which is responsible for breast development. The normal range for the onset of puberty is now 8 to 13 years of age. Although there are conflicting and inconsistent reports, the age of pubertal onset appears to be decreasing for girls. This earlier onset appears primarily in breast development, not age of menarche. On average, breast development begins at age 10.4 for white girls and 9.5 years for black girls. The average age for menarche is 12.6 years for white girls and 12.1 for black girls. However, 5% of white girls and 15% of all girls will begin puberty before age 8. Both precocious puberty and delayed puberty have implications for the child's social interactions and self-esteem.

Delayed or Absent Puberty

About 3% of children living in North America experience delayed development of secondary sex characteristics. One of the first signs of puberty in girls is thelarche, or breast development; it should begin by 13 years of age. Normally, boys tend to mature later than girls, around 14 to 14.5 years of age. In boys, the first sign of maturity is enlargement of the testes and thinning of the scrotal skin. In delayed puberty, these secondary sex characteristics develop later.

In about 95% of cases, delayed puberty is a normal physiologic event. Hormonal levels are normal, the hypothalamic-pituitary-gonadal (HPG) axis is intact, and maturation is slowly occurring. Treatment is seldom needed unless the delayed
puberty is causing psychosocial problems. The other 5% of cases are caused by the disruption of the hypothalamic-pituitary-gonadal axis or by the outcomes of a systemic disease. Treatment depends on the cause (Table 33-1 and Box 33-1), and referral to a pediatric endocrinologist is recommended.

GnRH, Gonadotropin-releasing hormone.

## Box 33-1
Causes of Delayed Puberty

**Hypergonadotropic Hypogonadism (Increased Follicle-Stimulating Hormone [FSH] and Luteinizing Hormone [LH])**

1. Gonadal dysgenesis, most commonly Turner syndrome (45,X/46,XX; structural X or Y abnormalities; or mosaicism)

2. Klinefelter syndrome (47,XXY)

3. Bilateral gonadal failure
   a. Traumatic or infectious
   b. Postsurgical, postirradiation, or postchemotherapy
c. Autoimmune

d. Idiopathic empty-scrotum or vanishing-testes syndrome (congenital anorchia) or resistant-ovary syndrome

**Hypogonadotropic Hypogonadism (Decreased LH, Depressed FSH)**

1. Reversible

   a. Physiologic delay

   b. Weight loss/anorexia

   c. Strenuous exercise

   d. Severe obesity

   e. Illegal drug use, especially marijuana

   f. Primary hypothyroidism

   g. Congenital adrenal hyperplasia

   h. Cushing syndrome

   i. Prolactinomas

2. Irreversible

   a. Gonadotropin-releasing hormone (GnRH) deficiency (Kallmann syndrome) or idiopathic hypogonadotropic
hypogonadism (IHH)

b. Hypopituitarism

c. Congenital central nervous system (CNS) defects

d. Other pituitary adenomas

e. Craniopharyngioma

f. Malignant pituitary tumors

**Eugonadism**

These conditions are associated with amenorrhea but may have otherwise normal pubertal development:

1. Congenital anomalies

   a. Müllerian agenesis

   b. Vaginal septum or imperforate hymen

2. Androgen insensitivity syndrome

3. Inappropriate positive feedback

**Precocious Puberty**

Precocious puberty is a rare event, affecting about 1 in 10,000 girls and fewer than 1 in 50,000 boys. Precocious puberty has been defined as sexual maturation occurring before age 6 in black girls or age 7 in white girls and before age 9 in boys. Precocious puberty for boys of all ethnic/racial groups is defined as sexual maturation occurring before age 9. Precocious puberty may be caused by many conditions (Box 33-2), including obesity, an increase in protein consumption, and
endocrine disruptors in common household products, pesticides, plasticizers, and pharmaceuticals\textsuperscript{15,16} as well as lethal central nervous system tumors. All cases of precocious puberty require thorough evaluation.

**Box 33-2**

**Primary Forms of Precocious Puberty**

**Complete Precocious Puberty**

Premature development of appropriate characteristics for the child's gender

Hypothalamic-pituitary-ovarian axis functioning normally but prematurely

In about 10% of cases, lethal central nervous system tumor may be the cause

**Partial Precocious Puberty**

Partial development of appropriate secondary sex characteristics

Premature thelarche (breast budding) seen in girls between 6 months and 2 years of age

Does not progress to complete puberty (ovulation and menstruation)

Premature adrenarche (growth of axillary and pubic hair) tends to occur between 5 and 8 years of age

Can progress to complete precocious puberty; may be caused by estrogen-secreting neoplasms or may be a variant of normal pubertal development

**Mixed Precocious Puberty**

Causes the child to develop some secondary sex characteristics of the opposite gender

Common causes: adrenal hyperplasia or androgen-secreting tumors

All forms of precocious puberty are treated by identifying and removing the underlying cause or administering appropriate hormones (see Boxes 33-2 and 33-3). In many cases, precocious puberty can be reversed. However, complete precocious puberty is the onset and progression of all pubertal features (i.e., thelarche, pubarche, and menarche), is a challenge to treat, and causes long bones to stop growing before the child has reached normal height.

Quick Check 33-1

1. Why does puberty occur too late or too early in some individuals?

2. Define the normal age range for the onset of puberty.

Box 33-3

Causes of Mixed Precocious Puberty

Female (Virilization)

Congenital adrenal hyperplasia

Androgen-secreting tumors

Adrenal

Ovarian

Teratoma

Exogenous androgens

Male (Feminization)

Estrogen-producing tumors

Adrenal
Teratoma

Hepatoma

Testicular

Exogenous estrogens

Increased peripheral conversion of androgens to estrogens

Disorders of the Female Reproductive System

Hormonal and Menstrual Alterations

Dysmenorrhea

**Primary dysmenorrhea** is painful menstruation associated with the release of prostaglandins in ovulatory cycles, but not with pelvic disease. Approximately 50% of all women experience dysmenorrhea and 10% are incapacitated for 1 to 3 days because of pain severity. Primary dysmenorrhea begins with the onset of ovulatory cycles and prevalence is highest during adolescence. The incidence steadily rises, peaks in women in the late teens and early twenties, and decreases slowly thereafter. **Secondary dysmenorrhea** is related to pelvic pathologic conditions, manifests later in the reproductive years, and may occur any time in the menstrual cycle.

Pathophysiology

Primary dysmenorrhea results mostly from excessive prostaglandin $F_2\alpha$ ($\text{PGF}_2\alpha$), a potent myometrial stimulant and vasoconstrictor, found in secretory endometrium. Elevated levels of prostaglandins, especially $\text{PGF}_2\alpha$ and $\text{PGE}_2\alpha$, increase myometrial contractions, constrict endometrial blood vessels, and enhance nerve hypersensitivity, resulting in pain. These changes can lead to ischemia and endometrial shedding. Increased synthesis of prostaglandins may result from increased cyclooxygenase (COX) enzyme activity. Inflammatory mediators produced in leukocytes (leukotrienes) also contribute to increased levels of pain. The first 48 hours of menstruation correlate with higher prostaglandin levels. Women who are anovulatory because they use oral contraceptives rarely have primary dysmenorrhea. Secondary dysmenorrhea results from disorders such as endometriosis (most common cause), endometritis (infection), pelvic inflammatory disease, adhesions, obstructive uterine or vaginal anomalies, inflammation, uterine fibroids, polyps, tumors, cysts, or intrauterine devices (IUDs).

Clinical manifestations

The chief symptom of dysmenorrhea is pelvic pain associated with the onset of menses. The severity is directly related to length and amount of menstrual flow. The pain often radiates into the groin and may be accompanied by backache, anorexia, vomiting, diarrhea, syncope, and headache. The latter symptoms are caused by the entry of prostaglandins and their metabolites into the systemic circulation. The discomfort commonly begins shortly before the onset of menstruation and rarely
persists 1 to 3 days during menstrual flow.\textsuperscript{18}

**Evaluation and treatment**

Primary dysmenorrhea can be differentiated from secondary dysmenorrhea by obtaining a thorough medical history and performing a pelvic examination. Nonsteroidal anti-inflammatory drugs (NSAIDs, e.g., ibuprofen) are the treatment of choice because they reduce COX enzyme activity, and thus prostaglandin production. NSAIDs are effective in the majority of women with primary dysmenorrhea and are most effective if started at the first sign of bleeding or cramping. In women who desire contraception, dysmenorrhea may be relieved with hormonal contraceptives. Hormonal contraception stops ovulation and creates an atrophic endometrium, thereby decreasing prostaglandin synthesis and myometrial contractility. Regular exercise and stress reduction are thought to prevent or reduce symptoms. Other palliative approaches with some evidence of effectiveness in pain relief include local application of heat; acupuncture; high-frequency transcutaneous electrical nerve stimulation (TENS); supplements, such as thiamine and vitamin E; and Chinese herbal treatment.\textsuperscript{19}

**Amenorrhea**

Amenorrhea means lack of menstruation; and the most common causes (aside from pregnancy) include hypothalamic dysfunction, polycystic ovarian syndrome, hyperprolactinemia, and ovarian failure. Primary amenorrhea is the failure of menarche and the absence of menstruation by age 13 years without the development of secondary sex characteristics or by age 15 years regardless of the presence of secondary sex characteristics\textsuperscript{20} (see p. 804 for a discussion of delayed puberty). Secondary amenorrhea is the absence of menstruation for a time equivalent to three or more cycles in women who have previously menstruated.

**Pathophysiology**

One approach to understanding the pathophysiology is to compartmentalize. **Compartment I disorders** are anatomic defects, including absence of the vagina and uterus. **Compartment II disorders** involve the ovary, primarily genetic disorders (such as Turner syndrome) and androgen insensitivity syndrome (AIS). The target organs (e.g., ovaries) in AIS are completely resistant to the action of androgens, resulting in a lack of estrogen. **Compartment III disorders** are of the anterior pituitary gland, including tumors, and result in failure of signaling to the ovaries through follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion. **Compartment IV disorders** include central nervous system (CNS)
disorders and primarily involve hypothalamic defects that prevent secretion of gonadotropin-releasing hormone (GnRH); thus, there is no signaling to the pituitary to release FSH and LH.

**Clinical manifestations**
The major clinical manifestation of primary amenorrhea is the absence of the first menstrual period. The cause of the amenorrhea determines whether secondary sex characteristics and height are affected.

**Evaluation and treatment**
Diagnosis of primary amenorrhea is based on the results of a history and physical examination and determination of the presence or absence of secondary sexual characteristics. Laboratory studies may be required to document abnormal levels of gonadotropins or ovarian hormones, or the presence of genetic conditions. Diagnostic imaging, including ultrasonography and MRI, is used to document structural abnormalities.

Treatment involves correction of any underlying disorders and implementation of hormone replacement therapy to induce the development of secondary sex characteristics. Although surgical alteration of the genitalia may be undertaken to correct abnormalities, it should be postponed until the individual can make a truly informed decision.

**Secondary Amenorrhea**
Many disorders and physiologic conditions are associated with secondary amenorrhea. Secondary amenorrhea is common (normal) during early adolescence, pregnancy, lactation, and the perimenopausal period, primarily because of anovulation. The most common causes (after pregnancy) are thyroid disorders (e.g., hypothyroidism); hyperprolactinemia; hypothalamic-pituitary-ovarian (HPO) interruption secondary to excessive exercise, stress, or weight loss; and polycystic ovary syndrome (PCOS).

**Pathophysiology**
The pathophysiology is dependent on the causes of secondary amenorrhea. These causes are summarized in Figure 33-2.
Clinical manifestations

The major manifestation of secondary amenorrhea is the absence of menses after previous menstrual periods. Depending on the underlying cause of the amenorrhea, infertility, vasomotor flushes, vaginal atrophy, acne, osteopenia, and hirsutism (abnormal hairiness) may be present.

Evaluation and treatment

Pregnancy is the most common cause of secondary amenorrhea and must be ruled out before any further evaluation. A thorough history and physical examination is important because the menstrual cycle may stop or become irregular in response to stress, extreme exercise, large dietary changes, eating disorders, or sleep abnormalities. Hypothyroidism also is a common cause and should be ruled out as well. Diagnosis of secondary amenorrhea involves identifying underlying hormonal or anatomic alterations. Evaluation of thyroid-stimulating hormone (TSH) or prolactin levels may be indicated. Depending on the cause of the amenorrhea, treatment may involve hormone replacement therapy or a corrective procedure, such as surgical removal of a pituitary tumor. The choice of treatment may be influenced by the woman's childbearing plans.
Abnormal Uterine Bleeding

Menstrual irregularity or abnormal bleeding patterns (Table 33-2) account for approximately 33% of all gynecologic visits. The most common cause of cycle irregularity is failure to ovulate related to age, stress, or endocrinopathy. Common causes of abnormal bleeding based on age group and frequency are presented in Table 33-3.

**Dysfunctional uterine bleeding (DUB)** is heavy or irregular bleeding in the absence of organic disease (i.e., uterine fibroids, polyps, infection, or systemic disease). DUB is a diagnosis of exclusion made only after other causes have been ruled out. DUB accounts for 70% of all hysterectomies, and almost all endometrial ablation procedures. Perimenopausal women are by far the most affected by DUB.

### Pathophysiology

The majority of DUB is associated with lack of ovulation. Although DUB may occur at any time during the reproductive years and many conditions are associated with irregular ovulation, more than 50% of cases occur in perimenopausal women ages 40 to 50 years when they are more likely to ovulate irregularly. Women who fail to ovulate experience irregularities in their menstrual bleeding because of a lack of progesterone and, in some cases, an excess of estrogen. This results in excessive and irregular endometrial thickness and subsequent excessive and irregular bleeding. PCOS, obesity, and thyroid disease also are common
contributors. Abnormal bleeding can result from defects of the corpus luteum resulting in progesterone deficiencies or from abnormalities of the uterus or cervix, such as endometrial polyps, uterine fibroids, or uterine or cervical cancers.

Abnormal menstrual bleeding in ovulatory cycles is less common, and mechanisms underlying the bleeding are unclear but can include defects of the corpus luteum and abnormalities of the uterus or cervix, such as polyps, fibroids, or cancer. Excessive fibrinolytic activity, use of anticoagulants, diseases of coagulation, infection, and changes in prostaglandin production may be implicated.

**Clinical manifestations**

DUB is characterized by unpredictable and variable bleeding in terms of amount and duration. Especially during perimenopause, dysfunctional bleeding also may involve flooding and the passing of large clots, leading to excessive blood loss. Excessive bleeding can lead to iron deficiency anemia and associated symptoms, including fatigue or shortness of breath.

**Evaluation and treatment**

DUB is diagnosed after other organic conditions that could cause abnormal bleeding are eliminated. If no cause is found it is usually assumed that the bleeding is caused by lack of regular ovulation. NSAIDs are often first-line treatments for excessive menstrual bleeding because they reduce prostaglandin synthesis within the endometrial tissues, leading to vasoconstriction and decreased bleeding. For the best effect they should be taken in the few days preceding the beginning of the menstrual period and be continued through the days of heaviest bleeding. NSAIDs are not as effective in controlling menstrual blood loss as hormonal therapies but they are readily available without a prescription.

Goals of therapy are to control bleeding, prevent hyperplasia, prevent or treat anemia, and treat concurrent endocrine problems if present. Common treatments include administration of oral contraceptive pills that contain estrogen and progesterone, prescription of long-term therapy with medroxyprogesterone (Depo-Provera) (although the U.S. Food and Drug Administration [FDA] black box warning about potential bone loss has greatly curtailed the use of this therapy), and placement of a levonorgestrel intrauterine device (LNG-IUD). The LNG-IUD has a dual indication from the FDA for both birth control and suppression of abnormal menstrual bleeding. The device releases a steady amount of progesterone directly into the uterus to stabilize and suppress the uterine lining. In addition, the progesterone works to suppress the HPG axis and prevent ovulation.

Women who do not wish to have future pregnancies also can opt for treatments that permanently suppress their uterine lining. These treatments include ablation,
where the lining is burned to prevent future proliferation of the endometrial cells, and complete removal of the uterus in hysterectomy. If a woman is menopausal and has not had a menstrual period for greater than 1 year, all vaginal bleeding should be investigated to rule out uterine and other cancers.

**Polycystic Ovary Syndrome**

Polycystic ovary syndrome (PCOS) remains one of the most common endocrine disturbances affecting women (Figure 33-3). International criteria for the diagnosis of PCOS require at least two of the following conditions: few or anovulatory menstrual cycles, elevated levels of androgens, and polycystic ovaries. Thus polycystic ovaries do not have to be present to diagnose PCOS and their presence alone does not establish the diagnosis. Furthermore, PCOS should not be confused with benign ovarian cysts, which are common during the reproductive years and have a different etiology (see Benign Ovarian Cysts, p. 815). PCOS is a leading cause of infertility in the United States. PCOS has a large incidence of inheritability. Signs and symptoms of PCOS can vary over time, with metabolic syndrome becoming more prominent with age.23

![Polycystic Ovary. Surgical view of polycystic ovaries.](image)

**Pathophysiology**

The direct cause of PCOS is related to a genetic predisposition and an obesity-prone
lifestyle related to insulin resistance and an excess of insulin and androgens. A hyperandrogenic state is a cardinal feature in the pathogenesis of PCOS. However, glucose intolerance/insulin resistance (IR) and hyperinsulinemia often occur concurrently and markedly aggravate the hyperandrogenic state, thus contributing to the severity of signs and symptoms of PCOS.\textsuperscript{23} PCOS predisposes to obesity and preexisting obesity predisposes to more severe PCOS.

Insulin resistance and resultant compensatory hyperinsulinemia overstimulates androgen secretion by the ovarian stroma and reduces hepatic secretion of serum sex hormone–binding globulin (SHBG). The net effect is an increase in free testosterone levels. Excessive androgens affect follicular growth, and insulin affects follicular decline by suppressing apoptosis and enabling the survival of follicles that would normally disintegrate (Figure 33-4). Further, there seems to be a genetic ovarian defect in PCOS that makes the ovary either more susceptible to or more sensitive to insulin's stimulation of androgen production in the ovary.

Inappropriate gonadotropin secretion triggers the beginning of a vicious cycle that perpetuates anovulation. Typically, levels of follicle-stimulating hormone (FSH) are low or below normal, and the luteinizing hormone (LH) level is elevated.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure33-4.png}
\caption{Insulin Resistance and Hyperinsulinemia in Polycystic Ovary Syndrome (PCOS). See text for explanation. FSH, Follicle-stimulating hormone; LH, luteinizing hormone; SHBG, sex hormone–binding globulin.}
\end{figure}
Persistent LH level elevation causes an increase in the concentration of androgens (dehydroepiandrosterone sulfate [DHEAS] from the adrenal glands and testosterone, androstenedione, and dehydroepiandrosterone [DHEA] from the ovary). Androgens are converted to estrogen in peripheral tissues, and increased testosterone levels cause a significant reduction (approximately 50%) in SHBG level, which, in turn, causes increased levels of free estradiol. Elevated estrogen levels trigger a positive feedback response in LH and a negative feedback response in FSH. Because FSH levels are not totally depressed, new follicular growth is continuously stimulated, but not to full maturation and ovulation (see Figure 33-4).\textsuperscript{23,24}

**Clinical manifestations**

Clinical manifestations of PCOS usually appear within 2 years of puberty, but may appear after a period of normal menstrual function and pregnancy. Symptoms are related to anovulation and hyperandrogenism and include dysfunctional uterine bleeding or amenorrhea, hirsutism, acne, and infertility (Box 33-4). Hypertension and dyslipidemia also are frequently found in association with PCOS. PCOS is often found in association with other endocrine disorders.\textsuperscript{24}

<table>
<thead>
<tr>
<th>Presenting Signs and Symptoms (% of Women Affected)</th>
</tr>

<tr>
<td>Infertility (73% of anovulatory infertility)</td>
</tr>
</tbody>
</table>
Asymptomatic (20% of those with polycystic ovary syndrome)

**Hormonal Disturbances**

Increased insulin (independent of obesity)

Decreased SHBG

Increased androgens (testosterone, androstenedione)

Increased DHEA (occurs in 50% of women)

Increased LH (genetic variant LH-β subunit)

Increased prolactin

Increased leptin, especially in obesity (independent of insulin)

Suggested decreased insulin-like growth factor 1 (IGF-1) receptors on theca cells

Possible decreased estrogen receptors (intraovarian and along hypothalamic-pituitary axis)

**Possible Late Sequelae**

Dyslipidemia: increased low-density lipoproteins, decreased high-density lipoproteins, increased triglycerides

Diabetes mellitus (30% of women with or without obesity will develop type 2 diabetes mellitus by age 30)

Cardiovascular disease; hypertension

Endometrial hyperplasia and carcinoma (anovulatory women are hyperestrogenic)

**Other**

Women with PCOS are at increased risk of gestational diabetes mellitus, pregnancy-induced hypertension, preterm birth, and perinatal mortality

*DHEA*, Dehydroepiandrosterone; *LH*, luteinizing hormone; *PCOS*, polycystic
ovary syndrome; SHBG, sex hormone–binding globulin.

**Evaluation and treatment**

Diagnosis of PCOS is based on evidence of androgen excess (hirsutism, male pattern hair distribution, acne), chronic anovulation (as evidenced by irregular menstrual patterns, amenorrhea, and infertility), insulin resistance (obesity may be an indication, as well as abnormal glucose tolerance testing), and inappropriate gonadotropin secretion (low serum FSH concentration, and elevated levels of LH and DHEA). Treatment of PCOS often includes use of combined oral contraceptives to control irregular menstrual cycles and to oppose estrogens and androgens. Insulin sensitizers, such as metformin, may be used to decrease insulin resistance, prevent diabetes and heart disease, and restore fertility. Insulin sensitizers combined with clomiphene citrate may be effective for ovulation induction for women who are trying to become pregnant. Reductions in weight can dramatically improve insulin sensitivity and return of ovulatory cycles.

**Premenstrual Disorders Syndrome**

Premenstrual syndrome (PMS) and premenstrual dysphoric disorder (PMDD) are the cyclic recurrence (in the luteal phase of the menstrual cycle) of distressing physical, psychologic, or behavioral changes that impair interpersonal relationships or interfere with usual activities. The luteal phase of ovulatory cycles is linked with complex hormonal changes of the menstrual cycle. PMDD is often considered a severe, sometimes disabling extension of premenstrual syndrome (PMS). The prevalence of PMS and PMDD is difficult to determine, possibly because of the wide-ranging nature of accepted symptoms. Symptoms for PMS and PMDD begin after ovulation during the luteal phase and persist up to 4 days into the menstrual cycle. It has been estimated that 91% of women experience some form of distress around their menstrual period; 30% experience enough distress to interrupt their daily routine; but a much smaller number, as low as 3.1%, meet the criteria for PMDD.

**Pathophysiology**

There are many theories to explain PMS/PMDD and the mechanisms, including an increased vulnerability to fluctuations in ovarian-derived hormones, and hypothalamic-pituitary-adrenal (HPA) axis changes. Poorly understood are the
neuroendocrine mechanisms of the hormonal environment of the menopausal transition that might trigger depression. Erratic ovarian hormone fluctuation may be a mediator of risk for both vasomotor symptoms (hot flashes) and perimenopausal depression. Under investigation are the effects of changes in estradiol concentrations and the altered anti-inflammatory and neuroprotective consequences and modulation of limbic processing and memory. Neurotransmitters, such as serotonin, gamma-aminobutyric acid (GABA), and norepinephrine, have demonstrated interactions with estrogen and progesterone and have established mood and behavior effects, including negative mood, irritability, aggression, and impulse control. Additionally, neurotransmitters may have mediating or moderating roles on symptom manifestation. Sex steroids also interact with the renin-angiotensin-aldosterone system (RAAS), which could explain some PMS/PMDD signs and symptoms (e.g., water retention, bloating, weight gain). Levels of inflammatory mediators may be elevated with menstrual symptom severity and PMS.

A predisposition to PMS occurs in families, perhaps because of genetics or shared environment. A woman's menstrual experience is often similar to her mother's or her sister's experience. Evidence supports a relationship between severity and frequency of PMS/PMDD and reports of low well-being, major affective disorder, and personal characteristics, such as increased stress, poor nutrition, lack of exercise, low self-esteem, perfectionism, history of sexual abuse, and family conflict. In turn, when PMS/PMDD is distressing, the quality of interpersonal relationships and self-image are negatively affected.

Clinical manifestations

The pattern of symptom frequency and severity is more important than specific complaints. Nearly 300 physical, emotional, and behavioral symptoms have been attributed to PMS/PMDD. Emotional symptoms, particularly depression, anger, irritability, and fatigue, have been reported as the most prominent and the most distressing, whereas physical symptoms seem to be the least prevalent and problematic. The presence of underlying physical or psychologic disease may be aggravated premenstrually and must be diagnosed and treated independently of PMS/PMDD.

Evaluation and treatment

Diagnosis of PMS/PMDD is based on health history and symptoms. Current treatment is symptomatic because the cause is complex and cannot be reduced to a single biologic explanation and occurrence and severity are mediated by lifestyle, social, and psychologic factors. For many women, nonpharmacologic therapies,
with or without medication, can be as effective in controlling symptoms as medication alone.\textsuperscript{28} Approaches may include stress reduction, exercise, family or individual counseling, biofeedback, diet (see \textit{Health Alert: Nutrition and Premenstrual Syndrome}), imagery, acupuncture, and rest. Two major forms of treatment include the use of hormonal cycle regulation and use of selective serotonin reuptake inhibitor (SSRI) antidepressants.\textsuperscript{29} If a woman does not desire immediate fertility, the oral contraceptive pill containing estrogen and progesterone has shown benefits in decreasing PMS/PMDD. In severe cases, menses can be abolished using GnRH agonists.

\textbf{Health Alert}

\textbf{Nutrition and Premenstrual Syndrome}

Women who are affected by premenstrual syndrome (PMS) often look for ways to decrease their symptoms. Dietary interventions that can help are multiple: eating six small meals each day; increasing intake of complex carbohydrates, fiber, and water; and decreasing caffeine, alcohol, refined sugar, and animal fat consumption. A low-fat vegetarian diet has been associated with decreased symptoms, possibly because of an increase in serum sex hormone–binding globulin concentration that lowers serum estrogen levels. It also may be helpful to limit sodium intake, and some limited evidence suggests that moderate doses (50 mg/day) of vitamin B\textsubscript{6} may reduce emotional symptoms of depression, irritability, and fatigue. This finding needs to be confirmed.

High food intake of thiamine and riboflavin was observed to lower risk of PMS. Thiamine, riboflavin, niacin, vitamin B\textsubscript{6}, folate, and vitamin B\textsubscript{12} are required to synthesize neurotransmitters. Limited data suggest that dietary minerals may be useful in preventing PMS. Prospective analyses suggest that higher plasma vitamin D levels may be inversely related to the development of specific menstrual symptoms. Vitamin D deficiency is associated with increased renin-angiotensin-aldosterone system (RAAS) activity, a system that regulates fluid balance and blood pressure. Vitamin D may lower the risk of unipolar depression. More research needs to confirm all of these findings.

Some researchers have suggested links between serotonin, endorphins, and high sugar intake and PMS risk. One interesting craving is chocolate. Some researchers suggest that a craving for chocolate is an unconscious desire for a compound called phenylethylamine (PEA) in chocolate that stimulates the release of the neurotransmitter dopamine, which regulates mood.
Quick Check 33-2

1. Why does amenorrhea occur?

2. Why do anovulatory cycles lead to dysfunctional uterine bleeding?

3. Discuss insulin resistance, hyperinsulinemia, anovulation, and androgen production in PCOS.

4. What are the current theories of pathophysiology for PMS/PMDD?

Infection and Inflammation

Infections of the genital tract may result from exogenous or endogenous microorganisms. Exogenous pathogens are most often sexually transmitted. Endogenous causes of infection include microorganisms that are normally resident in the vagina, bowel, or vulva. Infection occurs if these microorganisms migrate to a new location or overproliferate when the immune system and other defense mechanisms are impaired.

Skin disorders that can affect the vulva include reactive dermatitis, contact dermatitis, psoriasis, and impetigo. (For a discussion of skin disorders, see Chapter 41.) Most infectious disorders, however, that affect the vulva and vagina are sexually transmitted. These currently recognized sexually transmitted infections are described in Table 34-1 on p. 877.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an acute inflammatory process caused by infection (Figure 33-5). PID may involve any organ, or combination of organs, of the upper genital tract—the uterus, fallopian tubes, or ovaries—and, in its most severe form, the entire peritoneal cavity. Many infectious disorders that affect the vulva and vagina are sexually transmitted, such as chlamydia and gonorrhea that migrate from the vagina to the uterus, fallopian tubes, and ovaries. However, microorganisms that comprise the vaginal flora (e.g., anaerobes, Gardnerella vaginalis, Haemophilus influenzae, enteric gram-negative rods, and Streptococcus
agalactiae) also are implicated with PID. Additionally, cytomegalovirus (CMV), Mycoplasma hominis, Ureaplasma urealyticum, and Mycoplasma genitalium may be associated with PID. The risk factors for PID include infection by a previous sexually transmitted disease (STD) that was not treated (delaying treatment increases complications from PID); having multiple sex partners or a sex partner who has had multiple sex partners or a previous PID; being sexually active at age 25 or younger; using douches; and using an intrauterine device (IUD) for birth control. Other causes of infection include spontaneous or induced abortions, normal or abnormal deliveries (called puerperal infections), or other surgical procedures; these infections are often polymicrobial.

**Pathophysiology**

The development of upper genital tract infections is mediated by a number of defense mechanisms, including virulence of the microorganism, size of the inoculum, and immune defense status of the individual. PID develops when pathologic microbes ascend from an infected cervix to infect the uterus and adnexae (uterine appendages). The initial infection usually involves the endocervical mucosa, but it can start in the Bartholin gland and other glands. From these sites the infection can move upwards to involve the fallopian tubes and tubo-ovarian region (Figure 33-6). STDs from gonorrhea and chlamydia are the main infectious causes of PID; however, other infections not sexually transmitted (e.g., induced abortion, dilation and curettage of the uterus, and other surgical procedures) also can cause PID. Many anaerobic bacteria have been implicated in increasing the risk of PID because they alter the pH of the vaginal environment and may decrease the integrity
of the mucus blocking the cervical canal. Bacterial vaginosis (BV) is present in up to 66% of women with PID and other anaerobes, such as *Bacteroides*, and *Gardnerella vaginalis*, *Haemophilus influenzae*, and genital tract mycoplasmas (*Mycoplasma hominis*, *Mycoplasma genitalis*, and *Ureaplasma urealyticum*) are frequently isolated from women with PID. *Escherichia coli* may contribute to pelvic infections in older women. Therefore, although gonorrhea and chlamydia are the main pathogens in PID, the disease is actually polymicrobial in origin and is treated with a broad spectrum of antibiotics to ensure that all the causative agents are eliminated.
Salpingitis

Salpingitis is inflammation of the fallopian tubes (see Figure 33-6). The inflammatory process develops after the infection has been established and induces changes in the columnar epithelia that line the upper reproductive tract. The inflammation causes localized edema and sometimes necrosis of the area. Gonorrhea gonococci attach to the fallopian tubes and excrete a substance toxic to
the tubal mucosa, causing further inflammation and damage. Chlamydia enters the tubal cells and replicates, bursting the cell membrane as it reproduces, causing permanent scarring. Gonorrhea and chlamydia can spread to the abdominal cavity through the openings of the fallopian/uterine tubes. Other mechanisms that may contribute to PID include lymphatic drainage with parametrial spread of the infection. The acute complications of PID include peritonitis and bacteremia, which can increase the risk for endocarditis, meningitis, and infectious arthritis. The chronic consequences of PID include infertility and tubal obstruction, ectopic pregnancy, pelvic pain of varying degrees, and intestinal obstruction from adhesions between the bowel and pelvic organs.31

Clinical manifestations
The clinical manifestations of PID vary from sudden, severe abdominal pain with fever to no symptoms at all. An asymptomatic cervicitis may be present for some time before PID develops. The first sign of the ascending infection may be the onset of low bilateral abdominal pain, often characterized as dull and steady with a gradual onset. Symptoms are more likely to develop during or immediately after menstruation. The pain of PID may worsen with walking, jumping, or intercourse. Other manifestations of PID include dysuria (difficult or painful urination) and irregular bleeding.

Evaluation and treatment
PID often has limited or vague clinical symptoms, leading to undertreatment and long-term health effects.32 Because PID is a substantial health risk to a woman, the Centers for Disease Control and Prevention (CDC) encourage clinicians to consider PID as a likely diagnosis when a sexually active woman has abdominal or pelvic tenderness and one of the following: cervical motion tenderness, uterine tenderness, or adnexal tenderness.30 Box 33-5 lists the diagnostic criteria for PID. No labs or studies are needed to begin treatment; however, additional information can improve the specificity of diagnosis. Abdominal pain in women can have many causes, and it is important to rule out other diagnoses, which can be done while treating for PID.30

Box 33-5
Diagnostic Criteria for Pelvic Inflammatory Disease

Minimum Criteria (One or More Needed for Diagnosis)
Cervical motion tenderness, or
Uterine tenderness, or
Adnexal tenderness

**Additional Criteria That Increase Specificity of Diagnosis**

- Body temperature >38.3° C (>101° F)
- Mucopurulent cervical or vaginal discharge
- Numerous white blood cells on saline wet prep
- Elevated C-reactive protein
- Elevated erythrocyte sedimentation rate
- Documented infection with *Chlamydia trachomatis* or *Neisseria gonorrhoeae*

**Definitive Criteria (Not Needed for Treatment)**

- Transvaginal ultrasound, magnetic resonance imaging, or
- Doppler studies showing thickened and fluid-filled tubes
- Laparoscopic visualization of PID-related abnormalities

*PID*, Pelvic inflammatory disease.

The complications of PID can be significant; therefore, rapid treatment is recommended even before the causative pathogen can be identified. Because treatment is empiric, it needs to be effective against a broad range of pathogens, especially chlamydia, gonorrhea, and anaerobic bacteria. Treatment is usually done on an outpatient basis unless the woman has symptoms of advanced infection, cannot take oral medications, is pregnant, or exhibits other pathologies that cannot be excluded. The CDC-recommended outpatient regimen is shown in Box 33-6.
Box 33-6

CDC Outpatient Recommended Regimen for PID

Ceftriaxone 250 mg IM in a single dose

Plus

Doxycycline 100 mg orally twice a day for 14 days

With or without

Metronidazole 500 mg orally twice a day for 14 days

Or

Cefoxitin 2 g IM in a single dose and probenecid 1 g orally administered concurrently in a single dose

Plus

Doxycycline 100 mg orally twice a day for 14 days

With or without

Metronidazole 500 mg orally twice a day for 14 days

Or

Other parenteral third-generation cephalosporin (e.g., ceftizoxime or cefotaxime)
**Plus**

**Doxycycline** 100 mg orally twice a day for 14 days

**With or without**

**Metronidazole** 500 mg orally twice a day for 14 days

Although alternative treatment regimens are available, the growing antibiotic resistance of gonorrhea limits antibiotic choices. The CDC is closely monitoring gonorrhea’s antibiotic sensitivity and updates treatment guidelines periodically to reflect new information. To prevent recurrence, sexual partners of women with PID should also receive treatment, even if they are asymptomatic. Women receiving treatment should be reevaluated by their care provider in 3 days to ensure antibiotic treatment is effective. Because women with a history of PID are at increased risk for ectopic pregnancy, they should seek care as soon as they know they are pregnant because ectopic pregnancy is a major cause of maternal mortality.

The diagnosis of PID is based on history, abdominal tenderness, the presence of uterine and cervical movement tenderness on bimanual pelvic examination, mucopurulent discharge at the cervical os, white blood cells on Gram stain or wet mount of cervical discharge, leukocytosis, and increased erythrocyte sedimentation rate. To support the diagnosis, tests for chlamydia and gonorrhea are done; sonography, laparoscopy, and culdocentesis are indicated when a woman has recurrent symptoms or symptoms unresponsive to outpatient treatment regimens, a temperature greater than 38°C (100.4°F), or an adnexal mass. Other conditions that cause pelvic pain must be excluded, including ectopic pregnancy, threatened abortion, ovarian torsion, ovarian cyst, or appendicitis. Recommendations for physical rest and avoidance of intercourse are often given as precautionary and comfort measures during initial recovery (i.e., 1 to 2 weeks).

**Vaginitis**

**Vaginitis** is irritation or inflammation of the vagina, typically caused by infection. Vaginitis is characterized by an increase in white blood cells on saline wet prep examination. Vaginal irritation without white blood cells is known as *vaginosis*. The major causes of vaginitis are overgrowth of normal flora, sexually transmitted
diseases, and vaginal irritation related to low estrogen levels during menopause (a condition known as atropic vaginitis). The incidence of sexually transmitted vaginitis remains highest in women 15 to 24 years of age.

The development of vaginitis is related to alterations in the vaginal environment and includes changes with complications in local defense mechanisms, such as skin integrity, immune reaction, and particularly vaginal pH. The pH of the vagina (normally 4.0 to 4.5) depends on cervical secretions and the presence of normal flora that help maintain an acidic environment. Changes in the vaginal pH may predispose a woman to infection. Variables that affect the vaginal pH and therefore the bactericidal nature of secretions and the predisposition to infection include douching; using soaps, spermicides, feminine hygiene sprays, and deodorant menstrual pads or tampons; and having conditions associated with increased glycogen content of vaginal secretions, such as pregnancy and diabetes.

Antibiotics often destroy normal vaginal flora, facilitating overgrowth of Candida albicans and causing a yeast infection. Increased vaginal alkalinity also may enhance susceptibility to trichomoniasis and BV.

Diagnosis is based on history, physical examination, and examination of the discharge by wet mount. Infection is suggested with a marked change in color or if the discharge becomes copious, malodorous, or irritating.

Treatment involves developing and maintaining an acidic environment, relieving symptoms (usually pruritus and irritation), and administering antimicrobial or antifungal medications to eradicate the infectious organism. If the infection can be sexually transmitted, the woman's partner will also need to be treated. Research suggests that probiotics, especially Lactobacillus crispatus, can encourage proliferation of normal vaginal flora and decrease the incidence of vaginitis in women at risk for this disease.\(^{34,35}\) A probiotic bacterial strain, Lactobacillus plantarum P17630, can attach to vaginal epithelium and reduce the adhesion of C. albicans, and may help reduce Candida recurrence.\(^ {36} \)

**Cervicitis**

Cervicitis is a nonspecific term used to describe inflammation of the cervix. The CDC defines cervicitis as having two major diagnostic signs: a purulent or mucopurulent discharge from the cervical os or endocervical bleeding induced by gently introducing a cotton swab into the cervix.\(^ {37} \) Either sign or both may be present. Cervicitis can have infectious or noninfectious causes. Chemicals and substances introduced into the vagina can cause cervicitis as well as disruptions in the normal vaginal flora. However, there are conflicting definitions of cervicitis used clinically and in research. Age and risk factors are important in assessing a
woman with cervicitis. Younger women are at risk for sexually transmitted infections (STIs) and should be tested for chlamydia, gonorrhea, and trichomoniasis. Older women with cervicitis may have STIs but are at risk for irritation from abnormal vaginal flora related to low vaginal estrogen levels.

**Mucopurulent cervicitis (MPC)** is usually caused by one or more sexually transmitted pathogens, such as *Trichomonas, Neisseria, Chlamydia, Mycoplasma*, or *Ureaplasma*. Infection causes the cervix to become red and edematous. A mucopurulent (mucus- and pus-containing) exudate drains from the external cervical os, and the individual may report vague pelvic pain, bleeding, or dysuria. Bleeding can occur during sexual intercourse or with pelvic examinations, or both, and Pap smears. Because mucopurulent cervicitis is a symptom of PID, women at risk for STIs, especially those less than 26 years old, should receive treatment for PID while awaiting results of microbial testing. If the woman is not at risk for STIs, a thorough evaluation often reveals another cause for the inflammation. Partners should be notified and examined if chlamydia, gonorrhea, or trichomoniasis was identified or suspected in the affected woman; these partners should then be treated for the STIs. To avoid reinfection, women and their sex partners should abstain from sexual intercourse until therapy is completed (i.e., 7 days after a single-dose regimen or after completion of a 7-day regimen). The infectious microorganisms are cultured or identified by immunoassay. Definitive diagnosis is followed by oral antibiotic therapy.

**Vulvodyniavestibulitis**

**Vulvodyniavestibulitis (VV)** (also referred to as vulvitis, vestibulitis, or vulvovestibulitisdynia) is chronic vulvar pain lasting 3 months or longer without visible dermatosis; inflammation of the vulva or vaginal vestibule, or both; infection; neoplasia; or identifiable neurologic disorder. The classification of vulvodynia is based on the location of the pain, whether it is localized or generalized, and whether the pain is provoked, unprovoked, or mixed. *Localized* is characterized by pain from a cause that usually does not cause pain (allodynia) to the vulvar vestibule (entrance of vagina) area. *Generalized* is a diffuse pain pattern involving all of the pudendal nerve distribution and beyond. *Provoked* means any touch or stimulation that elicits pain, *unprovoked* is pain that occurs in the absence of touch or stimulation, and *mixed* is pain that varies with or without touch or stimulation. Individuals describe the pain as burning, stinging, irritation, or rawness. In many cases it may represent several disorders without an identifiable cause. Vulvodynia is fairly common with lifetime estimates of prevalence ranging from 10% to 28% among reproductive-aged women; in addition, it can affect girls.
occurs across races and the incidence seems to decrease with increasing age.

The cause of vulvodynia is unknown. Theories suggest it is multifactorial in origin including embryonic factors, chronic inflammation, genetic immune factors, nerve pathways, increased sensitivity to environmental factors (infection, trauma, irritants), hormonal changes, human papillomavirus (HPV), and oxalates.\footnote{39} Although the inflammation of VV may be caused by contact dermatitis (i.e., exposure to soaps, detergents, lotions, sprays, shaving, menstrual pads/tampons, perfumed toilet paper, tight-fitting clothes), the condition may be more complex and represent abnormalities in three interdependent systems: vestibular mucosa, pelvic floor musculature, and central nervous system pain regulatory pathways. The condition also may represent an autoimmune reaction. The suggested pathophysiology of vulvodynia is a chronic disorder of the nerves that supply the vulva. Some evidence has documented nerve fiber proliferation or neural hyperplasia in the affected tissue.\footnote{39} An important trigger is chronic inflammation caused by contact irritants, recurrent infections, hormonal changes, and chronic skin conditions. Overall, with normal sensations there is a heightened sensitivity. Vulvodynia often occurs in the context of other pain conditions and includes irritable bowel syndrome, interstitial cystitis, recurrent yeast infections, and fibromyalgia.\footnote{40} Because the mechanisms of vulvodynia are poorly understood it is often a difficult condition to evaluate and treat.

After ruling out and treating conditions that can contribute to or cause vulvar inflammation (e.g., Candida, STIs, seborrhea, psoriasis), there are few treatment options. Cotton swab testing is used to identify painful areas. Studies on treatments are limited but suggest that women may benefit from topical lidocaine (Xylocaine), topical or systemic antidepressants, behavioral treatment, Botox injections into the affected nerve, or vestibulectomy. Bathing in lukewarm water in a mild baking soda solution can be soothing and ice packs may help.\footnote{39} Hot water may incite vulvar symptoms. Suggested approaches include use of hydrocortisone cream, application of a water barrier (such as thick skin cream or solid vegetable shortening) during a period of healing, behavioral treatment (35% to 83% of women benefit), or vestibulectomy (61% to 94% success rate), a procedure that is understandably unacceptable to many women. Women also are advised to avoid irritants, wear loose cotton clothing, and use appropriate antimicrobial/antifungal treatments for any recurrent vaginitis.

**Bartholinitis**

**Bartholinitis,** or **Bartholin cyst,** is an acute inflammation of one or both of the ducts that lead from the introitus (vaginal opening) to the Bartholin/greater
vestibular glands (Figure 33-7). Most lesions of the Bartholin gland are cysts or abscesses. The usual causes are microorganisms that infect the lower female reproductive tract, such as streptococci, staphylococci, and sexually transmitted pathogens. Acute bartholinitis may be preceded by an infection, such as cervicitis, vaginitis, or urethritis.

Infection or trauma causes inflammatory changes that narrow the distal portion of the duct, leading to obstruction and stasis of glandular secretions. The obstruction, or cyst, varies from 1 to 8 cm in diameter and is located in the posterolateral portion of the vulva. The affected area is usually red and painful, and pus may be visible at the opening of the duct. This exudate should be cultured. The individual may have fever and malaise. Diagnosis is based on the clinical manifestations and the identification of infectious microorganisms.

Chronic bartholinitis is characterized by the presence of a small cyst that is slightly tender but otherwise is asymptomatic. Most Bartholin cysts require no treatment. Symptoms only occur if an exacerbation of infection causes an abscess to form in the gland itself.

Diagnosis is based on the clinical manifestations and the identification of infectious microorganisms. Treatment is controversial but involves broad-spectrum antibiotics. Some clinicians attempt to drain the cyst using hot soaks, needle aspiration, insertion of a catheter, or marsupialization (cutting a slit and suturing the edges) of the infected gland. No single treatment has proved superior for both relief
and prevention of recurrence. Pain is relieved with analgesics and warm sitz baths. If an abscess forms, it may be surgically drained.

**Pelvic Organ Prolapse**

The bladder, urethra, and rectum are supported by the endopelvic fascia and perineal muscles. This muscular and fascial tissue loses tone and strength with aging and may fail to maintain the pelvic organs in the proper position. Progressive descent of the pelvic support structures may cause pelvic floor disorders, such as urinary and fecal incontinence, and pelvic organ prolapse. *Pelvic organ prolapse (POP)* is the descent of one or more of the following: the vaginal wall, the uterus, or the apex of the vagina (after a hysterectomy). Although more than 50% of women have some version of POP on physical examination, most women have no symptoms. When prolapse becomes severe, the function of the surrounding organs can be altered. POP is thought be caused by direct trauma (such as childbirth); pelvic floor surgery; or damage to pelvic innervation, particularly the pudendal nerve. Risk factors in nulliparous women, however, include occupational activities that require heavy lifting or chronic medical conditions, such as chronic lung disease or refractory constipation (chronically increased intra-abdominal pressure). The most frequently cited risk factors are aging, obesity, and hysterectomy. Other risk factors include a strong familial tendency (from family and twin studies) and possibly a multifactorial genetic component.\(^4^{2}\) Prolapse of the bladder, urethra, rectum, or uterus may occur many years after an initial injury to the supporting structure.

**Uterine prolapse** is descent of the cervix or entire uterus into the vaginal canal, and in severe cases the uterus falls completely through the vagina and protrudes from the introitus, creating ulceration and obvious discomfort. Figure 33-8 illustrates the different degrees (grades) of uterine prolapse, showing descent of the cervix or the entire uterus into the vaginal canal. Grade 1 prolapse is not treated unless it causes discomfort. Grades 2 and 3 prolapse usually cause feelings of fullness, heaviness, and collapse through the vagina. Symptoms of other pelvic floor disorders also may be present.
A common first-line treatment is a **pessary**, which is a removable mechanical device that holds the uterus in position. The pelvic fascia may be strengthened through Kegel exercises (repetitive isometric tightening and relaxing of the pubococcygeal muscles) or by estrogen therapy in menopausal women. Maintaining a healthy body mass index, preventing constipation, and treating chronic cough may help prevent prolapse. Surgical repair, with or without hysterectomy, is the treatment of last resort.

**Figure 33-9** shows pelvic organ prolapse associated with cystocele and rectocele. **Cystocele** is descent of a portion of the posterior bladder wall and trigone into the vaginal canal and is usually caused by childbirth. In severe cases, the bladder and anterior vaginal wall bulge outside the introitus. Symptoms are usually insignificant in mild to moderate cases. Increased bulging and descent of the anterior vaginal wall and urethra can be aggravated by vigorous activity, prolonged standing, sneezing, coughing, or straining and can be relieved by rest or by assumption of a recumbent or prone position. If the prolapse is large, women may complain of vaginal pressure. Medical management can include vaginal pessary, Kegel exercises, and estrogen therapy for postmenopausal women. Surgical treatment is used for severe injury unresponsive to medical treatment (see *Health Alert: Vaginal Mesh*).
Vaginal Mesh

Because pelvic organ prolapse is often a result of weakened pelvic fascia and musculature, a surgical mesh was developed to improve pelvic support. This mesh was designed to be placed surgically along the area needing support. The goal was to have the woman's tissues grow through the mesh and provide consistent, long-term support. However, women who received the surgical mesh had a high rate of complications, including infection and persistent postoperative pain. In many cases the mesh eroded through the tissue, protruding into the vagina and perforating other organs. In addition, the mesh may shrink over time, causing vaginal shortening, tightening, and pain.

Some large studies have shown a benefit from mesh use for some women. However, once implanted, the mesh is difficult to remove if it is ineffective, resulting in long-term pain and the need for intensive surgeries and repairs. The U.S. Food and Drug Administration has issued several warnings about the mesh to caution women and practitioners and encourage fully informed consent about the risks and benefits of mesh placement.

A rectocele is the bulging of the rectum and posterior vaginal wall into the vaginal canal. Childbirth may increase damage, ultimately leading to a rectocele, but symptoms may not appear until after menopause. Genetic and familial predisposition and bowel habits contribute to rectocele development. Lifelong chronic constipation and straining may produce or aggravate a rectocele. A large rectocele may cause vaginal pressure, rectal fullness, and incomplete bowel evacuation. Defecation may be difficult and can be facilitated by applying manual pressure to the posterior vaginal wall. Medical treatment focuses on the management and prevention of constipation and, if needed, the use of a pessary. Rectocele alone (without associated enterocele, uterine prolapse, and cystocele) seldom requires surgery.

An enterocele is a herniation of the rectouterine pouch into the rectovaginal septum (between the rectum and the posterior vaginal wall). It can be congenital or
acquired. Although congenital enterocele rarely causes symptoms or progresses in size, those acquired can result from muscular weakness caused by previous surgery, especially those through the vagina, or from pelvic relaxation disorders, such as uterine prolapse, cystocele, and rectocele. Most large enteroceles are often found in grossly obese and older adults. Treatment is surgical. Box 33-7 summarizes the symptoms and treatment of POP.

**Benign Growth and Proliferative Conditions**

**Benign Ovarian Cysts**

Benign cysts of the ovary may occur at any time during the life span, but are most common during the reproductive years and, in particular, at the extremes of those years (Figure 33-10). An increase in benign ovarian cysts occurs when hormonal imbalances are more common, around puberty and menopause. Benign ovarian cysts are quite common, comprising one third of gynecologic hospital admissions. Two common causes of benign ovarian enlargement in ovulating women are follicular cysts and corpus luteum cysts. These cysts are called **functional cysts** because they are caused by variations of normal physiologic events. Follicular and corpus luteum cysts are unilateral. They are typically 5 to 6 cm in diameter but can
grow as large as 8 to 10 cm. Most women are asymptomatic.

Benign cysts of the ovary are produced when a follicle or a number of follicles are stimulated but no dominant follicle develops and completes the maturation process. Every month about 120 follicles are stimulated, and generally, only 1 succeeds in ovulation of a mature ovum. Normally, in the early follicular phase of the menstrual cycle, follicles of the ovary respond to hormonal signals from the brain. The pituitary gland produces FSH to mature follicles in the ovary. If the dominant follicle develops properly before ovulation, the corpus luteum becomes vascularized and secretes progesterone. Progesterone arrests development of other follicles in both ovaries in that cycle. LH, proteolytic enzymes, and prostaglandins trigger follicular rupture and release of the ovum.

**Follicular cysts** (also called ovarian or functional cysts) are filled with fluid and can be caused by a transient condition in which the dominant follicle fails to rupture or one or more of the nondominant follicles fails to regress. This disturbance is not well understood. It may be that the hypothalamus does not receive or send a message strong enough to increase FSH levels to the degree necessary to develop or mature a dominant follicle. The hypothalamus monitors blood levels of estradiol and progesterone; when FSH level is low, estradiol concentration does not increase enough to stimulate LH surge. Research indicates that when progesterone is not being produced, the hypothalamus releases gonadotropin-releasing hormone (GnRH) to increase the FSH level. FSH continues to stimulate follicles to mature, and the granulosa cells grow and, presumably, estradiol level increases. This abnormal cycle continues to stimulate follicular size and causes follicular cysts to
develop. Although individuals may experience no symptoms, some have pelvic pain, a sensation of feeling bloated, tender breasts, and heavy or irregular menses. After several subsequent cycles in which hormone levels once again follow a regular cycle and progesterone levels are restored, cysts usually will be absorbed or will regress. Follicular cysts can be random or recurrent events.

A corpus luteum cyst may normally form by the granulosa cells left behind after ovulation. This cyst is highly vascularized but usually limited in size, and with the normal menstrual cycle it spontaneously regresses. With an imbalance in hormones, low LH and progesterone levels may cause an abnormal or hemorrhagic cyst. In some cases, large cysts can rupture and cause hemorrhage.

Corpus luteum cysts are less common than follicular cysts, but luteal cysts typically cause more symptoms, particularly if they rupture. Manifestations include dull pelvic pain and amenorrhea or delayed menstruation, followed by irregular or heavier-than-normal bleeding. Rupture occasionally occurs and can cause massive bleeding with excruciating pain; immediate surgery may be required. Corpus luteum cysts usually regress spontaneously in nonpregnant women. Oral contraceptives may be used to prevent cysts from forming in the future.

Dermoid cysts are ovarian teratomas that contain elements of all three germ layers; they are common ovarian neoplasms. These growths may contain mature tissue including skin, hair, sebaceous and sweat glands, muscle fibers, cartilage, and bone. Dermoid cysts are usually asymptomatic and are found incidentally on pelvic examination. Dermoid cysts have malignant potential and should be removed.

Torsion of the ovary is a rare complication of ovarian cysts or tumors or enlargement of the ovary; and it can occur in girls or women. If a cyst is sufficiently large, it can cause the ovary to twist on its ligaments, decreasing blood supply to the ovary and causing extreme pain. Ovarian torsion is rare but is a gynecologic emergency when present. It usually presents with acute, severe unilateral abdominal or pelvic pain and is treated surgically.

Quick Check 33-3

1. Why is prompt treatment of pelvic inflammatory disease (PID) critical to reproductive health?

2. Why do benign ovarian cysts develop in women who ovulate?

3. What is the difference between a follicular cyst and a corpus luteum cyst?
Endometrial Polyps

An endometrial polyp is a benign mass of endometrial tissue and contains a variable amount of glands, stroma, and blood vessels. Endometrial polyps are usually solitary and can occur anywhere within the uterus. Polyps are structurally diverse and are usually classified as hyperplastic, atrophic (or inactive), or functional. Hyperplastic polyps are often pedunculated (stalk or mushroom-like) and may be mistaken for endometrial hyperplasia or, if large, adenosarcoma (Figure 33-11). Although polyps most often develop in women between ages 40 and 50 years, they can occur at all ages. Hyperestrogenic states, obesity, tamoxifen use, and hypertension are risk factors for developing polyps.

![Endometrial Polyp](image)

FIGURE 33-11 Endometrial Polyp. Polyp is protruding through the cervical os. (From Symonds EM, Macpherson MBA: Color atlas of obstetrics and gynecology, London, 1994, Mosby)

Most polyps are asymptomatic; however, they are a common cause of intermenstrual bleeding or even excessive menstrual bleeding. Diagnosis is made by hysteroscopy or ultrasonography. The lesions can be removed with small, curved forceps but there is a high rate of spontaneous resolution. Coexistence of a separate endometrial atypical hyperplasia or adenocarcinoma is possible but malignancy is extremely rare.

Leiomyomas

Leiomyomas, commonly called myomas or uterine fibroids, are benign tumors that develop from smooth muscle cells in the myometrium. Leiomyomas are the most
common benign tumors of the uterus, affecting 70% to 80% of all women, and most remain small and asymptomatic. Prevalence increases in women ages 30 to 50 years but decreases with menopause. The incidence of leiomyomas in black and Asian women is two to five times higher than that in white women.

The cause of uterine leiomyomas is unknown, although the size of the tumor appears to be related to hormonal fluctuations, including estrogen and progesterone, growth factors, and reduced apoptosis. Because leiomyomas are estrogen and progesterone sensitive, uterine leiomyomas are not seen before menarche, are common during the reproductive years, and generally shrink after menopause if present. Tumors in pregnant women enlarge rapidly but often decrease in size after the end of the pregnancy. Risk factors include heredity, nulliparity, obesity, PCOS, diabetes, black race, and hypertension.

Pathophysiology

Most leiomyomas occur in multiples in the fundus of the uterus, although often occurring singly and throughout the uterus. Leiomyomas are classified as subserous, submucous, or intramural, according to location within the various layers of the uterine wall (Figure 33-12). Most leiomyomas have normal karyotypes but some have simple chromosomal abnormalities. Recently, mutations in the Mediator Subcomplex 12 (MED12) gene have been identified in about 70% of uterine leiomyomas. Uterine leiomyomas are usually firm and surrounded by a connective tissue layer. Degeneration and necrosis may occur when the leiomyoma outgrows its blood supply, which is more common in larger tumors and is frequently accompanied by pain.
Leiomyomas. A, Uterine section showing whorl-like appearance and locations of leiomyomas, which are also called uterine fibroids. B, Multiple leiomyomas in sagittal section. Typical, well-circumscribed, solid, light gray nodules distort uterus. (B from Damjanov I, Linder J: Pathology: a color atlas, St Louis, 2000, Mosby.)
**Clinical manifestations**

The major clinical manifestations of leiomyomas are abnormal vaginal bleeding, pain, and symptoms related to pressure on nearby structures. Fibroids also may contribute to infertility and subfertility, as well as obstruction during birth if large enough. The leiomyoma can make the uterine cavity larger, thereby increasing the endometrial surface area. This enlargement may account for the increased menstrual bleeding associated with leiomyomas. Although pain is not an early symptom, it occurs with the devascularization of larger leiomyomas and is associated with blood vessel compression that limits blood supply to adjacent structures. Because the fibroid is relatively slow growing, enabling adjacent structures to adapt to pressure, symptoms of abdominal pressure develop slowly. Pressure on the bladder may contribute to urinary frequency, urgency, and dysuria. Pressure on the ureter may cause it to become distended “upstream” from the pressure point; rectosigmoid pressure may lead to constipation. Larger fibroids may cause a sensation of abdominal or genital heaviness.

**Evaluation and treatment**

Uterine leiomyomas are suspected when bimanual examination discloses irregular, nontender nodularity of the uterus. Pelvic sonography or MRI confirms the diagnosis. Treatment depends on symptoms, tumor size, and age, reproductive status, and overall health of the individual. Most leiomyomas are asymptomatic and can be managed by observation only. Medical treatment is aimed at shrinking the myoma or reducing the symptoms. Use of hormonal contraceptives may shrink or enhance growth and should be closely monitored. Mifepristone (formerly RU-486), a progesterone receptor agonist, also may be useful as a conservative treatment, as well as GnRH agonists for temporary management. Myomectomy or removal of the fibroid from the muscle of the uterus may be less invasive than a full hysterectomy and remains the standard of cure for women wishing to preserve their fertility. Other treatments, such as uterine artery embolization (UAE), laser ablation, and levonorgestrel-intrauterine system (LNG-IUS), all hold promise. A Cochrane review found UAE appears to have an overall satisfaction rate similar to hysterectomy and myomectomy.\textsuperscript{45} UAE is associated with a higher rate of minor complications and a much higher risk of requiring future surgical intervention within 2 to 5 years of the initial procedure.\textsuperscript{45} Benefits and risks of all treatments should be carefully considered, as well as a woman's desire for future pregnancy.

**Adenomyosis**
Adenomyosis is the presence of islands of endometrial glands surrounded by benign endometrial stroma within the uterine myometrium. It commonly develops during the late reproductive years, with the highest incidence among women in their forties and in women taking tamoxifen. Parity also increases the risk for adenomyosis. Adenomyosis may be asymptomatic or may be associated with abnormal menstrual bleeding, anemia, dysmenorrhea, uterine enlargement, and uterine tenderness during menstruation. Secondary dysmenorrhea becomes increasingly severe as disease progresses. On examination, the uterus is enlarged, globular, and most tender just before or after menstruation. Diagnosis is confirmed with ultrasonography or MRI. Treatment is symptomatic, and similar to that for dysmenorrhea (i.e., nonsteroidal anti-inflammatory drugs [NSAIDs], hormonal contraceptives, or levonorgestrel-intrauterine system [LNG-IUS]). Other options include surgical resection or, if severe, hysterectomy. UAE and LNG-IUDs have shown good initial results but need further testing.

Endometriosis

Endometriosis is the presence of functioning endometrial tissue or implants outside the uterus. Like normal endometrial tissue, the ectopic (out-of-place) endometrium responds to the hormonal fluctuations of the menstrual cycle. The incidence of endometriosis is difficult to determine, especially in asymptomatic adolescent and fertile women. About 50% of women evaluated for pelvic pain, infertility, or pelvic mass are diagnosed with endometriosis. Additionally, the frequency and severity of symptoms do not correlate with the extent or site of lesions. Many theories exist on the cause of endometriosis including the implantation of endometrial cells during retrograde menstruation, in which menstrual fluids move through the fallopian tubes and into the pelvic cavity. It is now known, however, that retrograde menstruation occurs in almost all women, but not all women develop endometriosis. The main theories include coelomic metaplasia (peritoneal mesothelium, the müllerian ducts, and the germinal epithelium of the ovary are all derived from coelomic wall epithelium), retrograde menstruation, embryonic cell rest (primitive “at rest” embryonic cells become activated), iatrogenic mechanical transplantation, and lymphatic and vascular dissemination. A genetic predisposition to endometriosis has been documented. Some genetic polymorphisms have been identified.

Pathophysiology

Endometriosis is a multifactorial estrogen-dependent condition that may affect 5% to 10% of women of childbearing age in developed countries (Figure 33-13). Emerging evidence suggests that endometriosis can have heterogeneous
characteristics and therefore the pathogenesis is modulated by many factors including genetic, epigenetic, environmental, and cellular factors. The endometrium is highly dynamic tissue with regenerative tissue undergoing cyclic processes of growth, differentiation, shedding, and regeneration as part of the menstrual cycle. These processes depend on steroid hormones, growth factors, and leukocytes that affect the balance between proliferation and apoptosis. Although endometriosis is considered benign, approximately 1.0% of affected women have an increased risk of malignant transformation involving multiple pathways of development. The defining feature of endometriosis is the presence and proliferation of endometrial-like tissue (implants), including stromal and glandular tissue, in locations outside of the uterine cavity, primarily in the ovaries, fallopian tubes, bladder, rectosigmoid colon, and uterine myometrium (adenomyosis), often causing infertility and pain (Figure 33-14).
The pathophysiology of endometriosis remains poorly understood but several characteristics are being investigated, including the following: (1) High levels of estrogen production are observed in endometriosis and a key enzyme in estrogen production is aromatase, which has been correlated with the severity of endometriosis. (2) There is evidence of switching of cell fates during development, where epithelial and mesenchymal markers highlight a contribution of the mesenchymal-epithelial transition (MET) and of the epithelial-mesenchymal transition (EMT) in endometriosis (see Chapter 10). (3) The roles of inflammation and of peritoneal leukocytes and their mediators may facilitate the progression of endometriotic lesions. (4) Some components of the innate immune system are involved in endometriosis (dendritic cells, macrophages, Toll-like receptors), and components of the adaptive immune system (T- and B-cell functions) can promote apoptosis, tissue damage, and multiorgan involvement. (5) The development of lesions is dependent on new blood vessel development (angiogenesis). (6) Genetic and epigenetic roles are present in endometriotic lesions and some ovarian cancers (clear cell carcinoma, endometrioid adenocarcinoma). (7) Stem cells play a role in the development of endometriotic lesions. Changes in stem cell populations of endometriotic lesions are associated with genetic and epigenetic alterations.

Cyclic changes depend on the blood supply of the lesions (implants) and the presence of glandular and stromal cells. Given that the blood supply is sufficient, the ectopic endometrium proliferates, breaks down, and bleeds with the normal menstrual cycle. The bleeding is one cause of inflammation, triggering a cascade of
cellular inflammatory mediators, including cytokines, chemokines, growth factors, and protective factors such as secretory leukocyte protease inhibitor and superoxide dismutase. The inflammation may lead to fibrosis, scarring, adhesions, and pain.

**Clinical manifestations**
The clinical manifestations of endometriosis vary in frequency and severity and can mimic other pelvic disease (i.e., pelvic inflammatory disease, ovarian cysts, irritable bowel syndrome). Symptoms include infertility, pelvic pain, dyschezia (pain on defecation), dyspareunia, (pain on intercourse), and, less commonly, constipation and abnormal vaginal bleeding. If implants are located within the pelvis, an asymptomatic pelvic mass having irregular, movable nodules and a fixed, retroverted uterus are found on examination. Most symptoms can be explained by the proliferation, breakdown, and bleeding of the ectopic endometrial tissue with subsequent formation of adhesions. In most instances, however, the degree of endometriosis is not related to the frequency or severity of symptoms.

Dysmenorrhea, for example, does not appear to be related to the degree of endometriosis. With involvement of the rectovaginal septum or the uterosacral ligaments, dyspareunia develops. Dyschezia, a hallmark symptom of endometriosis, occurs with bleeding of ectopic endometrium in the rectosigmoid musculature and subsequent fibrosis.

Up to 25% to 40% of women with infertility have endometriosis. The relationship between endometriosis and infertility is strong; however, the degree of disease is not as closely associated. More simply, women with untreated minimal to mild disease may have high pregnancy rates or may experience infertility. The exact reason for infertility in women with endometriosis is unknown.

**Evaluation and treatment**
A presumptive diagnosis is based on the previously described symptoms, but pelvic laparoscopy is required for a definitive diagnosis. A uniform classification system that includes both extent and severity has been developed including stage I, minimal; stage II, mild; and stage III, moderate. The classification, however, still does not correlate well with a woman's symptoms. Treatment is based on preventing progression of the disease, alleviating pain, and restoring fertility. Medical therapies include suppression of ovulation with various medications, such as noncyclic estrogen-progestin–combined oral contraceptive pill (COCs), depot medroxyprogesterone acetate (DMPA), danazol, GnRH agonists, mifepristone, or gestrinone, and promotion of atrophy of the endometrium with progestins or an LNG-IUD. Conservative surgical treatment includes laparoscopic removal of endometrial implants with conventional or laser techniques and presacral
neurectomy for severe dysmenorrhea. All treatments have risks or side effects and recurrent symptoms will develop in the majority of women within a few years, even with surgical treatments. Women should be fully informed of all options and understand the risk-to-benefit ratio of treatments, especially nonreversible treatments.

Cancer

Malignant tumors of the female reproductive system are common. Because the pelvis and abdomen are poorly innervated and designed to accommodate a growing fetus, cancers of the female reproductive tract can often grow large before causing pain. Reproductive cancers are likely to be diagnosed early if there are symptoms; for example, vaginal bleeding prompts women to seek treatment. Cervical cancer has minimal symptoms until late in the process, but is easy to detect early with Pap smears. Three percent of cancers in women begin in the cervix but the death rate from cervical cancer has plummeted since the advent of screening techniques. Investigators are researching new biomarkers for the screening, diagnosis, and surveillance for ovarian cancer. Obtaining an early diagnosis for ovarian cancer is very challenging.

Cervical Cancer

Cervical cancer is the fourth most common cancer in women worldwide, and has the fourth highest death rate among cancers in women. An estimated 12,900 new cases of invasive cervical cancer will be diagnosed in the United States for 2015, with an estimated 4100 deaths. Black women have the highest rate of cervical cancer, followed by Hispanics, whites, American Indian/Alaska Natives, and Asian/American/Pacific Islanders. Death rates are highest for black women. The rates of invasive cervical cancer have steadily decreased (since the 1960s) and death rates have declined significantly in the United States (and other developed countries), mainly attributed to the prevalence and frequency of screening with the Pap test. Death rates were stable among women younger than 50 years but decreased by 1.1% per year among women aged 50 years and older (Health Alert: Screening with the Papanicolaou [Pap] Test and with the Human Papillomavirus [HPV] DNA Test: Benefits and Harms from Cervical Cancer Screening [PDQ®]).

Health Alert

Screening with the Papanicolaou (Pap) Test and with the Human
Screening with the Papanicolaou (Pap) Test: Benefits

Based on solid evidence, regular screening of appropriate women for cervical cancer with the Pap test reduces mortality from cervical cancer. The benefits of screening women younger than 21 years are small because of the low prevalence of lesions that will progress to invasive cancer. Screening is not beneficial in women older than 65 years if they have had a history of recent negative tests.\(^1-3\)

**Magnitude of Effect:** Regular Pap screening decreases cervix cancer incidence and mortality by at least 80%.

- Study Design: Population-based and cohort studies
- Internal Validity: Good
- Consistency: Good
- External Validity: Good

Screening with the Pap Test: Harms

Based on solid evidence, regular screening with the Pap test leads to additional diagnostic procedures (e.g., colposcopy) and treatment for low-grade squamous intraepithelial lesions (LSILs), with long-term consequences for fertility and pregnancy. These harms are greatest for younger women, who have a higher prevalence of LSILs, lesions that often regress without treatment. Harms are also increased in younger women because they have a higher rate of false-positive results.

**Magnitude of Effect:** Additional diagnostic procedures were performed in 50% of women undergoing regular Pap testing. Approximately 5% were treated for LSIL. The number with impaired fertility and pregnancy complications is unknown.

- Study Design: Evidence obtained from cohort or case-control studies
- Internal Validity: Good
- Consistency: Good
- External Validity: Good
Screening with the Human Papillomavirus (HPV) DNA Test: Benefits

Based on solid evidence, screening with HPV DNA or HPV RNA detects high-grade cervical dysplasia, a precursor lesion for cervical cancer. Additional clinical trials show that HPV testing is superior to other cervical cancer screening strategies. In April 2014, the U.S. Food and Drug Administration approved an HPV DNA test that can be used alone for the primary screening of cervical cancer risk in women aged 25 years and older.4

  **Magnitude of Effect:** In one prospective, clustered, randomized trial, HPV testing was superior to other strategies for preventing cervical cancer mortality.5,6

• Study Design: Clustered randomized controlled trial (RCT)

• Internal Validity: Good

• Consistency: Good

• External Validity: Good

Screening with the HPV DNA Test: Harms

Based on solid evidence, HPV testing identifies numerous infections that will not lead to cervical dysplasia or cervical cancer. This is especially true in women younger than 30 years, in whom rates of HPV infection may be higher.

  **Magnitude of Effect:** In one study, 86.7% of women with a positive HPV test did not develop cervical cancer or related premalignant disease after more than a decade of follow-up.7

• Study Design: Long-term observational trials

• Internal Validity: Good

• Consistency: Good

• External Validity: Good

Screening with the Pap Test and the HPV DNA Test (Cotesting): Benefits

Based on solid evidence, screening every 5 years with the Pap test and the HPV DNA test (cotesting) in women 30 years and older is more sensitive in detecting
cervical abnormalities, compared with the Pap test alone. Screening with the Pap test and HPV DNA test reduces the incidence of cervical cancer.³

**Magnitude of Effect:** HPV-based screening provides 60% to 70% greater protection against invasive cervical carcinoma, compared with cytologic studies.⁸

- **Study Design:** RCTs
- **Internal Validity:** Good
- **Consistency:** Good
- **External Validity:** Good
Screening with the Pap Test and the HPV DNA Test (Cotesting): Harms

Based on solid evidence, HPV and Pap cotesting is associated with more false-positive results than the Pap test alone. Abnormal test results can lead to more frequent testing and invasive diagnostic procedures.\(^3\)

_Magnitude of Effect:_ The percentage of U.S. women undergoing cotesting who will have a normal cytologic test result and a positive HPV test result (and who will therefore require additional testing) ranges from 11% among women aged 30 to 34 years to 2.6% among women aged 60 to 65 years.\(^3\)

- Study Design: RCTs
- Internal Validity: Good
- Consistency: Good
- External Validity: Good

Screening Women Without a Cervix

Based on solid evidence, screening is not helpful in women who do not have a cervix as a result of a hysterectomy for a benign condition.

_Magnitude of Effect:_ Among women without cervices, fewer than 1 per 1000 had abnormal Pap test results.

- Study Design: Evidence obtained from a single cohort study
- Internal Validity: Good
- Consistency: Good
- External Validity: Good

References

It is now widely known that HPV infection is a necessary condition in the development of almost all precancerous and cancerous cervical lesions. There are multiple subtypes of HPV and the “high-risk” (oncogenic) types of HPV (predominantly 16 and 18) have been most closely associated with high-grade dysplasia and cancer (also see Chapters 10 and 11). The precancerous lesion or dysplasia, also called cervical intraepithelial neoplasia (CIN) and cervical carcinoma in situ (CIS), is a more advanced form of the cell changes and can progress to become invasive cancer. This process can be very slow. About 30% to 70% of those untreated for in situ carcinoma will develop invasive carcinoma over 10 to 12 years; but in about 10% of women, progression from in situ to invasive cancer can occur in less than 1 year.\textsuperscript{52} Other risk factors for cervical cancer include multiple sexual partners, a male partner with multiple previous or current sexual partners, young age at first sexual intercourse, high parity, persistent infection with HPV-16 or HPV-18, immunosuppression, use of oral contraceptives, certain human leukocytic antigen (HLA) subtypes, and use of nicotine.\textsuperscript{31,52}

Pathogenesis
As discussed earlier, HPV-16 and HPV-18 are the most important risk factors for cervical disease progression and cancer. HPV-16 accounts for about 60% of
cervical cancer cases and HPV-18 for about another 10%; other types contribute less than 5% of cases. The cervix is lined by two types of epithelial cells: squamous cells at the outer aspect and columnar glandular cells along the inner canal (Figure 33-15). The site of the cellular transformation zone, called the squamocolumnar junction, is illustrated in Figure 33-16. HPVs infect immature basal cells of the squamous epithelium in the areas of epithelial breaks or injury, or immature metaplastic squamous cells present at the squamocolumnar junction. Establishing HPV infection in the mature squamous cells that cover the ectocervix, vagina, or vulva requires damage to the surface epithelium. The cervix, with its large areas of immature epithelium, is very vulnerable to HPV infection.31 The ability of HPV to act as a carcinogen depends on the viral proteins E6 and E7 because they interfere with the activity of tumor-suppressor proteins that regulate cell growth and survival.31 Replication of HPV occurs in the maturing squamous cells, and studies have shown that HPV activates the cell cycle by interfering with two tumor-suppressor genes, Rb and p53.31 Although HPV is a causative factor for cervical cancer, it is not the only factor. Other important cocarcinogens must play a role because in spite of the high percentage of young women infected with one or more HPV types during their reproductive years, only a few develop cancer. The other factors that appear to be associated include immune responses, hormonal responses, and other environmental factors that determine regression or persistence of the HPV infection.31 Cervical cancer is a slowly progressive disease and moves from normal cervical epithelial cells to dysplasia to carcinoma in situ and, eventually, to invasive cancer (see Figure 33-16, B). Table 33-4 summarizes the staging of cervical cancer. Testing for high-risk HPV is often positive for many years (10 years or more) before dysplasia progresses to high-grade squamous intraepithelial lesions (HSILs) that can develop into invasive cervical cancer (CIN III, Table 33-5).
Cervix is lined by two types of epithelial cells: squamous cells and columnar glandular cells.

**FIGURE 33-15** Cervix Is Lined by Two Types of Epithelial Cells: Squamous Cells and Columnar Glandular Cells.
Cervical Disease Progression\textsuperscript{1-6}

Most HPV infections will clear, and most cervical lesions will not progress\textsuperscript{1-3}

![Diagram showing cervical disease progression]

- CIN 2/3 lesions are more likely to progress to cervical cancer than CIN 1 lesions\textsuperscript{1}

**FIGURE 33-16** Cervical Intraepithelial Neoplasia (CIN). A. Normal multiparous cervix including the transformation zone where precancerous and cancerous changes occur. CIN stage I note the white appearance of part of the anterior lip of the cervix associated with neoplastic changes; CIN stage II, lesions also are reflected in distant capillaries; CIN stage III, lesions are predominantly around the external os. B. Normal epithelium, HPV infection progressing to CIN stage I, and then with more time persistent HPV infections progressing to precancerous lesions CIN II and CIN III and eventually cervical cancer. Most cervical lesions do not progress to cervical cancer. CIN, Cervical intraepithelial neoplasia; SIL, squamous intraepithelial lesion.

Clinical manifestations

Because cervical neoplasms are predominantly asymptomatic, about 90% of cervical cancers can be detected early through the use of Pap and HPV testing. If symptoms exist, they may include a change in vaginal discharge or bleeding. Bleeding varies and may occur after intercourse or between menstrual periods. At times, women will complain of abnormal menses or postmenopausal bleeding. A less common symptom may be a serosanguineous or yellowish vaginal discharge. A new or foul odor also may be present. Advanced disease may cause urinary or rectal symptoms and pelvic or back pain.
Evaluation and treatment

About 90% of cervical cancers can be detected early through the use of regular screening tests (see Health Alert: Screening with the Papanicolaou [Pap] Test and with the Human Papillomavirus [HPV] DNA Test: Benefits and Harms from Cervical Cancer Screening [PDQ®], p. 820). When dysplasia is detected, colposcopy is usually indicated to identify lesions and obtain needed biopsies. If invasive carcinoma is found, lymphangiography, computed tomography (CT) scan, MRI, ultrasonography, or radioimmunodetection methods are used to further assess tissue involvement.

Treatment depends on the degree of neoplastic change, the size and location of the lesion, and the extent of metastatic spread. Treatment for invasive carcinoma depends on the stage of the tumor and includes surgery, radiation therapy, chemotherapy, and targeted treatment. Prognosis is excellent with early detection and treatment. The prevention of HPV infection appears to be key for substantially reducing the risk of cervical cancer and the FDA-approved vaccines for two of the high-risk types of HPV show excellent promise (see Health Alert: Cervical Cancer Primary Prevention).

Health Alert

Cervical Cancer Primary Prevention

Individuals not sexually active almost never develop genital HPV infections. HPV vaccination before sexual activity can reduce the risk of infection by HPV types targeted by the vaccine.

The Food and Drug Administration (FDA) has approved three vaccines to prevent HPV infection: Gardasil, Gardasil 9, and Cervarix. These vaccines provide strong protection against the HPV targeted infections but they are not effective for treating established infections or disease caused by HPV. All three vaccines prevent infections with HPV types 16 and 18, the two high-risk HPVs that cause about 70 percent of cervical cancers. Gardasil also prevents infection with HPV types 6 and 11, which causes about 90 percent of genital warts. Gardasil 9 prevents infection with the same four high-risk HPV types plus five additional high-risk types (31, 33, 45, 52, and 58). All three vaccines are given as a series of three injections into muscle tissue over a 6-month period.

Importantly, consistent and correct condom use is associated with reduced HPV transmission and less frequent use is not. The virus can infect areas not covered by the condom.
Vaginal Cancer

Cancer of the vagina is the rarest (about 0.6 per 100,000 women yearly) of the female genital cancers. It can occur at any age but is found predominantly in women 50 years of age and older. More than 90% of women with vaginal cancer have squamous cell carcinoma. Most squamous cell carcinomas of the vagina are associated with high-risk HPVs. Risk factors include age 60 or older, diethylstilbestrol (DES) exposure in utero, HPV type 16 (cause), human immunodeficiency virus (HIV), genital warts (associated most often with the nononcogenic types HPV-6 and HPV-11, which can infect female and male genital organs and the anal area; the relationship of developing precancerous cell changes (called vaginal intraepithelial neoplasia [VAIN]) because of also harboring oncogenic HPV types is controversial), and previous carcinoma of the cervix or vulva. A large proportion (30% to 50%) of women with vaginal carcinomas have had a prior hysterectomy for benign, premalignant, or malignant disease.

Vaginal cancer can be asymptomatic. Therefore, regular pelvic examinations, particularly for women with a history of intrauterine DES exposure, are extremely important. Clinical manifestations that occur include abnormal vaginal bleeding or discharge not related to menstrual periods, pain during intercourse, pain in the pelvic area, pain when urinating, and constipation.

Very careful biopsy techniques confirm the tumor type and determine its size, location, and extent. Treatment depends on these findings and on the age of the individual. Treatments include surgery, chemotherapy, and radiation therapy.

Vulvar Cancer

Cancer of the vulva most often affects the labia majora and less often the labia minora, clitoris, or vaginal glands. An incidence for cancer of the vulva of 5100 new cases was estimated for 2015. The majority (90%) are squamous cell carcinomas. Risk factors for vulvar cancer include HPV type 16 (cause), HIV, HPV-18 (probable cause), increasing age, previous cancer (untreated high-grade vulvar intraepithelial neoplasia [VIN]), cervical cancer survivor, previous cervical intraepithelial neoplasia, women with certain autoimmune conditions (increased risk of HPV-associated tumors), organ transplant recipients (perhaps because of immunosuppression to clear HPV), and tobacco use (may relate to inability to clear HPV infection). The development of vulvar cancer is preceded by condyloma or squamous dysplasia. Other possible risk factors include having many sexual
partners, having first sexual intercourse at a young age, and having a history of abnormal Pap tests. Risk factors for STIs are risk factors for vulvar cancer. Early detection is critical. Treatment includes surgery, radiation, chemotherapy, and biologic therapy.

**Endometrial Cancer**

Carcinoma of the endometrium is the most common type of uterine cancer and most prevalent gynecologic malignancy (Figure 33-17). Estimates in the United States include 54,870 new cases in 2015, with approximately 10,170 deaths. It is the sixth most common cancer worldwide and the incidence is highest in high-income countries including North America and Northern and Western Europe. Since 2002, overall incidence rates in the United States have not changed significantly, whereas mortality rates have been slowly rising since 2001. The primary risk factor is unopposed estrogen exposure (without progesterone). Exposure to unopposed estrogen includes estrogen-only hormone replacement therapy, tamoxifen, early menarche, late menopause, never having children, and a failure to ovulate (i.e., PCOS and anovulatory cycles typical of the late reproductive years). Less is known about the association with other types of hormone therapy. Chronic hyperinsulinemia, hyperglycemia, body fatness and adult weight gain, chronic inflammation, and lack of physical activity confer an increased risk of endometrial cancer (Figure 33-18).

![FIGURE 33-17 Endometrial Cancer. Tumor fills the endometrial cavity. Obvious myometrial invasion is shown. (From Damjanov I, Linder J, editors: Anderson’s pathology, ed 10, St Louis, 1996, Mosby)](image-url)
Epidemiologic studies suggest an association between type 2 diabetes mellitus (T2DM) and endometrial cancer, as well as other cancers, and that T2DM increases mortality. Diabetes mellitus and cancer share several mechanisms, including insulin and insulin-like growth factor (IGF) signaling, dysregulation of ovarian steroid hormones, and chronic inflammation. Some studies have shown an elevated risk of endometrial cancer with polycystic ovary syndrome and insulin resistance. Additionally, another cause may be epigenetic silencing of the tumor-
Investigators recently found the use of long-cycle estrogen and progestin hormone replacement therapy (HRT) was related to a tendency toward an elevated risk of developing endometrial cancer for exposure less than 5 years or more. For exposure of more than 10 years, the risk for endometrial cancer was elevated among users of long-cycle HRT and sequential HRT. Norethisterone acetate and medroxyprogesterone acetate (MPA) (HRT) did not differ in their endometrial cancer risk. The relationship between the use of tibolone and increased risk for endometrial cancer is controversial. Although the numbers were small, a Cochrane review found no clear evidence of a tibolone effect on endometrial cancer compared with placebo. The use of continuous HRT or estradiol plus a levonorgestrel-releasing intrauterine device system showed a decreased risk of endometrial cancer. Other risk factors not directly related to estrogen include gallbladder disease and hypertension, although being overweight may be a mediating factor for these risks. A family history of colon, endometrial, or ovarian cancer could signal hereditary nonpolyposis colorectal cancer (HNPCC, also known as Lynch syndrome); women with this family history may wish to explore genetic testing and more aggressive screening.

Ninety-five percent of endometrial cancers occur in postmenopausal women, with the peak incidence occurring in the late fifties to early sixties. Although incidence rates are slightly higher in white women than in blacks, death rates in black women are nearly twice as high as those for other ethnic/racial groups. Factors related to reductions in risk of endometrial cancer include delayed menarche; history of pregnancy or breast-feeding, or both; use of combined hormonal contraception; use of progestin-containing IUDs; and engagement in physical activity. So far, the lone dietary factor that may lower risk of endometrial cancer is drinking coffee regularly. A large study first investigated the link between coffee and endometrial cancer risk, and then researchers looked at dietary factors in two U.S. studies—the Nurses Health Studies I and II. For those in the European study, the average high coffee intake was about 3 cups a day, and in the United States it was 4.5 cups of coffee a day.

**Pathogenesis**

Endometrial hyperplasia is associated with prolonged estrogenic stimulation of the endometrium. Endometrial hyperplasia and carcinoma share acquired genetic alterations in genes linked to carcinogenesis. Frequent alterations in endometrial cancer include (1) altered estrogen receptor (ER) and progesterone receptor (PR) expression; (2) genetic mutation causing loss of function (inactivation) of the tumor-suppressor gene **PTEN**, which may enhance (3) the PI3K/AKT signaling
pathway to become overactive, increasing the ability of the estrogen receptor to “turn on” the expression of target genes; and (4) mutations to several genes, including fibroblast growth factor receptor (FGFR) and tumor protein 53 (TP53). All of these events are predicted to affect PR actions in cancer pathogenesis. Progesterone inhibits estrogen-driven growth in the uterus. The antagonistic effects of progesterone on the estrogen-induced proliferation and growth occur mostly during the luteal phase and are dependent on the presence of functional PR expression. Investigators are studying the importance of stromal PR and its role in progesterone inhibition of epithelial proliferation (Figure 33-19). The interactions between the epithelial and stromal cells of the endometrium may determine the eventual role in the actions of progesterone. Progesterone receptor has two isoforms: PR-A and PR-B. These isoforms are both expressed in the epithelial and stromal cells of the endometrium and their expression fluctuates during the menstrual cycle as well as during pregnancy. The delicate balance of the PR isoforms can tip the scales to foster endometrial hyperplasia and atypia and enhance expression of uterine growth factors. Overall, depending on isoform expression, progesterone can be either an anti- or a pro-proliferative force on the endometrium. Misregulation of isoform expression can lead to abnormal function and precancerous changes.

Two broad categories of endometrial carcinoma include type I and type II. About 80% of cases are type I. Type I and type II endometrial carcinoma are summarized in Table 33-6.

### Clinical manifestations, evaluation, and treatment

Abnormal vaginal bleeding is the most common clinical manifestation of endometrial cancer. Postmenopausal women, obese women, and women with unopposed estrogenic conditions (i.e., anovulatory cycles) should be evaluated in the event of unscheduled or persistent, irregular vaginal bleeding. Pain and weight loss are symptoms of more advanced disease. Transvaginal ultrasound (TVUS) may be used to measure endometrial thickness. If the endometrium is abnormally thick (defined as >5 mm), then further testing, such as an endometrial biopsy, is done. Treatment is based on the extent of the disease and may include curettage for carcinoma in situ, total abdominal hysterectomy, chemotherapy, radiation, and (although controversial) progestins. The data supporting the use of metformin in the prevention and treatment of cancers are increasing, including those for endometrial cancer.75,76

### Ovarian Cancer

Among gynecologic malignancies, ovarian cancer is the leading cause of mortality in developed countries with 239,000 new cases and 152,000 estimated deaths worldwide49 (Figure 33-20). Globally, ovarian cancer is the seventh most common cancer and the eighth cause of death from cancer in women.49 Incidence rates are
highest in more developed regions and lowest in sub-Saharan Africa.\textsuperscript{49} In the United States, 21,290 new cases of ovarian cancer and 14,180 ovarian cancer deaths are estimated for 2015.\textsuperscript{48} The understanding of incidence patterns both within and between populations is essential to revealing potential causes of and risk factors for ovarian cancer (Figure 33-21). Worldwide, ovarian cancer is responsible for more deaths than all other gynecologic malignancies combined.\textsuperscript{49} Risk factors for ovarian cancer are summarized in Table 33-7.

\textbf{FIGURE 33-20} Ovarian Tumors. A serous borderline tumor displays a cyst cavity lined by papillary tumor growths (A). The cyst is opened (B) to reveal a large bulky tumor mass called cystadenocarcinoma (C), a tumor on the ovarian surface. Bilaterality of tumors is common, occurring in 20\% of benign tumors, 30\% of serous borderline tumors, and approximately 66\% of serous carcinomas. A significant proportion of both borderline malignant and malignant tumors involve the surface of the ovary (C). (From Kumar V et al: Robbins & Cotran pathologic basis of disease, ed 9, Philadelphia, 2015, Saunders.)
**FIGURE 33-21** Map of Ovarian Cancer Worldwide. Rates are per 100,000 women and are age-standardized to the 1960 world standard population. Data were not included for white areas on the map. (From Ferlay J et al: GLOBOCAN 2012 v1.0, Cancer incidence and mortality worldwide: IARC CancerBase No. 11, Lyon, France, 2013, International Agency for Research on Cancer. Available at: http://globocan.iarc.fr/Default.aspx.)

**TABLE 33-7**
Risk Factors for Ovarian Cancer

<table>
<thead>
<tr>
<th>Risk Factor</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Advancing age</td>
<td>Incidence of ovarian cancer increases with advancing age. Most cases occur in postmenopausal women.</td>
</tr>
<tr>
<td>Genetic factors</td>
<td>About 5% to 15% of all ovarian cancers are inherited. Of these, the majority are related to mutations in <em>BRCA1/2</em> genes and others include mismatch repair genes (e.g., Lynch syndrome), TP53 in the germ line (e.g., Li-Fraumeni syndrome), and Peutz-Jeghers syndrome. Fallopian tube cancer and peritoneal carcinomas also are part of the <em>BRCA</em>-associated disease spectrum.</td>
</tr>
<tr>
<td>Family history</td>
<td>A family history of ovarian cancer in a first-degree relative (e.g., mother, daughter, or sister) is the most important risk factor. The highest risk appears in women who have two or more first-degree relatives with ovarian cancer. Risk may be higher if the affected relative was diagnosed at a younger age, previous breast cancer diagnosed before the age of 40, and previous breast cancer and a history of ovarian cancer. A cohort study showed ovarian cancer risk is higher in women whose sibling has/had liver, stomach, breast, prostate, connective tissue cancer, or melanoma; or whose parent has/had breast or liver cancer.</td>
</tr>
<tr>
<td>Overweight and obesity</td>
<td>Meta-analysis found higher risk of ovarian cancer in premenopausal women with a BMI &gt;30 and no effect in postmenopausal women. Another meta-analysis found a link between high BMI and ovarian cancer risk in women who had never used menopausal hormone therapy (MHT).</td>
</tr>
<tr>
<td>Height</td>
<td>Greater adult attained height (reflects factors that promote childhood growth) is classified by WCRF/AICR as a probable cause of ovarian cancer. A pooled analysis of Nordic data and meta-analyses showed ovarian cancer risk is 7% to 10% higher per 5-cm increment in height.</td>
</tr>
<tr>
<td>Reproductive/hormonal factors</td>
<td>Ovarian cancer risk is associated with factors affecting lifetime ovulations (and breaks between) or sex hormone levels (estrogens, progesterone, and androgens), or both. Structural changes to the ovary can occur with ovulation that may stimulate cancer development. These changes may be affected and enhanced by hormonal factors. Having more children, breast-feeding, or using oral contraceptives decreases the number of ovulations and therefore reduces the risk of ovarian cancer.</td>
</tr>
</tbody>
</table>
Cysts. Newer evidence suggests that tumors arise from three ovarian components: (1) tumors to arise from just epithelial cells that cover the ovarian surface or line subserosal evident in ovarian tumors. Previously, the majority of ovarian cancers were thought to be heterogeneous in character, or having many genetic and epigenetic changes are evident in ovarian tumors. Previously, the majority of ovarian cancers were thought to arise from just epithelial cells that cover the ovarian surface or line subserosal cysts. Newer evidence suggests that tumors arise from three ovarian components: (1) ovarian epithelial, fallopian tube, and primary peritoneal cancer treatment, Bethesda, Md, 2015, Author. Date last modified March 27, 2015. Available at: http://cancer.gov/cancertopics/pdq/treatment/ovarianepithelial/HealthProfessional. Accessed May 2, 2015.

Pathogenesis

The biology of ovarian cancer is changing and it is clear that ovarian cancer is diverse in character, or heterogeneous. Many genetic and epigenetic changes are evident in ovarian tumors. Previously, the majority of ovarian cancers were thought to arise from just epithelial cells that cover the ovarian surface or line subserosal cysts. Newer evidence suggests that tumors arise from three ovarian components: (1)
from the fimbriae of fallopian tubes and from deposits of endometriosis; (2) from germ cells, which are pluripotent and migrate to the ovary from the yolk sac; and (3) from stromal cells, including the sex cords, which precede endocrine changes of the postnatal ovary. Some ovarian tumors remain too difficult to classify. The normal ovary contains three major cell types: (1) germ cells that are derived from the endoderm and migrate to the gonadal ridge, where they proliferate and differentiate into oocytes; (2) the endocrine and interstitial hormone producing cells that produce estrogen and progesterone; and (3) epithelial cells derived from the müllerian duct that cover the ovary and line inclusion cysts just beneath the ovarian surface. During normal ovulation, oocytes released from mature follicles enter the fallopian tube where fertilization usually occurs. The fimbriae of the fallopian tube cover the ruptured follicle and promote uptake of oocytes. Both benign and malignant tumors come from each of the three ovarian cell types (Figure 33-22). Epithelial ovarian cancers constitute about 90% of malignant ovarian tumors and generally develop after age 40. Sex cord–stromal tumors arise from connective tissue, often secrete hormones, can occur in women of all ages, and comprise about 7% of ovarian tumors. Tumors that arise from germ cells occur in the second and third decades and account for about 3% to 5% of ovarian tumors. Borderline tumors of low malignant potential can contain structural and molecular evidence of transformed epithelial cells that do not invade the underlying stromal tissue. Approximately 10% of borderline tumors can recur after surgical resection and prove lethal.

Heterogeneous Ovarian Tumors. A, Diverse ovarian tumors originate from different cell subtypes. B, Type I and type II ovarian tumors. Type I tumors progress from benign tumors through borderline tumors that give rise to low-grade carcinoma, and type II tumors arise from inclusion cysts/fallopian tube epithelium through intraepithelial precursors that often are unidentifiable. These tumors demonstrate high-grade features and are commonly of serous histology. STIC, Serous tubal intraepithelial carcinoma. (B from Kumar V et al: Robbins & Cotran pathologic basis of disease, ed 9, Philadelphia, 2015, Elsevier/Saunders.)

There are three major histologic types of epithelial tumors: serous, mucinous, and endometrioid. These types all have a benign, borderline, and malignant category. The most common histologic subtype is high-grade serous cancers, and they may originate from a precursor lesion that arises from the fimbriae of the fallopian tubes. In women who underwent prophylactic salpingo-oophorectomies, studies showed that fallopian tubal lesions were present in almost 100% of women with early serous cancers associated with familial BRCA mutations. Investigators recently proposed that the fallopian tube is the primary site of most serous carcinomas. Although historically investigators proposed that the vast majority of serous carcinomas arose from cortical inclusion cysts, a newer hypothesis is that the cysts arise from implantation of detached fallopian tube epithelium at sites where ovulation has disrupted the surface of the ovary. These findings have led to changes in management of women at high risk for ovarian cancer (BRCA mutation carriers and women with a strong family history of breast/ovarian cancer); they are now recommended to have salpingo-oophorectomy and not just a simple...
Additionally, histologically similar cancers diagnosed as primary peritoneal carcinomas share molecular findings (i.e., inactivation of *p53* and *BRCA1* and *BRCA2* proteins). Therefore, tumors arising from fallopian tube and other locations from the peritoneal cavity, together with most ovarian epithelial cancers, are classified as “extrauterine adenocarcinomas of Müllerian epithelial origin,” and are included, staged, and treated similarly to ovarian cancer.78

The defining characteristics of malignant tumors are stromal invasion and increased epithelial atypia. Ovarian tumors are now classified as type I (low-grade) and type II (high-grade) (see Figure 33-22, B). Low-grade tumors arising in serous borderline tumors have several oncogene mutations, whereas high-grade tumors have a high frequency of *TP53* mutations. Gene amplifications are noted in many tumors, as well as deletions of tumor-suppressor genes. The majority of *BRCA* mutations are high-grade serous carcinomas with *TP53* mutations. *BRCA*-associated cancer risks are determined by the mutation location and variation of the *BRCA1/2* gene function.77 Endometrioid ovarian carcinomas may arise in the setting of endometriosis and are sometimes associated with borderline tumor.31

**Clinical manifestations**

Generally, individuals with ovarian cancer have no early symptoms. Because there are no effective screening techniques to detect it, the disease is usually advanced by the time treatment is sought. Some women may experience vague symptoms that include abdominal distention, loss of appetite, early satiety, and pelvic pain. These symptoms are important as nonspecific symptoms and can lead to delays in treatment. Symptoms of advanced disease include pain, abdominal swelling and distention, dyspepsia, vomiting, and alterations in bowel habits. Abnormal vaginal bleeding may occur if the postmenopausal endometrium is stimulated by a hormone-secreting tumor. The tumor also may cause ulcerations through the vaginal wall that result in bleeding. There also can be a feeling of pressure in the pelvis and leg pain. Given the location of the ovaries, assessing abnormalities on routine gynecologic examination poses difficulty, especially in obese women. Ovarian cancer is generally considered a silent disease.

Tumor obstruction of vascular channels can cause venous and, occasionally, arterial thrombosis. Alterations in coagulation also occur, contributing to clot formation. Metastasis often causes pleural effusion (Figure 33-23).
Evaluation and treatment

There is no sensitive and specific test for ovarian cancer for screening low-risk women, and routine screening of women without risk factors has not been shown to be beneficial and may cause harm because more women have unnecessary surgical procedures.\textsuperscript{81} Solid evidence indicates that screening with a CA-125 blood test and transvaginal ultrasound (TVU) does not result in a decrease in ovarian cancer mortality after a research follow-up of 12.4 years.\textsuperscript{80} Importantly, ovarian cancer deaths were higher in the screened group than in the usual care group (3.1 deaths versus 2.6 deaths/10,000 women). These effects are attributed to false-positive test results, higher rates of oophorectomy, and surgical complications. Pelvic examination may detect advanced disease.\textsuperscript{80} Several biomarkers with potential application to screening are under investigation. A malignant tumor is confirmed by biopsy and extent of disease evaluated with imaging techniques. The International Federation of Gynecologists and Obstetricians (FIGO) staging system is described
in Table 33-8.

*The International Federation of Gynecologists and Obstetricians.

The initial approach to treatment is surgery, which is performed to determine the stage of disease and to remove as much of the tumor as possible. Survival increases with the expertise of the surgeon. Understanding the biology of cancers and decreasing tumor implantation (seeding) have mandated highly skilled surgical and biopsy techniques. Treatment is then customized based on the stage of the cancer, the woman's desires, the cell type, and the sensitivity of the cancer cells. Radiation and chemotherapy are common treatments. New therapies under investigation include monoclonal antibodies, epidermal growth factor receptor, gene therapy, and small-molecular-weight inhibitors. Research into prevention and treatment of ovarian cancer is ongoing and expanding.

**Sexual Dysfunction**

**Sexual dysfunction** is the lack of satisfaction with sexual function resulting from pain or a deficiency in sexual desire, arousal, or orgasm/climax. Sexual function and dysfunction result from a complex set of personal and biologic factors that interact with culture. Both organic and psychosocial disorders can be implicated in sexual dysfunction. Additionally, studies have shown that up to 45% of adult women have some form of sexual dysfunction and adequate research is still needed. Chronic medical conditions can greatly affect both sexual desire and sexual function (Table 33-9).

**Disorders of desire (hypoactive sexual desire, decreased libido)** are the most common sexual dysfunction in women. The prevalence of hypoactive sexual desire increases with age and may be a biologic manifestation of depression, dissatisfaction with partner relationships, a history of sexual or physical abuse, alcohol or other substance abuse, prolactin-secreting pituitary tumors, or testosterone deficiency. Medications, such as β-adrenergic blockers used for heart disease, may inhibit sexual desire. Treatment may include counseling, psychotherapy, and antidepressants.

**Anorgasmia (orgasmic dysfunction)** is the inability of a woman to reach or achieve orgasm and ranges from difficulty in arousal to lack of orgasm. Any chronic illness may affect arousal. Specific disorders that may block orgasm are diabetes, alcoholism, neurologic disturbances, hormonal deficiencies, and pelvic disorders, such as infections, trauma, and surgical scarring. Other inhibitors include drugs, such as narcotics, tranquilizers, antidepressants (especially selective serotonin reuptake inhibitors [SSRIs]), and antihypertensive medications.

**Dyspareunia (painful intercourse)** is common. Women may experience pain at any time from the beginning of arousal to after intercourse. The pain may have a burning, sharp, searing, or cramping quality and may be described as external, vaginal, deep abdominal, or pelvic. A variety of psychosocial and organic causes have been identified. Inadequate lubrication may make penetration or intercourse difficult or painful. Drugs with a drying effect (such as antihistamines, certain tranquilizers, and marijuana) and disorders (such as diabetes, vaginal infections, and estrogen deficiency) can decrease lubrication. Other causes include skin
problems around the introitus or affecting the vulva; irritation or infection of the clitoris; disorders of the vaginal opening and disorders of the urethra or anus; disorders of the vagina, such as infections, thinning of the walls caused by aging or decreased estrogen level, or irritation caused by spermicides or douches; and pelvic disorders, such as infection, tumors, and cervical or uterine abnormalities.

**Vaginismus** is an involuntary muscle spasm in response to attempted penetration. Common psychologic causes include prior sexual trauma and fear of sex. Organic causes are similar to those that cause dyspareunia, including vulvovestibulitis. Even after the underlying organic problem is detected and successfully treated, vaginismus may persist.

Sexual dysfunction may develop as a coping mechanism. Women with a history of sexual trauma—rape, incest, or molestation—often have problems with desire, arousal, or orgasm or experience pain with sexual activity. In extreme cases, total sexual aversion may develop. At other times, sexual dysfunction may be a symptom of marital or relationship problems. Because sexual dysfunction has many causes, assessment and treatment should be holistic and culturally sensitive.

**Impaired Fertility**

**Infertility** affects approximately 15% of all couples and is defined as the inability to conceive over 1 year of unprotected intercourse. Fertility can be impaired by factors in the man or woman, or in both partners. Female infertility results from dysfunction of the normal reproductive process: menses and ovulation, fallopian tube function (transport of the egg to the uterus and as a site of fertilization), and implantation of the fertilized egg into a receptive endometrium. Ovarian dysfunction includes defective ovulation because of hormonal effects (e.g., PCOS, depressed hypothalamic activity, secondary physical or emotional stress), diminished ovarian reserve (lack of immature eggs secondary to congenital, medical, or unexplained factors), or premature ovarian insufficiency (failure of ovarian function before the age of 40). Fallopian tube dysfunction may result from acute pelvic infections with chlamydia or gonorrhea. Adhesions from pelvic infection, abdominal surgery, or endometriosis may cause blockage of one or both fallopian tubes, preventing access of the sperm to the ovum. The fertilized ovum must implant on a receptive endometrium.

Receptivity may be greatly diminished by fibroids or inadequate molecular or cellular preparation of the implantation site. A number of diagnostic procedures are required in the routine investigation of the infertile couple. Initial workup includes analysis of semen, determination of ovulation, and hysterosalpingography of the fallopian tubes. Treatment of infertility is aimed towards correction of problems identified during diagnostic workup. Male
infertility may be corrected surgically (varicoceles) or by artificial insemination with the husband's or donor sperm. Anovulation can be treated with hormonal medications that induce ovulation (e.g., clomiphene citrate, follicle-stimulating hormone, gonadotropin-releasing hormone). Women with fallopian tube defects, who have failed other approaches, or have no identifiable cause of their infertility are frequently treated by assisted reproductive technology (ART). The basic ART procedure is in vitro fertilization (IVF), which involves collecting eggs directly from the ovary, performing fertilization and early embryonic development in the laboratory, and then transferring the eggs into the uterus. Many variations of this procedure are available. Depending on the potential cause of infertility, appropriate modifications allow for the use of donor sperm, egg, or uterus (in the case of surrogacy). An essential treatment for infertility is prevention of sexually transmitted infection, which can result in scarring and adhesion formation in the reproductive tract of either the man or the woman.

Quick Check 33-4

1. Why is cervical cancer considered a sexually transmitted infection?
2. What are the risk factors and pathogenesis for endometrial cancer?
3. What factors reduce the risk of ovarian cancer?
4. Discuss the new hypothesis for pathogenesis of ovarian cancer.
Disorders of the Female Breast

Galactorrhea

Galactorrhea (inappropriate lactation) is the persistent and sometimes excessive secretion of a milky fluid from the breasts of a woman who is not pregnant or nursing an infant. Galactorrhea, which also can occur in men, may involve one or both breasts, and is not associated with breast cancer.

The incidence of galactorrhea is difficult to estimate because of differences among definitions of the condition, examination techniques, and populations of women who have been studied. Prevalence has been documented as 0.1% to 32% of all women.

Pathophysiology

Galactorrhea is a manifestation of pathophysiologic processes elsewhere in the body, rather than a primary breast disorder. These processes are chiefly hormone imbalances caused by hypothalamic-pituitary disturbances, pituitary tumors, or neurologic damage. Exogenous causes include drugs, estrogen, and manipulation of the nipples.

The most common cause of galactorrhea is nonpuerperal hyperprolactinemia, or excessive amounts of prolactin in the blood not related to pregnancy or childbirth. Nonpuerperal hyperprolactinemia can be caused by any factor that (1) stimulates or overstimulates the prolactin-secreting units of the pituitary gland; (2) interferes with production of prolactin-inhibiting factor (PIF), a neurotransmitter (probably dopamine) that inhibits prolactin secretion; or (3) interferes with pituitary receptors for PIF.

Certain drugs can cause nonpuerperal hyperprolactinemia. They include the phenothiazines, reserpine, and methyldopa; exogenous estrogens, particularly in oral contraceptives; morphine; and the tricyclic antidepressants.

Hypothyroidism causes increased secretion of hypothalamic thyroid-stimulating hormone (TSH), which stimulates prolactin release from the pituitary. Hypothyroidism also is associated with reduced metabolic clearance of prolactin, which prolongs its effects.

Many types of pituitary tumors cause hyperprolactinemia, particularly prolactinoma. Prolactinomas cause hyperprolactinemia by secreting prolactin, decreasing production of PIF, or applying pressure to the pituitary stalk, thus preventing delivery of PIF to the anterior pituitary. Growth hormone–secreting pituitary tumors may cause galactorrhea through the intrinsic lactogenic effect that growth hormone appears to have on mammary tissue. Prolactin-secreting lung and
kidney tumors also cause hyperprolactinemia.

Chronic stress may cause hyperprolactinemia by inhibiting PIF release. Head trauma, cervical spinal injuries, encephalitis, meningitis, herpes zoster, or thoracotomy scars may stimulate the suckling reflex. The suckling reflex increases prolactin secretion.

**Clinical manifestations**

Inappropriate lactation is manifested by the appearance of a milky breast secretion from one or both breasts of nonpregnant, nonlactating women. Most women with galactorrhea experience menstrual abnormality. If a pituitary process is involved, the woman usually experiences hirsutism and infertility; if a hypothalamic lesion is present, she may report central nervous system (CNS) symptoms, such as intractable headache, visual field disturbances, sleep disturbances, and abnormal temperature, thirst, or appetite.

**Evaluation and treatment**

Galactorrhea in nulliparous women (women who have never been pregnant) or in parous women who have not breast-fed for 12 months must be thoroughly evaluated. Evaluation includes a variety of diagnostic tests. Serum prolactin levels are measured, and at least two positive results are needed to diagnose hyperprolactinemia. Prolactin levels higher than 25 to 30 ng/ml (measured by radioimmunoassay) are considered elevated. Those in the range of 75 to 100 ng/ml are possibly caused by a pituitary tumor until proven otherwise. Serum thyroxine ($T_4$) and thyroid-stimulating hormone (TSH) levels are measured to rule out hypothyroidism, and LH and FSH levels are obtained if the individual is amenorrheic. MRI may assist in locating adenomas.

Treatment for galactorrhea consists of identification and treatment of the cause. Medical therapy is typical and surgical or radiation therapy is rarely required.

**Benign Breast Disease and Conditions**

**Benign breast disease (BBD)** is a spectrum of noncancerous changes in the breast. Numerous benign alterations in ducts and lobules occur in the breast, including lumps, cysts, sensitive nipples, and itching. The most common symptoms reported by women are pain, palpable mass, or nipple discharge; the majority of these prove to have a benign cause. Major determinants of the risk of breast cancer after a diagnosis of BBD include histologic or biologic features, or both; previous biopsy; and degree of family history.$^91$ Benign epithelial lesions can be broadly classified as (1) nonproliferative breast lesions, (2) proliferative breast disease without atypia,
and (3) atypical (atypia) hyperplasia. The majority of nonproliferative benign lesions are not precursors of cancer and generally not associated with an increased risk of breast cancer.\textsuperscript{91,92} Some benign breast lesions, for example, atypical hyperplasia, confer an increase in risk for development of breast cancer and these women are recommended for counseling about screening recommendations and risk reduction.\textsuperscript{91}

**Nonproliferative Breast Lesions**

Nonproliferative epithelial breast lesions are usually not associated with an increased risk of breast cancer. The nonproliferative lesions include (1) simple breast cysts, (2) papillary apocrine change, and (3) mild hyperplasia of the usual type. Terms such as fibrocystic changes (FCCs; or physiologic nodularity and cysts), fibrocystic disease, chronic cystic mastitis, and mammary dysplasia refer to nonproliferative lesions but are not definitive because they are a heterogeneous group of diagnoses.\textsuperscript{91} Simple cysts (fluid-filled sacs) are the most common nonproliferative breast lesion and are a specific type of lump that commonly occurs in women in their thirties, forties, and early fifties. Cysts feel “squishy” when they occur close to the surface of the breast but when deeply embedded they can feel hard. An estimated 50% to 80% of women normally experience some of these changes. The prevalence of fibrocystic lesions is probably related to hormonal changes, which in turn are affected by genetic background, age, parity, history of lactation, and use of caffeine and exogenous hormones. Cystic changes can be induced in experimental animals by altering ratios of estrogens and progesterone. It is assumed, therefore, that breast cysts are the result of ovarian alterations, but the exact mechanism is unknown. Cysts also can be associated with unilateral nipple discharge. Cysts often rupture with release of secretory material into the adjacent tissue. The resulting chronic inflammation and scarring fibrosis contribute to the palpable firmness of the breast. Fibrous tissue increases progressively until menopause and regresses thereafter.

**Papillary apocrine change** is an increase in ductal epithelial cells that has apocrine changes or an eosinophilic cytoplasm. **Mild hyperplasia of the usual type** is an increase in the number of epithelial cells within a duct that is more than two cells, but not more than four cells, in depth.\textsuperscript{91}

**Proliferative Breast Lesions without Atypia**

These disorders are characterized by proliferation of ductal epithelium or stroma, or both, without cellular signs of abnormality (atypia or deviation from normal). The following structurally diverse lesions are included and discussed next: (1) usual
ductal hyperplasia, (2) intraductal papillomas, (3) sclerosing adenosis, (4) radial scar, and (5) simple fibroadenoma.

1. **Usual ductal hyperplasia (UDH)** is additional or proliferating epithelial cells that fill and distend the ducts and lobules and are usually found as an incidental finding from mammography. The cells can vary in size and shape, but they retain features of benign cells. No additional treatment is needed and chemoprevention is not recommended.

2. **Intraductal papillomas** can occur as solitary or multiple lesions. *Solitary papillomas* are a monotonous (sameness) array of papillary cells that grow from the wall of the cyst into the lumen of the duct. Growth occurs within a dilated duct often near or beside the nipple, causing benign nipple discharge. These papillomas can harbor areas of atypia requiring surgical excision. **Diffuse papillomatosis** (multiple papillomas) may present as breast masses, nodules on ultrasound, or the cause of nipple discharge. Diffuse papillomatosis is defined as a minimum of five papillomas within a localized segment of breast tissue. Although the breast cancer risk is small, these lesions require surgical excision.

3. **Sclerosing adenosis** is a lobular lesion with increased fibrous tissue and scattered glandular cells. It is a common but poorly understood benign breast lesion. A recent study found increased Ki-67 expression (a proliferation marker) carried an approximate twofold increased chance of subsequent breast cancer. It is usually found as a suspicious lesion on mammography.

4. **Radial scar (RS)** refers to an irregular, radial proliferation of ductlike small tubules entrapped in a dense central fibrosis. The term *scar* refers to the structural appearance only because these lesions are not associated with prior injury, biopsy, or surgery. Radial scar also has been called *radial sclerosing lesions* and *sclerosing papillary proliferation*. RSs are usually discovered when a breast lesion or radiologic abnormality is biopsied or removed. Controversy exists about the need for surgical excision.

5. **Simple fibroadenomas** are benign solid tumors that contain glandular and fibrous lesions. In about 20% of cases, multiple fibroadenomas can occur in the same breast or bilaterally. The etiology for fibroadenomas is unknown but appears to be hormonal because they can persist during the reproductive years and can increase in size during pregnancy or with estrogen therapy. They usually regress after menopause. They are more common among women between 15 and 35 years of age. Fibroadenomas are now considered proliferative lesions and the histologic
features influence the risk of breast cancer. There is no increased risk of breast cancer in the majority of women with a simple fibroadenoma. It is not necessary to excise all biopsy-proven fibroadenomas.\textsuperscript{91} Disadvantages of excisional surgery include scarring at the incision site, dimpling of the breast from the removal of the tumor, damage to the breast's duct system, and mammographic changes (e.g., architectural distortion, skin thickening, increased focal density).\textsuperscript{91} If a biopsy-proven fibroadenoma is asymptomatic, it can then be left in place, although some women wish to have the mass excised so that they will not worry further.\textsuperscript{91}

**Proliferative Breast Lesions with Atypia**

**Atypical hyperplasia (AH)** is an increase in the number of cells (or proliferation) with the cells having some variation in structure—*atypia*. AH is a high-risk benign lesion found in about 10\% of biopsies with benign findings.\textsuperscript{92,95} These proliferative breast lesions with some atypia include atypical ductal hyperplasia and atypical lobular hyperplasia.\textsuperscript{92} **Atypical ductal hyperplasia (ADH)** refers to abnormal proliferating cells in breast ducts. **Atypical lobular hyperplasia (ALH)** refers to proliferation of cells in the lumen of lobular units.

Much of the next discussion will refer to just “atypical hyperplasia (AH).” Studies indicate that women with AH have an increased risk (about fourfold) of breast cancer compared with women who have nonproliferative lesions.\textsuperscript{96-99} Ongoing studies will further determine risk estimates with such factors, for example, as breast density\textsuperscript{92,96} (Figure 33-24). About 60\% of the subsequent breast cancers in women with AH occur in the ipsilateral breast (same side) as the biopsy.\textsuperscript{96,99,100} From long-term studies mentioned earlier, atypical hyperplasia has been shown to confer a relative risk of 4 for future breast cancer and recently the *absolute risk* has been better defined with a cumulative incidence of breast cancer about 30\% at 25 years of follow-up.\textsuperscript{97,101} This high cumulative risk is not widely appreciated and, therefore, women with atypical hyperplasia are not included in many high-risk guidelines, for example, screening with MRI and use of chemopreventive agents.\textsuperscript{95} Because some studies have shown a lack of concordance (agreement) among pathologists in differentiating atypical hyperplasia from carcinoma in situ,\textsuperscript{102} it is important that pathologists follow standardized, published criteria and this may be a factor for women to seek a second opinion. It appears that menopausal status at the time of benign breast biopsy influences the magnitude of subsequent breast cancer risk. For women who were premenopausal at the time of their breast biopsy, the risk of breast cancer was greater in those with ALH than among women with ADH.\textsuperscript{100} Overall, the younger a woman is when she receives a diagnosis of atypical hyperplasia, the higher the risk that breast cancer will develop.\textsuperscript{97-99} Among women who were
postmenopausal at the time of benign breast biopsy, the risk was similar with ALH and women with ADH.\textsuperscript{100} Overall, ADH and ALH are viewed best as “markers” of a generalized bilateral increase in breast cancer risk.\textsuperscript{91,100}

\textbf{FIGURE 33-24} Anatomic and Histologic Features of Atypical Hyperplasia. Panel A shows atypical ductal hyperplasia with proliferation of monotonous cells in architecturally complex patterns, including secondary lumens and micropapillary formations. Panel B shows atypical lobular hyperplasia, with expanded acini filled with monotonous polygonal cells and a loss of acinar lumen. Panel C shows multifocal atypical hyperplasia (in this case atypical lobular hyperplasia). Atypical lobular hyperplasia is present in more than one terminal duct lobular unit, and units are clearly separated from one another by interlobular mammary stroma (arrows). Panel D is an illustration of the microanatomy of the breast, including a photomicrograph of a terminal duct lobular unit. (From Hartmann LC, Degnim AC, Santen RJ, Dupont WD, Ghosh K: \textit{N Eng J Med} 372[1]:1271-1272, 2015.)
Evaluation and treatment

Breast problems are diagnosed from a multimodal approach that combines physical examination, mammography, ultrasonography, thermography, possibly MRI, and biopsy. The dense breast tissue often seen in young women can make mammographic interpretation extremely difficult (see Health Alert: Breast Cancer Screening Mammography).

Health Alert

Breast Cancer Screening Mammography

Joann G. Elmore MD, MPH

The idea behind screening healthy individuals for disease is the hope that we can diagnose disease early, when more treatment options are available and when we can positively impact the life of the individual. Screening programs that cover the entire population of a country are a large undertaking and usually require extensive resources. Therefore we need to make certain that the test has a high level of accuracy with reasonable costs and disadvantages, the disease is not too rare, and the treatment is effective for individuals who are diagnosed because of the screening.

Women have been encouraged to undergo breast cancer screening for many decades. Early screening programs encouraged women to perform self-breast exams and also to have their clinician perform a breast exam in the office—subsequent data have shown that these screening techniques lead to false-positive exams and are not associated with a reduction in mortality.

Breast cancer screening with mammography continues to be recommended by many groups, although the benefits are less than we had hoped and we are learning more about the harms. Mammography is an x-ray exam that takes views of each breast (see figure). The recommended age of first mammogram and the frequency of screening vary among guidelines and countries. The U.S. Preventive Services Task Force periodically reviews the evidence and issues guidelines to help aid discussions with women about screening.
The benefits, risks, and accuracy of mammography screening depend on numerous factors, including women's age, breast density, and time interval between screening exams. Possible risks of screening are important to consider because screening at a population level involves testing healthy individuals; we are to “first, do no harm.”

No medical test is perfect. About 10% of screening mammograms in the United States are interpreted as “abnormal,” requiring additional testing. The great majority of women with these “abnormal” exams do not have breast cancer; this is called a false-positive result. The false-positive results lead to additional diagnostic testing, which can result in anxiety and morbidity to women. It is estimated that at least 50% of women in the United States, who are screened annually for a decade, will have experienced at least one false-positive examination.

Another harm of screening mammography is overdiagnosis—a diagnosis that would never have harmed the woman during her lifetime; such diagnoses can be either of a preinvasive lesion, such as ductal carcinoma in situ (DCIS), or of invasive breast cancer. With more women undergoing screening with mammography, we have seen a sharp increase in the number of women diagnosed with DCIS and early stage breast cancer. By definition, DCIS is not an invasive carcinoma and not an immediate life-threatening cancer—it is confined to the duct; but DCIS is almost always treated as if it is an invasive early stage breast cancer. Women with DCIS are at increased risk of a subsequent, invasive breast cancer diagnosis; however, the majority of women with DCIS are never subsequently diagnosed with invasive cancer and treatment of DCIS does not alter mortality. Women with DCIS have the same death rates as women without DCIS. Some discussion has centered on changing the name of DCIS lesions to better differentiate preinvasive DCIS from invasive cancer because the term carcinoma is similar to the term cancer. However, it is not likely that the name will be changed
because of its current common usage.

Unfortunately, we are not able to identify which women with a new diagnosis of DCIS or invasive breast cancer have the type of lesion that is so low risk that it will never harm them during their lifetime. Thus, most women undergo treatment with either lumpectomy and radiation therapy or mastectomy. This is overtreatment if the DCIS or invasive cancer was overdiagnosed. Estimates of the prevalence of overdiagnosis vary in the literature from <10% to 50%; more research is clearly needed.

Women with abnormalities noted on screening mammography are often offered the option of a breast biopsy versus watchful waiting with follow-up mammograms in 6 to 12 months. Some women think that a breast biopsy will provide an immediate and definitive diagnosis; however, this is not always the case. Pathologists have been noted to disagree on the diagnoses of atypia and DCIS.

Balancing the benefits and harms of breast cancer screening is not an easy task for women or their clinicians. Every woman should be encouraged to make an informed decision.

Treatment consists largely of relieving symptoms. Reduction in the consumption of caffeinated beverages (e.g., cola, root beer) and chocolate, which can cause overstimulation for some women, may reduce pain and nodularity. Given time, the cysts may disappear without treatment.

Although still controversial, isoflavone exposure was associated with a decreased risk of proliferative benign fibrocystic changes, nonproliferative changes, and breast cancer. Genistein, a soy isoflavone, has been reported to down-regulate an enzyme important in cancer progression (i.e., telomerase) and contributes to inhibition in both breast benign and cancer cells. Toxicologists, in perhaps the first in vitro study quantifying the proliferative effects of isoflavone metabolites, conclude soy supplement intake will not induce proliferation of normal breast tissue and may even inhibit proliferation. The North American Menopause Society found that soy foods generally appear to be breast protective and recommended moderate lifelong soy consumption. Although quite controversial, another preventive factor may be iodine.
Breast Cancer

In 2012, 1.7 million women were diagnosed with breast cancer and there were 6.3 million women alive who had been diagnosed with breast cancer in the previous 5 years (Figure 33-25). Mortality has increased by 14%. Breast cancer is the most common cause of cancer death among women (522,000 deaths in 2012) and the most frequently diagnosed cancer among women in 140 of 184 countries worldwide. It now represents one in four of all cancers in women.
A  Estimated age-standardized rates (World) per 100,000
Breast cancer, the most common cancer in American women, is the leading cause of death in women 40 to 44 years of age and the second leading cause of cancer death in women of all ages after lung cancer. It is estimated that 234,190 women and 2350 men will be diagnosed with breast cancer, and 40,730 women and 440 men will die from breast cancer in 2015. African American women have a lower incidence of breast cancer (118.1/100,000) than white women (123.2/100,000) but have a higher death rate (31.6/100,000) than white women (22.4/100,000). More than two thirds of breast cancer cases occur in women older than age 55. Because ductal carcinoma in situ (DCIS) is almost exclusively detected by mammography, the large increase in incidence of DCIS over the past 20 years can be attributed to screening.

Although breast cancer is a multifactorial disease involving a complex web of interacting factors, risk is related to timing, duration, and pattern of exposures. Risk factors and possible causes of breast cancer can be classified broadly as reproductive, hormonal, environmental, and familial (Table 33-10). However, two
factors emerging as important are involution of the mammary gland and breast density, which are not as easily classified (see following discussion).

**Reproductive Factors: Pregnancy**

A clearer understanding of mammary gland structure (morphology) and function from fetal development to puberty, pregnancy, and aging will help elucidate fundamental changes to breast development and disease. A key element in that process is “branching morphogenesis,” in which the mammary gland fulfills its function by producing and delivering copious amounts of milk by forming a rootlike network of branched ducts from a rudimentary epithelial bud. Branching morphogenesis begins in fetal development, pauses after birth, starts again in response to estrogens at puberty, and is modified by cyclic ovarian hormonal action. This systemic hormonal action elicits local paracrine interactions between the developing epithelial ducts and their adjacent mesenchyme (embryonic) or postnatal stroma. The local cellular crosstalk then directs the tissue remodeling, ultimately producing a mature ductal tree.

A woman's age when her first child is born affects her risk for developing breast cancer—the younger she is, the lower the risk. Overall, lifetime risk of breast cancer is reduced in parous women compared with nulliparous women, but pregnancy must occur at a young age. The influence of pregnancy on the risk of
breast cancer also depends on family history, lactation postpartum, and overall parity.\textsuperscript{110} Findings from a large prospective study found a \textit{dual effect} from pregnancy—a transient postpartum increase in breast cancer risk followed by a long-term reduction in risk (compared with nulliparous women).\textsuperscript{111} \textbf{Pregnancy-associated breast cancer (PABC)} is defined as breast cancers that occur during pregnancy, and risk may persist to at least 5 years postpartum and longer.\textsuperscript{112,113} Delayed childbearing, observed in the United States and all developing countries, is expected to show a rise in diagnosed breast cancers.\textsuperscript{110} A recent hypothesis for risk at any age is that gland \textit{involution} after pregnancy and lactation uses some of the same tissue remodeling pathways activated during wound healing (i.e., proinflammatory pathways).\textsuperscript{114} The proinflammatory environment, although physiologically normal, promotes tumor progression. The presence of macrophages in the involuting mammary gland may be contributing to carcinogenesis and the normal involuting gland may be in an immunosuppressed state with T-cell suppression.\textsuperscript{114,115} Involution is discussed in the following section.

Although many mechanisms have been proposed for the \textit{protective} effect of pregnancy, newer data on the genomic profile of parous women have shown pregnancy induces a long-lasting “genomic signature” that reveals chromatin remodeling derived from the early first pregnancy. The chromatin modifications are accompanied by higher expression of genes related to cell adhesion and differentiation, and genes only activated during the first 5 years after pregnancy may contribute to increased risk but the long-lasting genetic signature may explain pregnancy's preventive effect.\textsuperscript{116}

\textbf{Lobular Involution and Age and Postlactational Involution}

Part of the uniqueness of the mammary gland is its profound physiologic changes throughout the phases of a woman's life. These phases include puberty, pregnancy, lactation, postlactational involution, and aging. The human breast is organized into 15 to 20 major lobes, each with terminal lobules containing milk-forming acini (see \textbf{Figure 32-10}, p. 792). \textbf{Terminal duct lobular units (TDLUs)}, structures of the breast that are responsible for lactation, are the predominant source of breast cancers.\textsuperscript{117} With aging, breast lobules regress or involute with a decrease in the number and size of acini per lobule and with replacement of the intralobular stroma with the denser collagen of connective tissue.\textsuperscript{118} With time, the glandular elements and collagen are replaced with fatty tissue. This process is called \textbf{lobular involution} and over many years the parenchymal elements progressively atrophy and disappear. The first study of its kind found lobular involution was associated with reduced risk of breast cancer.\textsuperscript{118} Breast cancer risk decreased with increasing \textit{extent}
of involution in both high- and low-risk subgroups defined by family history of breast cancer, epithelial atypia, reproductive history, and age. Based on pathologic and epidemiologic factors, these investigators propose that delayed involution (persistent glandular epithelium) is a major risk factor for breast cancer. Tissue involution involves massive epithelial cell death, recruitment and activation of fibroblasts, stromal remodeling, and immune cell infiltration, including macrophages with similarities to microenvironments present during wound healing and tumor progression.

Investigators suggest that the effect of lobular involution on breast cancer risk is a reduction in tissue from the involuting process, or the issue may be aging. Widely appreciated is that as women age, their risk of breast cancer increases. But, the rate of increase of breast cancer slows at about 50 years of age. This decline has been attributed to a reduction in ovarian hormone production; however, involution may contribute to this slowing rate. Importantly, investigators found an inverse association between lobular involution and parity. Other investigators have reported the more children a woman has, the more likely she is to have persistent lobular tissue, which Milanese and colleagues found was associated with increased risk of breast cancer. However, multiparity also has been found to reduce the risk of breast cancer. This apparent contradiction may be explained by studies documenting that full-term pregnancies after 35 years of age are correlated with an increased risk of breast cancer. In the Milanese study, the age of the mother at each child's birth was unknown.

Henson and colleagues propose that late pregnancy with its concomitant increase in the proliferation of the ductal-alveolar epithelium is likely to interrupt the process of involution, which typically begins between 30 and 40 years of age. Failure to undergo TDLU involution among women with benign breast disease has been associated with progression to breast cancer, independent of other breast cancer risk factors. The activated stromal environment (with the influx of immune cells similar to that which occurs during wound healing) in the process of involution is the “ideal niche” for carcinogenesis.

Major signaling pathways involved in mammary gland involution also are involved in breast cancer. Certain proteases activated during involution modify the extracellular matrix and are implicated in loss of cell anchoring, providing a microenvironment for tumor growth. Further, the normal involuting gland may be in an immunosuppressed state with the transient presence of immune-regulating cells that promote T-cell suppression. Overall, for breast cancer, the long-term protective effects of pregnancy from hormones released (with consequent genetic and epigenetic changes) during pregnancy affect remodeling of the stromal microenvironment by causing apoptosis and involution. However, a transient
increase in breast cancer risk following pregnancy may be caused by the process of mammary gland involution, which returns the tissue to its prepregnant state and is co-opted by the process of wound healing, resulting in a proinflammatory environment that, although physiologically normal, can promote carcinogenesis. In postlactational involution, the mammary gland regresses and remodels to its prepregnant state whereby fibroblasts secrete proteases that degrade the extracellular matrix proteins. Consequently, the increased release of bioactive matrix fragments can promote tumor growth, motility, and invasion. The extracellular matrix (ECM) is very different between nulliparous, lactating, and involuting glands as shown in Figure 33-26.

Oophorectomy, which is associated with a decrease in risk of breast cancer, leads to atrophy of breast parenchyma in young women, as is noted in older women. Thus the risk reduction of oophorectomy may be caused by an accelerated involution.

Investigators have shown that a benign biopsy demonstrating histologic changes consistent with incomplete or nonexistent involution or a mammogram classified as high density is independently associated with breast cancer risk, and that these factors combined are associated with an even greater risk. The assessment of these “phenotypes” shows promise for improving risk prediction, particularly because they reflect the cumulative interaction of numerous genetic and environmental breast cancer risk factors over time.

**Hormonal Factors**

The link between breast cancer and hormones is based on six factors that affect risk:
(1) the protective effect of an early (i.e., in the twenties) first pregnancy; (2) the protective effect of removal of the ovaries and pituitary gland; (3) the increased risk associated with early menarche, late menopause, and nulliparity; (4) the relationship between types of fat, free estrogen levels, and oxidative changes in estrogen metabolism; (5) the hormone-dependent development and differentiation of mammary gland structures; and (6) the efficacy of antihormone therapies for treatment and prevention of breast cancer. Throughout its existence, the mammary gland epithelium proceeds through critical “exposure periods” of rapid growth or cycles of proliferation, including neonatal growth, pubertal development, pregnancy lactation, and involution (after pregnancy and postmenopause, see p. 836). Importantly, lack of TDLU involution has been associated with increased breast cancer risk, but the role of sex hormone levels and TDLU assessments has only begun to be studied (also see p. 836). Investigators suggest that hormone levels may act, in part, to delay age-appropriate TDLU involution, resulting in a higher quantity of at-risk epithelium. These investigators found significant associations between higher TDLU counts, representing less involution, with higher levels of prolactin and lower levels of progesterone among premenopausal women, and higher levels of estradiol among postmenopausal women. Higher testosterone levels were suggestively associated with higher TDLU counts among postmenopausal women.

The understanding of the role of systemic hormones as powerful regulators of mammary gland development is shifting. Evidence is pointing to the wide-ranging effects of systemic hormones, possibly not because of their direct hormone action but rather because of their induced actions from multiple secondary paracrine effectors—thus the term hierarchical. Unraveling is a complex model of hormone, paracrine, and adhesion molecule signaling pathways affecting both epithelial and stromal cell fate in both breast development and carcinogenesis (Figure 33-27). Key is tissue remodeling that applies not only to pubertal growth but also immediately after pregnancy and during involution (see previous section).
The female reproductive hormones (estrogens, progesterone, and prolactin) have a major role and effect on mammary gland development and breast cancer. A vast majority of breast cancers are initially hormone dependent (estrogen positive [ER+] and/or progesterone positive [PR+]), with estrogens playing a crucial role in their development.\textsuperscript{127} Estrogens control processes critical for cellular functions by regulating activities and expression of key signaling molecules. These processes include regulation of receptor activity and receptor interaction with other intracellular proteins and DNA.\textsuperscript{127} Estrogens thus play prominent roles in cellular proliferation, differentiation, and apoptosis.\textsuperscript{127} Estrogens affect microtubules that are essential for establishing cell shape and cell polarity, processes necessary for epithelial gland organization.\textsuperscript{127}

It is possible to consider four major hormonal hypotheses for breast cancer: (1) ovarian androgen excess (testosterone, for example); (2) estrogen and progesterone
levels (ovarian and hormone replacement; (3) elevated estrogen levels alone (ovarian and hormone replacement); and (4) local biosynthesis of estrogens in breast tissue. These hypotheses, however, may not be mutually exclusive. Hormone replacement therapy (HRT), or the newer term **menopausal hormone therapy (MHT)**, is discussed later in a separate section; the present discussion is concerned with endogenous levels of hormones.

The first hypothesis that breast cancer risk is increased among women who have an ovarian androgen excess also includes chronic anovulation and reduction of luteal phase (menstrual cycle) progesterone production. Therefore, it is also called the “ovarian hyperandrogenism/luteal inadequacy hypothesis.” This hypothesis was based on the observation that women with breast cancer also reveal hyperplasia of the endometrium—a common symptom of ovarian androgen excess chronic anovulation and progesterone deficiency. From the combination of prospective studies, case-control studies, and laboratory data the association between circulating testosterone levels in postmenopausal women and subsequent risk of breast cancer is now well established. Unclear is whether the association with testosterone level is direct or indirect (i.e., enzyme conversion by aromatase of testosterone to estradiol) (**Figure 33-28**).
The androgen receptor (AR) has been implicated in prostate cancer, and now in the development and progression of breast cancer. Investigators used breast cancer cell lines and found that treatment of the breast cancer cells with 5α-dihydrotestosterone (DHT) promotes cell proliferation and decreases apoptosis. The reduction of testosterone levels in women with oophorectomy or hysterectomy also may be a protective factor.

The second hypothesis is breast cancer risk is increased among women with blood elevations of both estrogens and androgens—the “estrogen-plus-progesterone hypothesis.” These observations revealed increased proliferation rates of breast epithelium during the luteal phase of the menstrual cycle when the ovaries produce both estradiol and progesterone. Substantial evidence supports a positive association of circulating estrogens, androgens, and prolactin with postmenopausal breast cancer risk. New data identify mammary stem cells (MaSCs) as critical targets for ovarian hormones, especially during the normal reproductive cycle when progesterone levels surge and during pregnancy when the proliferation of
mammary stem cells is increased. Higher levels of progesterone among premenopausal women was associated with lower TDLU counts. Among postmenopausal women, higher levels of estradiol and testosterone were associated with higher TDLU counts. Select hormones may influence breast cancer risk through delaying TDLU involution (see p. 836).

The third hypothesis is often called the “estrogen-alone hypothesis.” Substantial prospective data have accrued on the relationship between levels of circulating estrogens and breast cancer risk in postmenopausal women. Overall, the positive association between levels of circulating estrogens in postmenopausal women and subsequent risk of breast cancer is now well established.

The fourth hypothesis suggests that local (in situ; paracrine) formation of estrogens in breast tumors may be more significant than circulating estrogens in plasma for the growth and survival of estrogen-dependent breast cancer in postmenopausal women. Investigators measured breast sex steroids in both benign and cancerous tissue. Estrogen and androgen concentrations varied greatly in both tissue and blood levels in benign and cancerous tissue. The estradiol/estrone ratio was lowest in premenopausal benign tissue and much higher in premenopausal cancerous tissue and postmenopausal benign and cancerous tissue. Estradiol and estrone levels were substantially higher in tissue than in plasma in both premenopausal and postmenopausal women. Hormone levels in breast adipose tissue revealed high levels of androstenedione and testosterone and significant estrone and estradiol levels in breast adipocytes from postmenopausal breast cancer patients consistent with an obesity-inflammation-aromatase axis (obesity with inflammation, cyclooxygenase [COX] elevation, and increased aromatase, which converts androgens to estrogen) occurring locally in breast tissue.

Overall, two main mechanisms of carcinogenicity of estrogens involve (1) a receptor-mediated hormonal activity shown to stimulate cellular proliferation, resulting in increased opportunities for accumulation of genetic damage; and (2) oxidative catabolism of estrogens mediated by various cytochrome complexes (P450 [CYP] system) that eventually activate and generate reactive oxygen species (ROS) that can cause oxidative stress and genomic damage directly. Oxidative metabolites of estrogens can develop ultimate carcinogens that react with DNA to cause mutations leading to carcinogenesis. Thus, imbalances in estrogen metabolites in breast tissue correlate with the development of tumors and suggest possible biomarkers related to the risk of developing breast cancer.

Hormone Replacement Therapy and Breast Cancer Risk: Estrogen Plus Progesterone Therapy (MHT) and Estrogen
Only Therapy (ET)

The International Agency for Research on Cancer lists estrogen-progestogen menopausal therapy and estrogen-progestogen contraceptives as carcinogenic agents with sufficient evidence in humans for breast cancer\textsuperscript{135} (see Table 11-1). Evidence from the Agency for Healthcare Research and Quality (AHRQ, United States) published a systematic review from 283 trials comparing effectiveness of treatments for menopausal symptoms.\textsuperscript{136} From this report, they state, “Over the long term, estrogen combined with progestogen has both beneficial effects (fewer osteoporotic fractures) and harmful effects (increased risk of breast cancer, gallbladder disease, venous thromboembolic events, and stroke). Estrogens given alone do not appear to increase breast cancer risk, although endometrial cancer risk is increased.” Evidence on the route of administration of MHT, oral versus transdermal (gel or patch), and the risk of breast cancer has limited research.

Insulin and Insulin-Like Growth Factors

Insulin-like growth factors (IGFs) regulate cellular functions involving cell proliferation, migration, differentiation, and apoptosis. Insulin-like growth factor 1 (IGF-1) is a protein hormone with a structure similar to that of insulin. IGF-1 is a potent mitogen, and after binding to the IGF-1R (receptor) triggers a signaling cascade leading to proliferation and anti-apoptosis.\textsuperscript{137}

Diabetes is associated with complex physiology of insulin resistance, increased insulin level, estrogen and growth hormone levels, inflammation, and signaling pathways leading to an increased risk of breast cancer.\textsuperscript{138} Insulin therapy and sulfonylurea were found to be mildly associated with increased breast cancer risk.\textsuperscript{138} A United Kingdom study showed that women treated with insulin glargine were not associated with breast cancer risk in the first 5 years; however, longer use may increase the risk.\textsuperscript{139} Metformin appears to have a protective role. Much more investigation is needed to understand the role of insulin, insulin-like growth factors, and diabetes mellitus and the risk of breast cancer and recurrence of breast cancers.

Melatonin as a regulator of circadian rhythm is the main focus of shift work and light at night and breast cancer risk. However, tumor growth (in vivo) can be accelerated by light at night in part from continuous activation of IGF-1 receptor (IGF-1R) signaling.\textsuperscript{140} A recent case-control study of 1679 women exposed to light at night during sleep was significantly associated with breast cancer risk.\textsuperscript{140} Although inconclusive, shift work and its disruptive effects on circadian rhythms and sleep deprivation at night have been suggested as a risk factor for breast cancer.\textsuperscript{141,142}
Prolactin and Growth Hormone

Growth hormone (GH) induces the production of IGFs in the liver; IGF signaling is important for breast development and is implicated in breast carcinogenesis. Two studies, however, have reported a link between growth hormone level and breast cancer risk.\textsuperscript{143,144} In the largest prospective analysis comparing circulating prolactin levels and breast cancer risk, those with the highest levels had the highest risk.\textsuperscript{145} From an EPIC cohort, higher circulating prolactin level was associated with increased risk of in situ breast cancer.\textsuperscript{146}

Oral Contraceptives

The International Agency for Research on Cancer (IARC) Group confirmed that combined estrogen-progestogen oral contraceptives (OCs) increase the risk for breast, cervix, and liver cancers.\textsuperscript{135,147} However, the efficacy of OCs in protecting against ovarian cancer and endometrial cancer is well established. Hormones are discussed further in the following Pathogenesis section (p. 842).

Mammographic Breast Density

\textbf{Mammographic density (MD)} is the radiologic appearance of the breast, reflecting variations in breast composition (Figure 33-29). Mammographic breast density (MBD) appears white or dense on a mammogram and is a strong and consistent risk factor for breast cancer.\textsuperscript{126} MBD decreases with age and is associated with body mass index (BMI), family history, and postmenopausal hormone use.\textsuperscript{148,149} Insulin-like growth factor 1 receptor (IGF-1R) may play an important role in breast cancer in individuals with mammographic breast tissue density.\textsuperscript{150} Investigators are studying if MBD is related to reduced lobular involution of breast tissue in dense breasts (reduced involution increases cancer risk). Having a combination of dense breasts and no lobular involution was associated with higher breast cancer risk than having nondense or fatty breasts and complete involution.\textsuperscript{126} Women with dense breasts occupying more than 60\% to 75\% of the breast have a fourfold to sixfold increased risk of breast cancer compared with those with little or no density.\textsuperscript{149,151} Dense area percentage is a stronger breast cancer risk factor than absolute dense area.\textsuperscript{152} Mammographic dense tissue has been thought to represent both epithelial and stromal components. One hypothesis is that the stromal-rich environment in MBD may have an abundance of growth factors that could stimulate the epithelium in a noninvoluted breast, thereby increasing the risk of malignant transformation.\textsuperscript{126} Finding tumors in women with MBD is a challenge because they both appear white; as Dr. Susan Love states, “…like trying to find a polar bear in a snow storm.”
Environmental Factors

The environmental causes of breast cancer possibly affect the breast the most during critical phases or “windows” of development including early differential stages—that is, undifferentiated cells to alveolar buds and then lobules, puberty, pregnancy and lactation, involution, and menopause. During these early phases, mitotic activity and cell division are greater than later in life.

Radiation.

Ionizing radiation is a known mutagen and established carcinogen for breast cancer. To date, only accidentally or medically induced radiation has been demonstrated to exert a carcinogenic effect on the breast. The Institute of Medicine (IOM) reports that the two most strongly associated environmental factors are exposure to ionizing radiation and combined postmenopausal HRT.\textsuperscript{153} There are many sources of ionizing radiation, including x-rays, CT scans, fluoroscopy, and other medical radiologic procedures (see Chapter 11). Although only about 10% of diagnostic radiologic procedures in large U.S. hospitals are CTs, they contribute an estimated 65% of the effective radiation dose to the public from all medical x-ray
examinations.\textsuperscript{154} The IOM conclusion of a causal relationship between radiation exposure in the same range as CT and cancer is consistent from a large varied literature.\textsuperscript{155} The IOM makes it clear that \textit{avoidance} of medical imaging is an important and concrete step that women (girls) can take to reduce their risk of breast cancer.\textsuperscript{156} Scientists and clinicians also have expressed concern about the increasing number of CT scans performed, including on children.\textsuperscript{156,157} Radiologic exposure of the upper spine, heart, ribs, lungs, shoulders, and esophagus also exposes breast tissue to radiation. Breast tissue may be exposed from abdominal CT scans; x-rays and fluoroscopy of infants may constitute whole-body irradiation. The duration of increased risk from radiation is unknown, but increased risk appears to have lasted at least 35 years in women treated for mastitis, those treated with fluoroscopy, and those who survived the atomic bombs during World War II. Breast cancer rates in atomic bomb survivors in Japan were highest among women younger than 20 years of age at time of exposure; importantly, those who had early full-term pregnancies were at significantly lower risk than those who had not. Thus, interacting factors can modulate the risks from radiation.

An important topic currently is the effect of low-dose ionizing radiation. The debate is that low-energy x-rays may be more hazardous per unit dose than previously reported. Conventional x-ray mammography is one of the most valuable diagnostic tools for imaging of the breast. Currently, full-field digital mammography (FFDM) is frequently used. Continuous technical development has led to several new imaging techniques, including digital breast tomosynthesis (DBT), phase contrast x-ray imaging, and computed tomography of the breast, as well as ultrasound and magnetic resonance imaging (MRI). Despite technical innovations, except for ultrasound and MRI, these modalities require exposure of breast tissue to ionizing radiation and the breast is considered a very radiosensitive organ.\textsuperscript{158} Therefore, it is critical to compare delivered radiation doses to the breast and measure x-ray–induced DNA damage. A new technique for the detection and quantification of in vivo DNA damage has been developed. DNA double-strand breaks (DSBs) are the most relevant lesion induced by ionizing irradiation.\textsuperscript{158} After induction of DSBs is the phosphorylation of the histone variant H2AX, named γ-H2AX. The γ-H2AX is a visible foci and a reliable and sensitive tool for the determination of DNA damage. Recently, investigators found mammography induces a slight but significant increase of γ-H2AX foci in systemic blood lymphocytes. A clear induction of DNA lesions was found both by FFDM and by DBT.\textsuperscript{158} These data will be important to compare different breast imaging techniques. Investigators are studying mammographic radiation–induced DNA damage in mammary epithelial cells from women with low or high family risk of breast cancer, including comparisons with the number of views performed during
screening. Radiobiologic effects have been found in both low-risk and high-risk women, but risks are greater in high-risk women. Investigators are looking for markers that are activated by DNA damage. One new marker may be CAV1 (caveolin protein, see Chapter 1). Caveolin protein acts as a sensor and early mediator in response to DNA damage and may be important as a biomarker for radiosensitivity. New biologic understandings of low doses of radiation are presented in Chapter 11.

Women treated with chest radiation for a pediatric or young adult type of cancer have a substantially increased risk of breast cancer. Investigators from international studies have concluded that diagnostic chest irradiation or radiation therapy for benign or malignant diseases increases the risk of breast cancer for cumulative doses as low as 130 mGy. The breast cancer risk did not decrease when increasing the number of radiologic treatment fractions for delivering the same total dose, but risk decreased greatly with increasing age of exposure to ionizing radiation. International agencies are assessing the utility of screening MRI and mammography in these high-risk populations. The risk of secondary lung malignancy (SLM) is an important concern for women treated with whole-breast radiation therapy after breast-conserving surgery for early-stage breast cancer. Investigators studied SLM risk associated with several common methods of delivering whole-breast radiation therapy (RT). Compared with supine whole-breast irradiation (WBI), prone breast irradiation is associated with a significantly lower predicted risk of secondary lung malignancy.

The United States Preventive Services Task Force (USPSTF) has updated the recommendations for mammography because of overdiagnosis and overtreatment issues related to screening mammography (Health Alert: Breast Cancer Screening Mammography).

Diet.

Prospective epidemiologic studies on diet and breast cancer risk fail to show an association that is consistent, strong, and statistically significant except for alcohol intake, being overweight, and weight gain after menopause (see following discussion). Diet has been postulated as important for breast cancer risk because of the international correlations of consumption of specific dietary factors (e.g., fats) and breast cancer incidence and mortality and because of migrant studies showing greater incidence of breast cancer among descendants who relocated to another country compared with those in the country of origin. International variations also can occur because of differences in reproductive history, physical activity, obesity, and other factors.
Dietary fat and breast cancer risk is the subject of much study, controversy, and debate.\textsuperscript{164} Potential biologic mechanisms between fat intake and breast cancer risk include the following: (1) fat may stimulate endogenous steroid hormone production (also affects weight gain, age of menarche), (2) fat interferes with immune or inflammatory function, and (3) fat influences gene expression. Although prospective studies and case-control studies on fat and breast cancer risk have been inconsistent, concern has been that any association with fat intake may be because of total energy intake. Moreover, there is limited evidence that modest reductions in fat intake (less than 20% of caloric intake) reduce breast cancer risk. Despite extensive investigation, there is no conclusive evidence overall that adult consumption of macronutrients including fat, carbohydrate, or fiber is strongly related to breast cancer incidence.

The association between individual foods and breast cancer is inconsistent, and new data on dietary patterns are emerging. The Mediterranean diet includes high intake of vegetables, legumes, fruits, nuts, and minimally processed cereals; moderately high intake of fish; and high intake of monounsaturated lipids coupled with low intake of saturated fat, low to moderate intake of dairy products, low intake of meat products, and moderate intake of alcohol. The Mediterranean diet may favorably influence the risk of breast cancer.\textsuperscript{165} The Western pattern includes higher intake of red and processed meats, refined grains, sweets and desserts, and high-fat dairy products.

Most prospective studies have not supported a link between fiber intake and breast cancer. Carbohydrate quality, however, rather than absolute amount, may be important for breast cancer risk, especially for premenopausal women.

Evidence exists that alcohol consumption increases breast cancer risk. Beer, wine, and liquor all contributed to the positive association and risks did not differ by menopausal status. In large prospective studies, high intake of folic acid appeared to decrease the enhanced risk for breast cancer caused by alcohol. The mechanisms by which alcohol intake increases the risk of breast cancer are unknown; however, physiologic studies have reported an estrogen level increase in women taking hormone replacement therapy (HRT) and IGF-1 level increases with alcohol intake. Alcohol may increase breast cancer risk through increasing mammographic breast density, especially in women at high risk.\textsuperscript{166} It is not known whether reducing or discontinuing alcohol consumption in midlife decreases the risk of breast cancer. The relationship between fruit and vegetable intake and reduction in breast cancer risk has been studied over three decades. To date, no protective effects have been firmly established.\textsuperscript{167}

Soybeans are the main source of isoflavones. The isoflavone compounds, including daidzein and genistein, can bind estrogen receptors but are far less potent
than estradiol. Soy may act like other antiestrogens (e.g., tamoxifen) by blocking the action of endogenous estrogens to reduce breast cancer risk. Thus, depending on the estradiol concentration, soy exhibits weak estrogenic or antiestrogenic activity. Many other mechanisms of action are proposed for isoflavones, including apoptosis and inhibition of angiogenesis. In 2011 the North American Menopause Society held a symposium to review the latest evidence-based science on the role of soy and found that soy foods generally appear to be breast protective and recommended moderate lifelong soy consumption. A recent large study of both American and Chinese women suggested that moderate intake of soy (≥10 mg of isoflavones/day) had a significant reduction in breast cancer recurrence as well as a nonsignificant trend toward reduced all-cause mortality. In addition, soy may optimize extrarenal 1,25-dihydroxycholecalciferol or vitamin D₃ (a prodifferentiating vitamin D metabolite), which could result in growth control and, conceivably, inhibition of tumor progression.

Iodine deficiency is hypothesized as contributing to the development of breast pathology and cancer. Iodine plays a significant role in breast health. Evidence reveals that iodine is an antioxidant and antiproliferative agent contributing to the integrity of normal mammary tissue. Seaweed, which is iodine-rich, is an important dietary item in Asian communities and has been associated with the low evidence of benign and breast cancer disease in Japanese women. Molecular iodine (I₂) supplementation exerts an inhibitory effect on the development and size of benign and cancerous tissue. Nutrition remains an important area of study.

**Obesity.**

Excess body fatness is known to increase cancer risk from cellular pathways that involve hormonal regulation, cellular proliferation, and immunity. Obesity, measured as body mass index (BMI), has been associated with a reduced risk of premenopausal breast cancer. Recently reported (from the Nurses' Health Study I and II), however, was that weight gain or weight loss since age 18 did not significantly decrease the risk of premenopausal breast cancer. Other data measuring adiposity using waist/hip ratio (WHR) have not found a reduced risk but rather no association (null) or an increased risk. Excess adiposity is positively associated with breast cancer recurrence and breast cancer specific mortality among both premenopausal and postmenopausal women.

In 2002 the International Agency for Research on Cancer (IARC) concluded that excess body weight (EBW) increased the risk of developing postmenopausal breast, colorectum, endometrium, kidney, and esophageal adenocarcinoma. The World
Cancer Research Fund (WCRF) used a more standardized approach to evaluate studies and concluded that evidence is convincing and that a probable association exists between body fat and postmenopausal breast cancer.\textsuperscript{179}

Despite strong links with endogenous estrogen levels, body fat has been consistently but \textit{weakly} related to increased postmenopausal risk.\textsuperscript{180} This observation (i.e., weakly) has been surprising because obese postmenopausal women have endogenous estrogen levels (estrone and estradiol) nearly double those of lean women.\textsuperscript{180,181} This weak association is possibly related to two factors. First, the premenopausal reduction in breast cancer risk related to being overweight possibly persists, opposing the adverse effect of elevated levels of estrogens after menopause. Thus, \textit{weight gain} should be more strongly related to postmenopausal breast cancer risk than attained weight. In two case-control studies and prospective studies, this was indeed true.\textsuperscript{182-185}

Obesity is associated with poor survival among women with breast cancer and the association of obesity with mortality from breast cancer appears to be stronger than its association with incidence.\textsuperscript{180,184} The increase in breast cancer risk with increasing BMI among postmenopausal women is most likely the result of increases in levels of estrogens by aromatase activity in adipose tissue.\textsuperscript{175} However, studies of hormones secreted by adipose tissue, \textit{leptin} and \textit{adiponectin}, may underlie the association between obesity and breast cancer risk. Increasing BMI and central fat deposition are associated with increased risk for breast cancer in prospective studies, and in vitro studies have shown leptin-stimulated breast carcinogenesis.\textsuperscript{186,187} From molecular mechanism studies, leptin enhances breast cancer cell proliferation by inhibiting cell death (pro-apoptosis) signaling pathways and by increasing in vitro sensitivity to estrogens.\textsuperscript{188} Leptin secreted by adipocytes and fibroblasts in the microenvironment act on breast cancer cells in a paracrine fashion.\textsuperscript{189} Adiponectin has been shown to exert antiproliferative effects in vitro on human breast cancer cells.\textsuperscript{188} Additionally, factors that may be related to recurrence of breast cancer in women with excess adiposity at the time of diagnosis include cytokines, IGF or immune function, or both.\textsuperscript{175}

\textbf{Environmental chemicals.}\n
Evidence linking chemicals to the cause of breast cancer is difficult to obtain. It is challenging because it is a life history of exposure that is important—not just a single chemical but complex mixtures of chemicals and their interaction with endogenous hormones. With industrial development, breast cancer rates increase. An estimated 100,000 synthetic chemicals are registered for use in the United States, another 1000 or more are added each year, and toxicologic screening for these
chemicals is minimal. In fact, toxicologic screening is only available for about 7% of these chemicals.\textsuperscript{190} For chemicals other than hormonal drugs, the IARC lists only ethylene oxide as a potential risk factor with limited evidence in humans.

Chemicals persist in the environment, accumulate in adipose tissue, interact with local adipose tissue physiology in an endocrine/paracrine manner, and remain in breast tissue for decades. Estrogen receptors are some of the main targets of endocrine-disrupting chemicals (EDCs), including the plasticizer bisphenol A and the flame retardant tetrachlorobisphenol A.\textsuperscript{191} Women who immigrate to the United States from Asian countries experience an enormous percent increase in risk within one generation. A generation later, the rate of their daughter's risk approaches that of women born in the United States. This change in risk suggests that in utero exposures affect subsequent disease risk. It is difficult to know whether these changes in risk emanate from nutritional content, pollutants, food additives, or other factors.

Xenoestrogens are synthetic chemicals that mimic the actions of estrogens and are found in many pesticides, fuels, plastics, detergents, and drugs. Because many factors correlated with breast cancer (e.g., early menarche, delayed pregnancy and breast-feeding, late menopause) are associated with lifetime exposure to estrogens, investigators reasoned that environmental chemicals affect estrogen metabolism and contribute to breast cancer. The most significant chemicals may be polychlorinated biphenyls (PCBs), such as dichlorodiphenyltrichloroethane (DDT), pesticides (dieldrin, aldrin, heptachlor, and others), bisphenol A (pervasive in polycarbonate plastics), tobacco smoke (active and passive), dioxins (vehicle exhaust, incineration, contaminated food supply), alkylphenols (detergents and cleaning products), metals, phthalates (makes plastics flexible, some cosmetics), parabens (antimicrobials), food additives (recombinant bovine somatotropin [\textit{rBST}] and zeranol to enhance growth in cattle and sheep), MHT (i.e., HRT), and others.

**Physical activity.**

Regular physical activity may reduce overall risk of breast cancer, especially in premenopausal or young postmenopausal women. Activity also may reduce the invasiveness of breast cancer.\textsuperscript{192} A sedentary lifestyle may increase cancer risk through several mechanism including increased insulin resistance, increased inflammation, and decreased immune function.\textsuperscript{193} Epidemiologic studies demonstrate that physical activity lowered the risk of breast cancer mortality in breast cancer survivors and improved their physiologic and immune functions.\textsuperscript{193}

**Inherited Cancer Syndromes, Genes, Epigenetic**
Considerations

The causes of breast cancer have been difficult to define because each woman has a different genetic profile, which is called genetic heterogeneity. Genetic heterogeneity is common among individuals but also at the level of the tumor itself, involving both genetic and epigenetic processes. These genetic factors interact with environmental factors. These facts are sobering and make the understanding of the genetic driving force behind tumor initiation, progression, and metastasis very complicated. However, recently, an experiment using a mouse model of breast tumor heterogeneity allowed investigators to probe the molecular basis of stable differences in cell (clonal) populations to contribute to various aspects of the cancer process, including the ability to form circulating tumor cells (CTCs) and ultimately metastases (see Pathogenesis).

A history of breast cancer in first-degree relatives (mother or sister) increases a woman's risk about two to three times. Risk increases even more if two first-degree relatives are involved, especially if the disease occurred before menopause and was bilateral. A small total proportion of breast cancers (5% to 10%, although the prevalence is significant) are the result of highly penetrant dominant genes (i.e., hereditary breast cancers). The most important of the dominant genes are the breast cancer susceptibility genes (BRCA1, BRCA2). BRCA1 (breast cancer 1 gene), located on chromosome 17, is a tumor-suppressor gene; therefore any mutation in the gene may inhibit or retard its suppressor function, leading to uncontrolled cell proliferation. BRCA2 (breast cancer 2 gene) is located on chromosome 13. A family history of both breast cancer and ovarian cancer increases the risk that an individual with breast cancer carries a BRCA1 mutation. Carriers of the BRCA1 gene also are at higher risk for ovarian cancer. The risks for breast or ovarian cancer, or both, however, are not equal in all mutation carriers and have been found to vary by several factors, including type of cancer, age at onset, and mutation position. This observed variation in penetrance has led to the hypothesis that other genetic and/or environmental factors modify cancer risk in mutation carriers. Men who develop breast cancer are more likely to have a BRCA2 mutation than a BRCA1 mutation (see Chapter 34). Options for those who have a positive test for BRCA1 or BRCA2 mutation include surveillance to find cancers early, prophylactic surgery (i.e., bilateral salpingo-oophorectomy), risk factor avoidance, promotion of breast-feeding, and chemoprevention. Several other genetic alterations can increase the risk of breast cancer.

Pathogenesis

Most breast cancers are adenocarcinomas and first arise from the ductal/lobular
epithelium as carcinoma in situ. **Carcinoma in situ** is a proliferation of epithelial cells that is confined to the ducts and lobules by the basement membrane. Tumors of the infiltrating (invasive) ductal type do not grow to a large size, but they metastasize early. This type accounts for 70% of breast cancers. Table 33-11 summarizes some types of breast cancer. Breast cancer is a heterogeneous—not a single—disease with diverse molecular, biologic, phenotypic, and pathologic changes. Heterogeneity is an important concept because the biologic attributes of a tumor as a whole are strongly influenced by its subpopulation of cells, as well as the tumor's surrounding neighborhood or microenvironment. Recent research suggests that breast cancer is heterogeneous from its initial preinvasive stages and within the same tumor.

The many genetic and epigenetic changes drive the sequential expansion of progressively more and more malignant cell populations. Breast tissue stem cells are thought to be the cell of origin for all breast cancers. Gene expression profiling studies have identified at least four major subtypes classified as luminal A, luminal

B, HER2+, and basal-like. Mounting evidence shows there are “subtypes within subtypes” and emerging evidence suggests that the biology of specific subtypes reflects contributions from the microenvironment. Many models of breast carcinogenesis have been suggested and three interrelated themes also have emerged and include (1) gene addiction, (2) phenotype plasticity, and (3) cancer stem cells.

Cancer gene addiction includes oncogene addiction, whereby these driver genes play key roles in breast cancer development and progression, and nononcogene addiction, whereby these genes may not initiate cancer but play roles in cancer development and progression. Examples of key driver genes include HER2 and MYC and examples of tumor-suppressor genes include TP53, BRCA1, and BRCA2. Once a founding tumor clone is established, genomic instability may assist through the establishment of other subclones and contribute to both tumor progression and therapy resistance. Phenotypic plasticity is exemplified by a distinctive phenotype called epithelial-to-mesenchymal transition (EMT) (see Chapter 10). EMT is involved in the generation of tissues and organs during embryogenesis, is essential for driving tissue plasticity during development, and is an unintentional process during cancer progression. The EMT-associated reprogramming is involved in many cancer cell characteristics, including suppression of cell death or apoptosis and senescence, is reactivated during wound healing, and is resistant to chemotherapy and radiation therapy. Remodeling or reprogramming of the breast during postpregnancy involution is important because it involves inflammatory and “wound healing-like” tissue reactions known as reactive stroma. These tissue reactions increase the risk for tumor invasion and may facilitate the transition of carcinoma in situ to invasive carcinoma. Activation of an EMT program during cancer development often requires signaling between cancer cells and neighboring stromal cells. In advanced primary carcinomas, cancer cells recruit a variety of cell types into the surrounding stroma, including fibroblasts, myofibroblasts, granulocytes, macrophages, mesenchymal stem cells, and lymphocytes (Figure 33-30). Overall, increasing evidence suggests that interactions of cancer cells with adjacent tumor-associated stromal cells induce malignant cell phenotypes (Figure 33-31).
Cells of the Tumor Microenvironment. A, Distinct cell types constitute most solid tumors including breast tumors. Both the main cellular tissue, called parenchyma, and the surrounding tissue, or stroma, of tumors contain cell types that enable tumor growth and progression. For example, the immune-inflammatory cells present in tumors can include both tumor-promoting and tumor-killing subclasses of cells. B, The microenvironment of tumors. Multiple stromal cell types create a succession of tumor microenvironments that change as tumors invade normal tissue, eventually seeding and colonizing distant tissues. The organization, numbers, and phenotypic characteristics of the stromal cell types and the extracellular matrix (hatched background) evolve during progression and enable primary, invasive, and metastatic growth. (Not shown are the premalignant stages.) (Data from Hanahan D, Weinberg R: Cell 144:646-674, 2011.)
Research is ongoing to define cancer stem cells in breast carcinogenesis including their origin and renewability properties. Studies have begun to identify the role of mammary stem cells (MaSCs) and to describe how they drive development of the gland and maintain homeostasis, the many cycles of proliferation and apoptosis needed to expand and maintain the breast during pregnancy, and return it
to a quiet (quiescent) state after involution. EMT generates multiple epithelial cell subsets with different states of stemness relative to more differentiated cells. The extracellular matrix (ECM) and the basement membrane (BM), in particular, are no longer just considered the “bricks and mortar” of a tissue but now a place where stem cells reside; and correct tissue architecture, together with the reservoir of growth factors, cytokines, and proteinases, is critical for mammary tissue to develop and function properly. Many of the biologic traits of high-grade malignancy—motility, invasiveness, and self-renewal—have been traced to subpopulations of stem cells within carcinomas. Hormones may act as accelerators as well as initiators, delay involution, and influence the susceptibility of the breast epithelium to environmental carcinogens because hormones control the differentiation of the mammary gland epithelium and, thereby, regulate the rate of stem cell division.

Two new concepts being investigated as important to metastases are tumor dormancy and vascular mimicry. Tumor dormancy has been noted in the care of people with cancer whereby microscopic and occult cancerous lesions can enter a latent or dormant phase in various stages of tumor progression. In fact, these microscopic and occult cancerous lesions are often found in healthy people. Ironically, in healthy people these are the slow-growing tumors (some called “pseudodisease”) detected by present screening methods that would not advance to routine clinical presentation over the individual’s lifetime. The current debates are over concern that individuals often undergo unnecessary treatment for a disease they were never destined to experience. Evidence exists that organ-specific molecular signaling can determine whether a metastatic lesion will expand or remain dormant. Significant to different signaling profiles that may determine this outcome are stress-activated kinases, transcription factors (such as p53), and cell cycle inhibitors. Thus, cell stress activated signaling may be increased, for example, with certain treatment modalities like surgery. Evidence has been accumulating that removal of a malignant tumor from a host is curative for many but—in some circumstances—is insufficient to prevent the cancer from reoccurring and can lead to rapid cancer recurrence. Immune cells in the ECM or stroma and the overall immune response has been recognized for its role in regulating tumor growth and is being investigated for its role in tumor dormancy.

Cancer metastases require that primary tumor cells evolve the ability to intravasate into the lymphatic system or vasculature, and extravasate into and colonize secondary sites. Investigators developed a mouse model of breast tumor heterogeneity and isolated a distinct clone of specialized cells that efficiently enter the vasculature and express two proteins, Serpine2 and Slpi, which were necessary and sufficient to program these cells for vascular mimicry. Vascular mimicry is a
blood supply pathway in tumors that is formed by tumor cells and is independent of endothelial cell–lined blood vessels—thus it mimics real blood vessels (Figure 33-32). This blood supply pathway facilitates perfusion of the primary tumors and correlates with poor clinical outcome. The increase in these blood supply pathways was associated with an increase in circulating tumor cells (CTCs) and a subsequent increase in lung metastases. Additionally, treatment with the anticoagulant warfarin increased the number of CTCs and lung metastases, suggesting that the anticoagulant function of Serpine2 and Slpi both maintains blood flow through the extravascular network and promotes intravasation. These remarkable findings identify Serpine2- and Slpi-driven vascular mimicry as a critical mechanism or driver of metastatic progression in cancer.195

Ductal and Lobular Carcinoma in Situ

Ductal carcinoma in situ (DCIS) is a heterogeneous group of proliferations limited to breast ducts and lobules without invasion of the basement membrane. About 84% of all in situ disease is DCIS; the remainder is mostly lobular carcinoma in situ (LCIS). DCIS occurs predominantly in females but can occur in males. Since 1980
the widespread adoption of screening mammography has led to an epidemic of diagnoses of DCIS.\textsuperscript{213} DCIS presents as microcalcifications (low grade) (Figure 33-33, \textit{B}) or rod-shaped branching (high grade) on a mammogram (Figure 33-33, \textit{A}).

![Figure 33-33](image)

Still controversial, DCIS does not appear to progress from sequential steps of low grade or risk types to higher grade or risk types during its route to cancer or cancer recurrence.\textsuperscript{199,214} This property, therefore, suggests a stable population.\textsuperscript{199} Because of these findings, some argue that the term is misleading and should be replaced by \textit{ductal intraepithelial neoplasia}, similar to the term used in prostate cancer, and that breast cancer statistics should exclude these DCIS cases with invasive breast cancer statistics.\textsuperscript{215} More than 60,000 women in the United States will be diagnosed with DCIS in 2015.\textsuperscript{216} Because of the large numbers of cases diagnosed yearly in the United States, the debate is whether mammography is causing the overdiagnosis of potential pseudodisease; for example, the Canadian National Breast Screening Study-2 of women aged 50 to 59 years found a fourfold increase in DCIS cases in those screened by clinical breast examination (CBE) plus mammography compared with those screened by CBE alone, with no difference in
breast cancer mortality.\textsuperscript{213,217} The difficulty for this clinical dilemma is that the natural history of DCIS is poorly understood because nearly all cases are treated. More directed research on DCIS with genetic expression profiling, best treatment to achieve disease regression, and studies of tumor characteristics and risk profiling is needed. An important, newer mission of the DCIS Discovery Enterprise at MD Anderson Cancer Center is to prevent invasive disease while also reducing unnecessary surgery or radiation.

Key to understanding the progression of breast cancer after treatment of DCIS depends on the characteristics of the lesion and on the delivered treatment. According to the National Cancer Institute (NCI), the best evidence indicates that most lesions of DCIS will not evolve to invasive cancer and those that do can be managed successfully, even after that transition.\textsuperscript{215} The detection and treatment of nonpalpable DCIS often represents overdiagnosis and overtreatment.\textsuperscript{215} Surprisingly, the overall death rate for women with DCIS is lower than that for women in the population as a whole.\textsuperscript{92,215} This favorable outcome may reflect the benign nature of the condition or the benefits of treatment, or is a marker for socioeconomic factors associated with longevity.\textsuperscript{92,215} Attempts to define low-risk DCIS cases that can be managed with fewer therapies are critical.\textsuperscript{215}

**Lobular carcinoma in situ (LCIS)** originates from the terminal duct lobular unit. Unlike DCIS, LCIS has a uniform appearance—the cells expand but do not distort involved spaces; thus the lobular structure is preserved. The cells grow in a noncohesive (discohesive) fashion usually because of a loss of the tumor-suppressive adhesion protein \textit{E-cadherin}.\textsuperscript{92} LCIS is found as an incidental lesion from a biopsy and not from mammography because it is not associated with calcifications or stromal reactions that produce mammographic densities. LCIS has an incidence of about 1% to 6% of all carcinomas and did not increase with mammographic screening.\textsuperscript{92} With biopsies in both breasts, LCIS is bilateral in 20% to 40% of cases, compared with 10% to 20% of cases of DCIS.\textsuperscript{92} The cells of atypical hyperplasia, LCIS, and invasive lobular carcinoma are structurally identical.\textsuperscript{92} Loss of cellular adhesion because of dysfunction of E-cadherin results in a rounded shape without attachment to adjacent cells, increasing the risk of invasion. E-cadherin functions as a tumor-suppressor protein and may be lost in neoplastic proliferations from various mechanisms, including mutation.

LCIS is a risk factor for invasive carcinoma and develops in 25% to 35% of women over a period of 20 to 30 years. Unlike DCIS, the risk is almost as high in the contralateral breast as in the ipsilateral breast. Treatments include close clinical follow-up and mammographic screening, tamoxifen, and bilateral prophylactic mastectomy.
Clinical manifestations

The majority of carcinomas of the breast occur in the upper outer quadrant, where most of the glandular tissue of the breast is located. The lymphatic spread of cancer to the opposite breast, to lymph nodes in the base of the neck, and to the abdominal cavity is caused by obstruction of the normal lymphatic pathways or destruction of lymphatic vessels by surgery or radiotherapy (see Figure 32-11). The less common inner quadrant tumors may spread to mediastinal nodes or Rotter nodes, which are located between the pectoral muscles (see Figure 32-11). Internal mammary chain nodes also are common sites of metastasis. Metastases from the vertebral veins can involve the vertebrae, pelvic bones, ribs, and skull. The lungs, kidneys, liver, adrenal glands, ovaries, and pituitary gland are also sites of metastasis.

The first sign of breast cancer is usually a painless lump. Lumps caused by breast tumors do not have any classic characteristics. Other presenting signs include palpable nodes in the axilla, retraction of tissue (dimpling) (Figure 33-34), or bone pain caused by metastasis to the vertebrae. Table 33-12 summarizes the clinical manifestations of breast cancers. Manifestations vary according to the type of tumor and stage of disease.

Evaluation and treatment
Clinical breast examination, mammography, ultrasound, thermography, MRI, biopsy, hormone receptor assays, and gene expression profiling are used in evaluating breast alterations and cancer.

Treatment is based on the extent or stage of the cancer. The extent of the tumor at the primary site, the presence and extent of lymph node metastases, and the presence of distant metastases are all evaluated to determine the stage of disease. Treatment includes surgery, radiation, chemotherapy, hormone therapy, and biologic therapy.

Quick Check 33-5

1. What types of fibrocystic breast changes increase the risk of breast cancer?

2. What is the role of hormones and growth factors in the pathophysiology of breast cancer?

3. Why are reproductive factors, such as early menarche and late menopause, important for the pathogenesis of breast cancer?

4. Why is complete breast involution important for reducing risk of breast cancer?

5. Discuss the role of the microenvironment or stromal tissue on breast cancer development.
Did You Understand?

Abnormalities of the Female Reproductive Tract

1. Normal development of the female reproductive tract requires absence of testosterone during embryonic and fetal life.

2. Alterations in the normal process include errors in cellular sensitivity to testosterone (androgen insensitivity) or failures of cell line migration resulting in changes in the structure of the reproductive organs.

3. Androgen insensitivity syndrome (AIS) is a disorder of hormone resistance characterized by a female phenotype in an individual with an XY karyotype or male genotype.

4. Other abnormalities of the uterus, cervix, and fallopian/uterine tubes have multifactorial origins, often the result of an interaction between genetic predisposition and environmental factors.

Alterations of Sexual Maturation

1. Sexual maturation, or puberty, is marked by the development of secondary sex characteristics, rapid growth and ultimately, the ability to reproduce. The normal range for the onset of puberty is now 8 to 13 years of age and can vary geographically.

2. Delayed puberty is the onset of sexual maturation after these ages; precocious puberty is the onset before these ages. Treatment depends on the cause.

Disorders of the Female Reproductive System

1. The female reproductive system can be altered by hormonal imbalances, infectious microorganisms, inflammation, structural abnormalities, and benign or malignant proliferative conditions.

2. Primary dysmenorrhea is painful menstruation not associated with pelvic disease. It results from excessive synthesis of prostaglandin F₂α. Secondary dysmenorrhea results from endometriosis, pelvic adhesions, inflammatory disease, uterine fibroids, or adenomyosis.
3. Primary amenorrhea is the continued absence of menarche and menstrual function by 13 years of age without the development of secondary sex characteristics or by 15 years of age if these changes have occurred.

4. Secondary amenorrhea is the absence of menstruation for a time equivalent to 3 or more cycles in women who have previously menstruated. Secondary amenorrhea is associated with many disorders and physiologic conditions.

5. Dysfunctional uterine bleeding (DUB) is heavy or irregular bleeding in the absence of organic disease.

6. Polycystic ovary syndrome (PCOS) is a condition in which excessive androgen production is triggered by inappropriate secretion of gonadotropins. This hormonal imbalance prevents ovulation and causes enlargement and cyst formation in the ovaries, excessive endometrial proliferation, and often hirsutism. Insulin resistance and hyperinsulinemia plays a key role in androgen excess.

7. Premenstrual syndrome (PMS) is the cyclic recurrence of physical, psychologic, or behavioral changes distressing enough to disrupt normal activities or interpersonal relationships. Emotional symptoms, particularly depression, anger, irritability, and fatigue, are reported as the most distressing symptoms; physical symptoms tend to be less problematic. Treatment is symptomatic and includes stress reduction, exercise, biofeedback, lifestyle changes, counseling, and medication.

8. Infection and inflammation of the female genitalia can result from microorganisms that are present in the environment often sexually transmitted or from overproliferation of microorganisms that normally populate the genital tract.

9. Pelvic inflammatory disease (PID) is an acute inflammatory process caused by infection. Many infections are sexually transmitted and microorganisms that comprise the vaginal flora are implicated. PID is a substantial health risk to women and untreated PID can lead to infertility.

10. Vaginitis is irritation or inflammation of the vagina, typically caused by infection. It is usually caused by sexually transmitted pathogens or Candida albicans, which causes candidiasis.

11. Cervicitis, which is infection of the cervix, can be acute (mucopurulent cervicitis) or chronic. Its most common cause is a sexually transmitted pathogen.
12. Vulvodynia vestibulitis (VV) is chronic vulvar pain lasting 3 months or longer. The cause of VV is unknown and theories include embryonic factors, chronic inflammation, genetic immune factors, nerve pathways, increased sensitivity to environmental factors, HPV, and hormonal changes.

13. Bartholinitis, also called Bartholin cyst, is an infection of the ducts that lead from the Bartholin glands to the surface of the vulva. Infection blocks the glands, preventing the outflow of glandular secretions.

14. The pelvic relaxation disorders—uterine displacement, uterine prolapse, cystocele, rectocele, and urethrocele—are caused by the relaxation of muscles and fascial supports, usually a result of advancing age or following childbirth or other trauma, and are more likely to occur in women with a familial or genetic predisposition.

15. Benign ovarian cysts develop from mature ovarian follicles that do not release their ova (follicular cysts) or from a corpus luteum that persists abnormally instead of degenerating (corpus luteum cyst). Cysts usually regress spontaneously.

16. Endometrial polyps consist of benign overgrowths of endometrial tissue and often cause abnormal bleeding in the premenopausal woman.

17. Leiomyomas, also called myomas or uterine fibroids, are benign tumors arising from the smooth muscle layer of the uterus, the myometrium.

18. Adenomyosis is the presence of endometrial glands and stroma within the uterine myometrium.

19. Endometriosis is the presence of functional endometrial tissue (i.e., tissue that responds to hormonal stimulation) at sites outside the uterus. Endometriosis causes an inflammatory reaction at the site of implantation and is a cause of infertility. Emerging is the relationship between endometriosis and ovarian cancer.

20. Cancers of the female genitalia involve the uterus (particularly the endometrium), the cervix, and the ovaries. Cancer of the vagina is rare.

21. Cervical cancer arises from the cervical epithelium and is triggered by human papillomavirus (HPV). The cellular transformational zone is called the squamocolumnar junction. The progressively serious neoplastic alterations are cervical intraepithelial neoplasia (cervical dysplasia), cervical carcinoma in situ,
and invasive cervical carcinoma. Cocarcinogens include immune responses, hormonal responses, and other environmental factors that determine regression or persistence of the HPV infection.

22. Primary cancer of the vagina is rare. Risk factors include 60 or older, DES, HPV type 16, HIV, genital warts, and the relationship of developing precancerous cell changes called vaginal intra-epithelial neoplasia (VAIN) is controversial.

23. Risk factors for vulvar cancer include HPV type 16 (cause), HIV, HPV-18 (probable cause), increasing age, previous cancer (untreated high-grade vulvar intraepithelial neoplasia [VIN]), cervical cancer survivor, previous cervical intraepithelial neoplasia, certain autoimmune conditions, organ transplant recipients (perhaps because of immunosuppression to clear HPV), and tobacco use (may relate to inability to clear HPV infection).

24. Carcinoma of the endometrium is the most common type of uterine cancer and most prevalent gynecologic malignancy. Primary risk factors for endometrial cancer include exposure to unopposed estrogen (e.g. estrogen-only hormone replacement therapy, tamoxifen, early menarche, late menopause, nulliparity, failure to ovulate), chronic hyperinsulinemia, hyperglycemia, body fatness and adult weight gain, chronic inflammation, lack of physical exercise.

25. Risk factors for ovarian cancer include advancing age, genetic factors, family history, overweight and obesity, height, reproductive/hormonal factors, HRT, endometriosis, diabetes, previous cancer, smoking, asbestos, talc-based powder, and ionizing radiation. Ovarian cancer causes more deaths than any other genital cancer in women.

26. The biology of ovarian cancer is changing and ovarian cancer is heterogeneous.

**Sexual Dysfunction**

1. Sexual dysfunction is the lack of satisfaction with sexual function resulting from pain or a deficiency in sexual desire, arousal, or orgasm/climax.

2. Sexual function and dysfunction result from a complex set of personal and biologic factors that interact with culture. Both organic and psychosocial disorders can be implicated in sexual dysfunction.
Impaired Fertility

1. Infertility, or the inability to conceive after 1 year of unprotected intercourse, affects approximately 15% of all couples. Fertility can be impaired by factors in the male, female, or both partners.

2. Female infertility results from dysfunction of the normal reproductive process: menses and ovulation, fallopian tube function (transport of the egg to the uterus and as a site of fertilization), ovarian dysfunction, and implantation of the fertilized egg into a receptive endometrium.

Disorders of the Female Breast

1. Most disorders of the breast are disorders of the mammary gland—that is, the female breast.

2. Galactorrhea, or inappropriate lactation, is the persistent secretion of a milky substance by the breasts of a woman who is not in the postpartum state or nursing an infant. Its most common cause is nonpuerperal hyperprolactinemia—a rise in serum prolactin levels.

3. Benign breast conditions are numerous and involve both ducts and lobules. Benign epithelial lesions can be broadly classified according to their future risk of developing breast cancer as (1) nonproliferative breast lesions, (2) proliferative breast disease, and (3) atypical (atypia) hyperplasia.

4. Nonproliferative lesions include simple breast cysts, papillary apocrine change, and mild hyperplasia of the usual type.

5. Proliferative breast lesions without atypia are diverse and include usual ductal hyperplasia, intraductal papillomas, sclerosing adenosis, radial scar, and simple fibroadenoma.

6. Proliferative breast lesions with atypia include atypical ductal hyperplasia (ADH) and atypical lobular hyperplasia (ALH).

7. Ductal carcinoma in situ (DCIS) refers to a heterogeneous group of proliferations limited to breast ducts and lobules without invasion of the basement membrane, Lobular carcinoma in situ (LCIS) originates from the duct lobular unit.
8. Breast cancer is the most common form of cancer in women and second to lung cancer as the most common cause of cancer death. However, controversial is the inclusion of DCIS with invasive breast cancer statistics. Breast cancer is a heterogeneous disease with diverse molecular, phenotypic, and pathologic changes.

9. The major risk factors for breast cancer are reproductive factors, such as nulliparity; hormonal factors and growth factors, such as excessive estradiol and IGF-1; familial factors, such as a family history of breast cancer; and environmental factors, such as ionizing radiation. Two factors emerging as important are delayed involution of the mammary gland and breast density. Physical activity and lack of postmenopausal weight gain may be risk-reducing factors.

10. A dominating movement in the field of cancer research is that epithelial function depends on the entire tissue including the stroma or microenvironment. Breast cancer is now known as a tissue-based disease with a possible abnormal, aberrant wound healing and inflammatory stromal (reactive stroma) component.

11. Models of breast carcinogenesis include three interrelated themes: gene addiction, phenotype plasticity, and cancer stem cells. The exact molecular events leading to breast cancer invasion are complex and not completely understood. These events involve genetic and epigenetic alterations and cancer cell and stromal interactions. New concepts for breast cancer metastases include tumor dormancy and vascular mimicry.

12. Most breast cancers arise from the ductal epithelium and then may metastasize to the lymphatics, opposite breast, abdominal cavity, lungs, bones, kidneys, liver, adrenal glands, ovaries, and pituitary glands.

13. The first clinical manifestation of breast cancer is usually a small, painless lump in the breast. Other manifestations include palpable lymph nodes in the axilla, dimpling of the skin, nipple and skin retraction, nipple discharge, ulcerations, reddened skin, and bone pain associated with bony metastases.

  Carcinoma, 877
Sexually Transmitted Diseases, 877
Alterations of the reproductive system span a wide range of concerns from delayed sexual development and suboptimal sexual performance to structural and functional abnormalities. Many common male reproductive disorders carry potentially serious physiologic or psychologic consequences. For example, sexual or reproductive dysfunction, such as impotence or infertility, can dramatically affect self-concept, relationships, and overall quality of life. Conversely, organic and psychosocial problems, such as alcoholism, depression, situational stressors, chronic illness, and medications, can affect sexual performance and may be risk factors for the development of some types of reproductive tract cancers. Aside from skin cancer, prostate cancer is the second leading cause of cancer deaths and is the most frequently diagnosed cancer in men. Incidence rates for prostate cancer changed substantially between the mid-1980s and mid-1990s and have since fluctuated widely from year to year, in large part reflecting changes in prostate cancer screening with the prostate-specific antigen (PSA) blood test.\(^1\) Diagnosis and treatment of male reproductive system disorders are, like female reproductive system disorders, often complicated by the stigma and symbolism associated with the reproductive organs and emotion-laden beliefs and behaviors related to reproductive health. Treatment or diagnosis for any problem may be delayed because of embarrassment, guilt, fear, or denial.
Alterations of Sexual Maturation

The process of sexual maturation, or puberty, is marked by the development of secondary sex characteristics, rapid growth, and, ultimately, the ability to reproduce. A variety of congenital and endocrine disorders can disrupt the timing of puberty. Puberty that occurs too late (delayed puberty) or too early (precocious puberty) is caused by the inappropriate onset of sex hormone production. While the average age of pubertal onset appears to be decreasing for girls, the age of pubertal onset has remained essentially unchanged for boys.

Delayed or Absent Puberty

About 3% of children living in North America experience delayed development of secondary sex characteristics. Normally, boys tend to mature later than girls, around 14 to 14.5 years of age. In boys, the first sign of maturity is enlargement of testes and thinning of the scrotal skin. In delayed puberty, these secondary sex characteristics develop later.

In about 95% of cases, delayed puberty is a normal physiologic event. Hormonal levels are normal, the hypothalamic-pituitary-gonadal axis is intact, and maturation is slowly occurring. Treatment is seldom needed unless the delayed puberty is causing psychosocial problems.

The other 5% of cases are caused by the disruption of the hypothalamic-pituitary-gonadal axis or by the outcomes of a systemic disease. Treatment depends on the cause (Box 34-1), and referral to a pediatric endocrinologist is necessary.

---

**Box 34-1**

**Causes of Delayed Puberty**

**Hypergonadotropic Hypogonadism (Low Testosterone, Increased Follicle-Stimulating Hormone [FSH] and Luteinizing Hormone [LH])**

1. Gonadal dysgenesis, most commonly Turner syndrome (45,X/46,XX; structural X or Y abnormalities, or mosaicism)

2. Klinefelter syndrome (47,XXY)

3. Bilateral gonadal failure
a. Traumatic or infectious

b. Postsurgical, postirradiation, or postchemotherapy

c. Autoimmune

d. Idiopathic empty-scrotum or vanishing-testes syndrome (congenital anorchia)

**Hypogonadotropic Hypogonadism (Low Testosterone, Decreased LH, Depressed FSH)**

1. Reversible

   a. Physiologic delay

   b. Weight loss/anorexia

   c. Strenuous exercise

   d. Severe obesity

   e. Illegal drug use, especially marijuana

   f. Primary hypothyroidism

   g. Congenital adrenal hyperplasia

   h. Cushing syndrome

   i. Prolactinomas
2. Irreversible

a. Gonadotropin-releasing hormone (GnRH) deficiency (Kallmann syndrome) or idiopathic hypogonadotropic hypogonadism (IHH)

b. Hypopituitarism

c. Congenital central nervous system (CNS) defects

d. Other pituitary adenomas

e. Craniopharyngioma

f. Malignant pituitary tumors

**Precocious Puberty**

*Precocious puberty* is a rare event, affecting fewer than 1 in 50,000 boys. Precocious puberty for boys of all ethnic/racial groups is defined as sexual maturation occurring before age 9. A recent study observed the mean ages of beginning male genital and pubic hair growth and early testicular volumes are leaning toward younger ages than earlier studies have suggested, although this seems to be dependent on race/ethnicity. Precocious puberty may be caused by many conditions (*Box 34-2*), including lethal central nervous system tumors. All cases of precocious puberty require thorough evaluation.

**Box 34-2**

**Primary Forms of Precocious Puberty**

**Complete Precocious Puberty**

Premature development of appropriate characteristics for the child's gender
Hypothalamic-pituitary-ovarian axis functioning normally but prematurely
In about 10% of cases, lethal central nervous system tumor may be the cause

**Partial Precocious Puberty**

Partial development of appropriate secondary sex characteristics

Premature adrenarche (growth of axillary and pubic hair) tends to occur between 5 and 8 years of age

Can progress to complete precocious puberty; may be caused by estrogen-secreting neoplasms or may be a variant of normal pubertal development

**Mixed Precocious Puberty**

Causes the child to develop some secondary sex characteristics of the opposite gender

Common causes: adrenal hyperplasia or androgen-secreting tumors

All forms of precocious puberty are treated by identifying and removing the underlying cause or administering appropriate hormones. In many cases, precocious puberty can be reversed. However, complete precocious puberty (development consistent with the gender of the individual) is difficult to treat and can cause long bones to stop growing before the child has reached normal height.

Quick Check 34-1

1. Why does puberty occur too late or too early in some individuals?
2. Why do all forms of precocious puberty require evaluation?
Disorders of the Male Reproductive System

Disorders of the Urethra

Urethritis and urethral strictures are common disorders of the male urethra. Urethral carcinoma, an extremely rare form of cancer, can occur in men older than 60 years.

**Urethritis**

Urethritis is an inflammatory process that is usually, but not always, caused by a sexually transmitted microorganism. Infectious urethritis caused by *Neisseria gonorrhoeae* is often called gonococcal urethritis (GU); urethritis caused by other microorganisms is called nongonococcal urethritis (NGU). Nonsexual origins of urethritis include inflammation or infection as a result of urologic procedures, insertion of foreign bodies into the urethra, anatomic abnormalities, or trauma.

Noninfectious urethritis is rare and is associated with the ingestion of wood or ethyl alcohol or turpentine. It is also seen with reactive arthritis.\(^7\)

Symptoms of urethritis include urethral tingling or itching or a burning sensation, and frequency and urgency with urination. The individual may note a purulent or clear mucous-like discharge from the urethra. Nucleic acid detection amplification tests allow early detection of *N. gonorrhoeae* and *Chlamydia trachomatis* in urine studies.\(^8\) Treatment consists of appropriate antibiotic therapy for infectious urethritis and avoidance of future exposure or mechanical irritation.

**Urethral Strictures**

A urethral stricture is a narrowing of the urethra caused by scarring. The scars may be congenital but can be present at any age and have a wide range of etiologic factors, including untreated urethral infection, trauma, and urologic instrumentation. Infections also can occur from long-term use of indwelling catheters. Prostatitis and infection secondary to urinary stasis are common complications. Severe and prolonged obstruction can result in hydronephrosis and renal failure.

The clinical manifestations of urethral stricture are caused by bladder outlet obstruction. Urethral stricture often manifests itself as lower urinary tract symptoms or urinary tract infections with significant impairment in the quality of life. The primary symptom is diminished force and caliber of the urinary system; other symptoms include urinary frequency and hesitancy, mild dysuria, double urinary stream or spraying, and dribbling after voiding. Urethral stricture is diagnosed on the basis of history, physical examination, flow rates, and cystoscopy. Treatment is
usually surgical and may involve urethral dilation, urethrotomy, or a variety of open surgical techniques. The choice of surgical intervention depends on the age of the individual and the severity of the problem.

**Disorders of the Penis**

**Phimosis and Paraphimosis**

Phimosis and paraphimosis are both disorders in which the foreskin (prepuce) is “too tight” to move easily over the glans penis. **Phimosis** is a condition in which the foreskin cannot be retracted back over the glans, whereas **paraphimosis** is the opposite: the foreskin is retracted and cannot be moved forward (reduced) to cover the glans (Figure 34-1). Both conditions can cause penile pathologic conditions.
FIGURE 34-1  Phimosis and Paraphimosis. A, Phimosis: the foreskin has a narrow opening that is not large enough to permit retraction over the glans. B, Lesions on the prepuce secondary to infection cause swelling, and retraction of foreskin may be impossible. Circumcision is usually required. C, Paraphimosis: the foreskin is retracted over the glans but cannot be reduced to its normal position. Here it has formed a constricting band around the penis. D, Ulcer on the retracted prepuce with edema. (A and C from Monahan FD et al: Phipps’ medical-surgical nursing: health and illness perspectives, ed 8, St Louis, 2007, Mosby; B from Taylor PK: Diagnostic picture tests in sexually transmitted diseases, St Louis, 1995, Mosby; D from Morse SA et al: Atlas of sexually transmitted diseases and AIDS, ed 4, London, 2011, Saunders.)

The inability to retract the foreskin is normal in infancy and is caused by congenital adhesions. During the first 3 years of life, congenital adhesions (between the foreskin and glans) separate naturally with penile erections and are not an indication for circumcision. Phimosis can occur at any age and is most commonly caused by poor hygiene and chronic infection. It rarely occurs with normal
foreskin.

Reasons for seeking treatment include edema, erythema, and tenderness of the prepuce and purulent discharge; inability to retract the foreskin is a less common complaint. Circumcision, if needed, is performed after infection has been eradicated. Complications of phimosis include inflammation of the glans (balanitis) or prepuce (posthitis) and paraphimosis. There is a higher incidence of penile carcinoma in uncircumcised males, but chronic infection and poor hygiene are usually the underlying factors in such cases. Approximately 40% to 63% of invasive penile carcinomas are attributable to human papillomavirus (HPV).\(^\text{10,11}\)

Paraphimosis, in which the foreskin is retracted, can constrict the penis, causing edema of the glans. If the foreskin cannot be reduced manually, surgery must be performed to prevent necrosis of the glans caused by constricted blood vessels. Severe paraphimosis is a surgical emergency.

**Peyronie Disease**

Peyronie disease ("bent nail syndrome") is a fibrotic condition that causes lateral curvature of the penis during erection (Figure 34-2). Peyronie disease develops slowly and is characterized by tough fibrous thickening of the fascia in the erectile tissue of the corpora cavernosa. A dense, fibrous plaque is usually palpable on the dorsum of the penile shaft. The problem usually affects middle-aged men and is associated with painful erection, painful intercourse (for both partners), and poor erection distal to the involved area.\(^\text{12}\) In some cases, impotence or unsatisfactory penetration occurs. When the penis is flaccid, there is no pain.
A local vasculitis-like inflammatory reaction occurs, and decreased tissue oxygenation results in fibrosis and calcification. The exact cause is unknown. Peyronie disease is associated with Dupuytren contracture (a flexion deformity of the fingers or toes caused by shortening or fibrosis of the palmar or plantar fascia), diabetes, tendency to develop keloids, and, in rare cases, use of beta-blocker medications.  

There is no definitive treatment for Peyronie disease; however, treatment can include pharmacologic agents and surgery. Spontaneous remissions occur in as many as 50% of individuals. However, men suffering with Peyronie disease and who have significant penile deformity precluding successful coitus should be appraised for surgical correction.  

**Priapism**

**Priapism** is an uncommon condition of prolonged penile erection. It is usually painful and is not associated with sexual arousal (Figure 34-3). Priapism is idiopathic in 60% of cases; the remaining 40% of cases can be associated with spinal cord trauma, sickle cell disease, leukemia, pelvic tumors, infections, or penile trauma.
Priapism must be considered a urologic emergency. Treatment within hours is effective and prevents impotence. Conservative approaches include iced saline enemas, ketamine administration, and spinal anesthesia. Needle aspiration of blood from the corpus through the dorsal glans is often effective and is followed by catheterization and pressure dressings to maintain decompression. More aggressive surgical treatments include the creation of vascular shunts to maintain blood flow. Erectile dysfunction results in up to 50% of prolonged cases.

**Balanitis**

Balanitis is an inflammation of the glans penis (Figure 34-4) and usually occurs in conjunction with posthitis, an inflammation of the prepuce. (Inflammation of the glans and the prepuce is called balanoposthitis.) It is associated with poor hygiene and phimosis. The accumulation under the foreskin of glandular secretions (smegma), sloughed epithelial cells, and *Mycobacterium smegmatis* can irritate the glans directly or lead to infection. Skin disorders (e.g., psoriasis, lichen planus, eczema) and candidiasis must be differentiated from inflammation resulting from poor hygienic practices. Balanitis is most commonly seen in men with poorly controlled diabetes mellitus and candidiasis. The infection is treated with antimicrobials. After the inflammation has subsided, circumcision can be considered to prevent recurrences.
Tumors of the Penis

Tumors of the penis are not common. The most frequent are the benign epithelial tumor condyloma acuminatum and penile carcinomas.

Condyloma acuminatum is a benign tumor caused by human papillomavirus (HPV), a sexually transmitted infection. HPV type 6 and, less often, type 11 are the most frequent types and can cause a common wart and moist surface of the external genitalia. Giant condylomata (Buschke-Löwenstein) affect older men and may be 5 to 10 cm in size. Atypia may be evident in longstanding, giant condylomata and assessment of other HPV subtypes may be indicated to distinguish from a noninvasive warty carcinoma.

Penile Cancer

Carcinoma of the penis is rare in the United States, constituting about 1 in 100,000 men. It does account, however, for about 10% of cancers in African and South American men. It can affect men 40 to 70 years of age, with two thirds of men diagnosed at 65 years of age and older. In the United States, about four out of five cases of the disease are diagnosed in men more than 55 years of age. Although the exact cause is unknown, risk factors include HPV infection, smoking, low socioeconomic status, poor personal hygiene, and psoriasis (possibly autoimmune diseases linked to the lack of clearance of HPV). Circumcision at birth decreases the
risk of penile cancer and penile cancer is more common in men with phimosis and those with acquired immunodeficiency syndrome (AIDS).\textsuperscript{15}

Squamous cell carcinoma accounts for 95% of invasive penile cancers. Other premalignant lesions, or in situ forms of epidermal carcinoma, that occur on the penis include leukoplakia (white plaque), Paget disease (red, inflamed areas), erythroplasia of Queyrat (raised red areas), and Buschke-Löwenstein patches (large venous areas). Recently, \textit{penile intraepithelial neoplasia} (PeIN, atypical cells) has been redesignated into two subcategories: differentiated PeIN and undifferentiated PeIN, including warty basaloid and mixed warty-basaloid subtypes.\textsuperscript{13} HPV6 and HPV11 associated with genital warts (condylomata acuminata) have low cancer risks.\textsuperscript{16} At times, the penis might be the site of metastatic spread of solid tumors from the bladder, prostate, rectum, or kidney. Early squamous cell carcinoma and premalignant epidermal lesions are easily treated, but delays in seeking treatment are attributed to denial, embarrassment, failure to detect lesions under a phimotic foreskin, fear, guilt, and ignorance.

Squamous cell carcinoma usually begins as a small, flat, ulcerative or papillary lesion on the glans or foreskin that grows to involve the entire penile shaft. Extensive lesions are associated with metastases and a poor prognosis.\textsuperscript{17,18} The regional femoral and iliac lymph nodes are common metastatic sites; the urethra and bladder are rarely involved. Weight loss, fatigue, and malaise accompany chronic suppurative lesions.

The specific diagnosis is made by biopsy after examination to document the location, size, and fixation of the lesion. After a positive biopsy, the extent of cancer spread is determined by imaging studies. Distant metastases are uncommon. Stages of carcinoma of the penis are presented in \textbf{Box 34-3}.

\section*{Box 34-3}

\textbf{Staging for Penile Cancer}

\textbf{Stage 0: Tis or Ta, N0, M0}

The cancer has not grown into tissue below the top layers of skin and has not spread to lymph nodes or distant sites.

\textbf{Stage I: T1a, N0, M0}

The cancer has grown into tissue just below the superficial layer of skin but has not grown into blood or lymph vessels. It is a grade 1 or 2. It has not spread to lymph nodes or distant sites.
Stage II: Any of the Following:

**T1b, N0, M0**
The cancer has grown into tissue just below the superficial layer of skin and is high grade or has grown into blood or lymph vessels. It has not spread to lymph nodes or distant sites.

Or

**T2, N0, M0**
The cancer has grown into one of the internal chambers of the penis (the corpus spongiosum or corpora cavernosa). The cancer has not spread to lymph nodes or distant sites.

Or

**T3, N0, M0**
The cancer has grown into the urethra. It has not spread to lymph nodes or distant sites.

Stage IIIA: T1 to T3, N1, M0
The cancer has grown into tissue below the superficial layer of skin (T1). It also may have grown into the corpus spongiosum, the corpora cavernosa, or the urethra (T2 or T3). The cancer has spread to a single groin lymph node (N1). It has not spread to distant sites.

Stage IIIB: T1 to T3, N2, M0
The cancer has grown into the tissues of the penis and may have grown into the corpus spongiosum, the corpora cavernosa, or the urethra (T1 to T3). It has spread to two or more groin lymph nodes. It has not spread to distant sites.

Stage IV: Any of the Following:

**T4, any N, M0**
The cancer has grown into the prostate or other nearby structures. It may or may not have spread to groin lymph nodes. It has not spread to distant sites.

Or

**Any T, N3, M0**
The cancer has spread to lymph nodes in the pelvis or spread in the groin lymph nodes and grown through the lymph nodes' outer covering and into surrounding tissue. The cancer has not spread to distant sites.

Or
Any T, any N, M1
The cancer has spread to distant sites.

\[ T, \text{ Primary tumor size}; \ N, \text{ regional lymph nodes}; \ M, \text{ distant metastasis}. \]

Penile carcinoma is managed primarily with surgery. Newer, innovative surgical techniques can preserve as much penile tissue as possible without compromising cancer control. A multimodal approach with chemotherapy is under study.\textsuperscript{19,20} Palliative treatment with radiation or chemotherapy may be used when the disease is inoperable and bulky inguinal metastases have occurred. Options for individuals with carcinoma in situ include local excision, radiation, laser surgery, cryosurgery, chemosurgery, or chemotherapy with topical (5%) 5-fluorouracil.\textsuperscript{17}

\[ \text{Quick Check 34-2} \]

1. Why are priapism and severe paraphimosis considered urologic emergencies?
2. What are the risk factors for cancer of the penis?

\[ \text{Disorders of the Scrotum, Testis, and Epididymis} \]

\[ \text{Disorders of the Scrotum} \]
Men may seek treatment for painful or painless scrotal masses. Masses may be serious (cancer or torsion) or benign (hydrocele or cyst), and may require immediate surgical intervention or allow for careful observation. Varicocele, hydrocele, and spermatocele are common intrascrotal disorders. A varicocele is an abnormal dilation of the testicular vein and the pampiniform plexus within the scrotum, and is classically described as a “bag of worms” (Figure 34-5). Varicoceles are one of the most commonly identified scrotal abnormalities and abnormal findings among infertile men. Advancements in diagnostic techniques indicate that the incidence of varicoceles is significantly greater than previously reported.\textsuperscript{21} Most (90%) occur on the left side because of discrepancies in venous drainage and may be painful or tender. Varicocele occurs in 10% to 15% of males and is seen most often after puberty.\textsuperscript{22} Because most develop in adolescence, physiologic changes in testosterone level may contribute to increasing blood flow to the testicle, causing venous dilation.\textsuperscript{23} Unilateral right-sided varicoceles are rare and result from compression or obstruction of the inferior vena cava by a tumor or thrombus. Varicoceles may be less likely to be diagnosed among obese men.\textsuperscript{24}
The cause of varicocele is poorly understood. Blood pools in the veins rather than flowing into the venous system. Varicocele decreases blood flow through the testis, interfering with spermatogenesis and causing infertility. Varicoceles can alter testosterone and follicle-stimulating hormone levels, cause oxidative stress, decrease sperm count, and affect sperm quality. Varicocele surgical repair is generally done when the male has a grade II or III varicocele and an abnormal semen analysis and the female has no known cause of infertility. If varicocele is mild and fertility is not an issue, a scrotal support is usually sufficient to relieve symptoms of scrotal heaviness or “dragging.” Color Doppler ultrasonography is used to confirm diagnosis.

A hydrocele is a collection of fluid between the layers of the tunica vaginalis (Figure 34-6). It is the most common cause of scrotal swelling. Hydroceles occur in 6% of male newborns and are congenital malformations that often resolve spontaneously in the first year of life. In North America, common infectious causes include epididymitis and viruses. Worldwide, however, filariasis is a major cause especially with recent travel to tropical countries. Other causes include trauma, torsion of the testicle or testicular appendage, and recent scrotal surgery. A
man presenting with a hydrocele in his third or fourth decade needs careful
evaluation for testicular cancer.27

Hydroceles vary in size and most are asymptomatic. The most important feature
on physical examination is a tense, smooth, scrotal mass that easily transluminates.
Translumination, or holding a light behind the scrotum, can help distinguish a
hydrocele from a hernia or a solid mass. Treatment includes watchful waiting in
infants and for those older than 1 year; 75% of hydroceles resolve within 6
months.26,27 Symptomatic or communicating hydroceles need definitive treatment.
Treatment includes surgical resection, aspiration, and sclerotherapy (injection of a
sclerosing agent into the scrotal sac [cystic dilation]) to excise the tunica vaginalis.21

Spermatoceles (epididymal cysts) are benign cystic collections of fluid of the
epididymis located between the head of the epididymis and the testis. Spermatoceles
are filled with a milky fluid containing sperm and are usually painless (Figure 34-
7). Spermatoceles that cause significant pain or discomfort are excised. Both
spermatoceles and epididymal cysts present clinically as discrete, firm, freely
mobile masses distinct from the testis that may be transilluminated. Usually, however, spermatoceles are asymptomatic or produce mild discomfort that is relieved by scrotal support. Neither hydroceles nor spermatoceles are associated with infertility.

![FIGURE 34-7 Spermatocele. Retention cyst of the head of the epididymis or of an aberrant tubule or tubules of the rete testis. The spermatocele lies outside the tunica vaginalis; therefore, on palpation it can be readily distinguished and separated from the testis. (From Lloyd-Davies RW et al: Color atlas of urology, ed 2, London, 1994, Wolfe Medical.)](image)

**Cryptorchidism and Ectopy**

**Cryptorchidism** is a group of abnormalities in which the testis fails to descend completely, whereas an **ectopic testis** has strayed from the normal pathway of descent. Ectopy may be caused by an abnormal connection at the distal end of the gubernaculum testis that leads the gonad to an abnormal position, usually at the superficial inguinal site. In cryptorchidism, the descent of one or both testes is arrested with unilateral arrest occurring more often than bilateral arrest. The testes may remain in the abdomen, or testicular descent may be arrested in the inguinal canal or the puboscrotal junction. Cryptorchidism is a common congenital anomaly, with an incidence of approximately 3% in full-term infants. However, this rate increases significantly with low birth weight; for instance, the rate of cryptorchidism at 3 months has been found to be 7.7% for infants with birth weights less than 2000 g, 2.5% for birth weights of 2000 to 2500 g, and 1.41% for birth weights of 2500 g or more.\(^{28,29}\) The incidence of cryptorchidism in adults is 0.7% to 0.8%.\(^{25}\) Cryptorchidism is commonly associated with vasal or epididymal abnormalities. These congenital anomalies affect about 33% to 66% of newborns with cryptorchidism. Other structural anomalies include posterior urethral valves
(less than 5%), upper genital tract abnormalities (less than 5%), and hypospadias. The presence of both hypospadias and cryptorchidism raises the suspicion of mixed gonadal dysgenesis (intersex infant). It has been hypothesized that cryptorchidism may result from an absence or abnormality of the gubernaculum—a cordlike structure that extends from the lower pole of the testis to the scrotum; a congenital gonadal or dysgenetic defect that makes the testis insensitive to gonadotropins (a likely explanation for unilateral cryptorchidism); or lack of maternal gonadotropins (a likely explanation for bilateral cryptorchidism of prematurity).

Mechanical possibilities include a short spermatic cord, fibrous bands or adhesions in the normal path of the testes, or a narrowed inguinal canal. Chromosomal studies do not support a genetic component. Physiologic cryptorchidism, also called retractile or migratory testis, is an involuntary retraction of the testes out of the scrotum that occurs with excitement, physical activity, or exposure to cold and is caused by the small mass of prepubertal testis and the strength of the cremaster muscle. This is a common phenomenon that is self-limiting (descent occurs at puberty).

Physical examination discloses the absence of one or both testes in the scrotum and an atrophic scrotum on the affected side. If the undescended testis is in a vulnerable position, over the pubic bone for example, an individual may complain of severe pain secondary to trauma. The adult male with bilateral cryptorchidism may be infertile.

Testicular cancer also is a well-established complication of cryptorchidism. In men with a history of unilateral cryptorchidism, neoplasms also develop more commonly in the contralateral testis. This finding suggests cryptorchidism affects the testes and is a process more significant than simply the position of the testis in childhood. The risk of testicular cancer is 35 to 50 times greater for men with cryptorchidism or a history of cryptorchidism than for the general male population. Because definite histologic change occurs in the cryptorchid testis by 1 year of age, surgical correction is recommended around that age. Treatment often begins with administration of gonadotropin-releasing hormone (GnRH) or human chorionic gonadotropin (hCG), hormones that may initiate descent and make surgery unnecessary. GnRH is available as a nasal spray in Europe and may enhance germ cell counts even when the testis does not descend. If hormonal therapy is not successful (success rates range from 6% to 75%), the testis is located and moved surgically (orchiopexy) in young children or removed (orchiectomy) in adults and children more than 10 years of age. The testis that is properly placed in the scrotum provides adequate hormonal function and gives the scrotum a normal appearance. A successful operation does not ensure fertility if the testis is congenitally defective. Approximately 20% of males with unilateral undescended
testis remain infertile even though orchiopexy is performed by age 1 year; most individuals with treated or untreated bilateral testicular maldescent have poor fertility.

**Torsion of the Testis and Testicular Appendages**

In **torsion of the testis**, the testis rotates on its vascular pedicle, interrupting its blood supply (Figure 34-8). Torsion of the testis is one of several conditions that cause an acute scrotum, which is testicular pain and swelling. **Testicular appendages** include the appendix testis (a remnant of the müllerian duct) and the appendix epididymis (a remnant of the wolffian duct). Torsion of the appendages can also cause acute scrotum and be confused with testicular torsion, a urologic emergency.

![Torsion of the Testis](image)

**FIGURE 34-8**  Torsion of the Testis. The testes appear dark red and partially necrotic as a result of hemorrhagic infarction. (From Damjanov I, Linder J, editors: Anderson’s pathology, ed 10, St Louis, 1996, Mosby)

Torsion of the testis can occur at any age but is most common among neonates and adolescents, particularly at puberty. Onset may be spontaneous or follow physical exertion or trauma. Torsion twists the arteries and veins in the spermatic cord, reducing or stopping circulation to the testis. Vascular engorgement and ischemia develop, causing scrotal swelling and pain not relieved by rest or scrotal support. Diagnostic testing includes urinalysis (to determine infection) and color Doppler ultrasonography. Torsion of the testis is a surgical emergency. If it cannot
be reduced manually (scrotal elevation), surgery must be performed within 6 hours after the onset of symptoms to preserve normal testicular function.

**Orchitis**

**Orchitis** is an acute inflammation of the testes (Figure 34-9) and is uncommon except as a complication of systemic infection or as an extension of an associated epididymitis\(^\text{31}\) (see p. 862). Infectious organisms may reach the testes through the blood or the lymphatics or, most commonly, by ascent through the urethra, vas deferens, and epididymis. Most cases of orchitis are actually cases of epididymo-orchitis (inflammation of both the epididymis and testis). Occasionally in middle-aged men, a nonspecific, apparently noninfectious, inflammatory process (called **granulomatous orchitis**) can occur, presumably a granulomatous response to spermatozoa.

![Depiction of Orchitis](From Ball JW et al: Seidel’s guide to physical examination, ed 8, St Louis, 2015, Mosby)

Mumps is the most common infectious cause of orchitis and usually affects postpubertal males. The onset is sudden, occurring 3 to 4 days after the onset of parotitis. Signs and symptoms include high fever, reaching 40° C (104° F), marked prostration, bilateral or unilateral erythema, edema and tenderness of the scrotum, and leukocytosis. An acute hydrocele may develop. Urinary signs and symptoms, which accompany epididymitis, are absent. Atrophy with irreversible damage to
spermatogenesis may result in 30% of affected testes. Bilateral orchitis does not affect hormonal function but may cause permanent sterility.

Treatment is supportive and includes bed rest, scrotal support, elevation of the scrotum, hot or cold compresses, and analgesic agents for relief of pain. If an acute hydrocele develops, it is aspirated. Testicular abscess usually requires orchiectomy (removal of the testis). Appropriate antimicrobial drugs should be used for bacterial orchitis, and corticosteroids are indicated in proven cases of nonspecific granulomatous orchitis.

Cancer of the Testis

Testicular cancer is a highly treatable, usually curable cancer that most often develops in young and middle-aged men. For men with seminoma (all stages combined), the cure rate exceeds 90%. For men with low-stage seminoma or nonseminoma, the cure rate approaches 100%. Overall, testicular cancers are uncommon, accounting for approximately 1% of all male cancers; yet they are the most common solid tumor of young adult men. Cancer of the testis occurs most commonly in men between the ages of 15 and 35 years. In the United States, the lifetime probability of developing testicular cancer is 0.3% for white men, an incidence that is 4.5 times higher than that found in blacks. Testicular tumors are slightly more common on the right side than on the left, a pattern that parallels the occurrence of cryptorchidism, and they are bilateral in 1% to 3% of cases (Figure 34-10).
Pathophysiology

Ninety percent of testicular cancers are germ cell tumors, arising from the male gametes. Germ cell tumors include seminomas (most common), embryonal carcinomas, teratomas, and choriocarcinomas. Testicular tumors also can arise from specialized cells of the gonadal stroma (Leydig, Sertoli, granulosa, theca cells).

The cause of testicular neoplasms is unknown (see Risk Factors: Cancer of the Testis). A genetic predisposition is suggested by the fact that the incidence is higher among brothers, identical twins, and other close male relatives. Genetic predisposition is supported statistically, showing that the disease is relatively rare among Africans, black Americans, Asians, and native New Zealanders. Risk factors include history of cryptorchidism, abnormal testicular development, human immunodeficiency virus (HIV) and AIDS, Klinefelter syndrome, and history of testicular cancer.32

Risk Factors

Cancer of the Testis
Clinical manifestations

Painless testicular enlargement commonly is the first sign of testicular cancer. Occurring gradually, it may be accompanied by a sensation of testicular heaviness or a dull ache in the lower abdomen. Occasionally acute pain occurs because of rapid growth resulting in hemorrhage and necrosis. Ten percent of affected men have epididymitis, 10% have hydroceles, and 5% have breast enlargement (gynecomastia). The testicular mass is usually discovered by the individual or by his sexual partner. At the time of initial diagnosis, approximately 10% of individuals already have symptoms related to metastases. Lumbar pain also may be present and usually is caused by retroperitoneal node metastasis. Signs of metastasis to the lungs include cough, dyspnea, and bloody sputum (hemoptysis). Supraclavicular node involvement may cause difficulty swallowing (dysphagia) and neck swelling. With metastasis to the central nervous system (CNS), alterations in vision or mental status, papilledema, and seizures may be experienced.

Evaluation and treatment

An incorrect diagnosis at the initial examination occurs in as many as 25% of men with testicular cancer. Epididymitis and epididymo-orchitis are the most common misdiagnoses; others include hydrocele and spermatocele. Evaluation begins with careful physical examination, including palpation of the scrotal contents with the individual in the erect and supine positions. Signs of testicular cancer include abnormal consistency, induration, nodularity, or irregularity of the testis. The abdomen and lymph nodes are palpated to seek evidence of metastasis, and tumor type is identified after orchiectomy. Although testicular self-examination has not been studied enough to be recommended by the American Cancer Society, many physicians recommend monthly examinations after puberty. Testicular biopsy is not recommended because it may cause dissemination of the tumor and increase the risk of local recurrence. Primary testicular cancer can be assessed rapidly and accurately by scrotal ultrasonography. Tumor markers are higher than normal in the presence
of a tumor and may help detect a tumor that is too small to be palpated during physical examination or to be visualized on imaging. Radiologic imaging and measurement of serum markers are used in clinical staging of the disease. Besides surgery, treatment involves radiation and chemotherapy singly or in combination. Factors influencing the prognosis include histologic studies of the tumor stage of the disease and selection of appropriate treatment. Most individuals treated for cancer of the testis can expect a normal life span; some have persistent paresthesias, Raynaud phenomenon, or infertility. Approximately 10% of men treated for testicular cancer will experience a relapse; if the relapse is discovered early and treated, 99% can be cured. Orchiectomy does not affect sexual function.

**Epididymitis**

Epididymitis, or inflammation of the epididymis, generally occurs in sexually active young males (younger than 35 years) and is rare before puberty (Figure 34-11). In young men, the usual cause is a sexually transmitted microorganism, such as *N. gonorrhoeae* or *C. trachomatis*. Coliform bacteria are the common pathogens in other age groups. Men who practice unprotected anal intercourse may acquire sexually transmitted epididymitis that results from infection with *Escherichia coli*, *Haemophilus influenzae*, tuberculosis, or *Cryptococcus* or *Brucella* species. In men older than 35 years, Enterobacteriaceae (intestinal bacteria) and *Pseudomonas aeruginosa* associated with urinary tract infections and prostatitis also may cause epididymitis. Epididymitis also may result from a chemical inflammation caused by the reflux of sterile urine into the ejaculatory ducts, which is then called chemical epididymitis. It is associated with urethral strictures, congenital posterior valves, and excessive physical straining in which increased abdominal pressure is transmitted to the bladder. Chemical epididymitis is usually self-limiting and does not require evaluation or intervention unless it persists.
Pathophysiology

The pathogenic microorganism usually reaches the epididymis by ascending the vasa deferentia from an already infected urethra or bladder. The resulting inflammatory response causes symptoms of bacterial epididymitis. Epididymitis caused by heavy lifting or straining results from reflux of urine from the bladder into the vas deferens and epididymis. Urine is extremely irritating to the epididymis and initiates the inflammatory response called chemical epididymitis.

Clinical manifestations

The main symptom of epididymitis is scrotal or inguinal pain caused by inflammation of the epididymis and surrounding tissues. The pain is usually acute and severe. Flank pain may occur if, as the urethra passes over the spermatic cord, edematous swelling of the cord obstructs the urethra. The individual may have pyuria, bacteriuria, and a history of urinary symptoms, including urethral discharge. The scrotum on the involved side is red and edematous. The tail of the epididymis near the lower pole of the testis usually swells first; then swelling ascends to the head of the epididymis. The spermatic cord also may be swollen and tender.

Complications include abscess formation, infarction of the testis, recurrent infection, and infertility. Infarction is probably caused by thrombosis (obstruction by blood clots) of the prostatic vessels secondary to severe inflammation. Recurrent epididymitis may result from inadequate initial treatment or failure to identify or
treat predisposing factors. Chronic epididymitis can cause scarring of the epididymal endothelium and infertility. Once scarring has occurred, treatment with antibiotics is ineffective because adequate antibiotic levels cannot be achieved within the epididymis.

**Evaluation and treatment**

A history of recent urinary tract infection or urethral discharge suggests the diagnosis of epididymitis. Common physical findings include a swollen, tender epididymis or testis located in the normal anatomic position with an intact same-side cremasteric reflex.  

The relief of pain when the inflamed testis and epididymis are elevated (Prehn sign) is also diagnostic. Definitive diagnosis is based on culture or Gram stain of a urethral swab. Epididymal aspiration may be necessary to obtain a specimen, especially if the individual has been taking antibiotics and has sterile urine.

Treatment includes antibiotic therapy for the infection itself. Analgesics, ice, and scrotal elevation can provide symptomatic relief. If the individual does not steadily improve, he should be reevaluated for possible complications, such as abscess formation, sepsis, or continued infection. Complete resolution of swelling and pain may take several weeks to months. The individual’s sexual partner should be treated with antibiotics if the causative microorganism is a sexually transmitted pathogen.

**Quick Check 34-3**

1. Why is a genetic predisposition suggested for testicular cancer?
2. Why is epididymitis rare in prepubescent males?
3. Why is testicular torsion considered a urologic emergency?

**Disorders of the Prostate Gland**

**Benign Prostatic Hyperplasia**

Benign prostatic hyperplasia (BPH), also called benign prostatic hypertrophy, is the enlargement of the prostate gland (Figure 34-12). (Because the major prostatic changes are caused by hyperplasia, not hypertrophy, benign prostatic hyperplasia is the preferred term.) This condition becomes problematic when prostatic tissue compresses the urethra, where it passes through the prostate, resulting in frequency of lower urinary tract symptoms. Similar to prostate cancer, BPH occurs more often
in Westernized countries (e.g., United States, United Kingdom, and Canada). BPH appears to be more common in black men than white men and family history may increase the risk. Being overweight or obese with central fat distribution (i.e., around the abdomen) increases the risk of developing BPH. The prevalence in the United States is about 50% in men 60 years and older and 90% among men 70 years or older. BPH is common and involves a complex pathophysiology with several endocrine and local factors and remodeled microenvironment. Its relationship to aging is well documented. At birth, the prostate is pea sized, and growth of the gland is gradual until puberty. At that time, there is a period of rapid development that continues until the third decade of life when the prostate reaches adult size (see Chapter 32). Around 40 to 45 years of age, benign hyperplasia begins and continues slowly until death. Although androgens, such as dihydrotestosterone (DHT), are necessary for normal prostatic development, their role in BPH remains unclear. Among all the androgen-metabolizing enzymes within the prostate, 5α-reductase is the most powerful. This reductase corresponds to an age-dependent DHT level. Therefore, although levels of 5α-reductase and DHT in the epithelium decrease with age, they remain constant in the stroma (microenvironment) of the prostate gland.
Prostate zones

FIGURE 34-12 Prostate Zones, Benign Prostatic Hyperplasia (BPH), and Prostate Cancer Locations. Benign prostatic hyperplasia (BPH) occurs in the peripheral zone of the prostate gland that can enlarge (not shown). BPH nodules and atrophy are associated with inflammation in the transition zone. Most cancer lesions occur in the peripheral zone. Carcinoma can involve the central zone but rarely occurs in isolation, suggesting that prostatic intraepithelial neoplasia (PIN) lesions do not easily progress to carcinoma in this region. (Adapted from De Marzo AM et al: Nat Rev Cancer 7:296-309, 2007.)

Pathogenesis

Current causative theories of BPH focus on aging and levels and ratios of endocrine factors such as androgens and estrogens (androgen/estrogen ratio), the role of chronic inflammation, and the effects of autocrine/paracrine growth-stimulating and growth-inhibiting factors. These factors include insulin-like growth factors (IGFs),
epidermal growth factors, fibroblast factors, and transforming growth factor-beta (TGF-β) and several others. Recent data show that human prostate stromal cells can actively contribute to the inflammatory process from the induction of inflammatory cytokines and chemokines\(^\text{36}\) (see *Cancer of the Prostate*, p. 865).

With aging, circulating androgens are associated with BPH and enlargement. Other effects related to estrogens include apoptosis, aromatase expression, and paracrine regulation that may be important for stimulating inflammation.\(^\text{37}\) BPH is a multifactorial disease and not all men respond well to currently available treatments, suggesting factors are involved other than androgens. Testosterone, the primary circulating androgen in men, also can be metabolized through CYPI9/aromatase into the potent estrogen estradiol-17β. The prostate is an estrogen target tissue and estrogens directly and indirectly affect growth and differentiation of the prostate. The precise role of endogenous and exogenous estrogens in directly affecting prostate growth and differentiation in the context of BPH is an understudied area. Estrogens and selective estrogen receptor modulators have been shown to promote or inhibit prostate proliferation, signifying potential roles in BPH.\(^\text{38,39}\) Taken together, these interactions lead to an increase in prostate volume. The remodeled stroma promotes local inflammation with altered cytokine, reactive oxygen/nitrogen species, and chemoattractants.\(^\text{40}\) The resultant increased oxygen demands of proliferating cells cause a local hypoxia that induces angiogenesis and changes to fibroblasts.

BPH begins in the periurethral glands, which are the inner glands or layers of the prostate. The prostate enlarges as nodules form and grow (nodular hyperplasia) and glandular cells enlarge (hypertrophy). The development of BPH occurs over a prolonged period of time, and changes within the urinary tract are slow and insidious.

**Clinical manifestations**

As nodular hyperplasia and cellular hypertrophy progress, tissues that surround the prostatic urethra compress it, usually, but not always, causing **bladder outflow obstruction**. These symptoms are sometimes called the spectrum of lower urinary tract symptoms (LUTS). Symptoms include the urge to urinate often, some delay in starting urination, and decreased force of the urinary stream. As the obstruction progresses, often over several years, the bladder cannot empty all the urine, and the increasing volume leads to long-term urine retention. The volume of urine retained may be great enough to produce uncontrolled “overflow incontinence” with any increase in intra-abdominal pressure. At this stage, the force of the urinary stream is significantly reduced, and much more time is required to initiate and complete voiding.\(^\text{41}\) Hematuria, bladder or kidney infection, bladder calculi, acute urinary
retention hydroureter, hydronephrosis, and renal insufficiency are common complications.\textsuperscript{41}

Progressive bladder distention causes diverticular outpouchings of the bladder wall. The ureters may be obstructed where they pass through the hypertrophied detrusor muscle, potentially causing hydroureter, hydronephrosis, and bladder or kidney infection.

**Evaluation and treatment**

Diagnosis is made from a medical history, physical examination, and laboratory tests, including urinalysis. Careful review of symptoms is necessary. Digital rectal examination (DRE) and measurement of prostate-specific antigen (PSA) level are conducted to determine hyperplasia. PSA level alone, however, cannot confirm symptoms attributable to BPH because PSA level is elevated in both BPH and prostate cancer. Annual DREs are used to screen men older than 40 years for BPH, sooner in high-risk men.\textsuperscript{42} If marked enlargement, moderate to severe symptoms, or complications are present, transrectal ultrasound (TRUS) is used to determine bladder and prostate volume and residual urine. Urinalysis, serum creatinine and blood urea nitrogen levels, uroflowmetry, postvoid residual (PVR) urine, pressure-flow study, cystometry, and cystourethroscopy are used to determine kidney and bladder function.\textsuperscript{41} BPH has been treated successfully with drugs. $\alpha_1$-Adrenergic blockers (prazosin and tamsulosin) are used to relax the smooth muscle of the bladder and prostate. Antiandrogen agents, such as finasteride (Proscar), selectively block androgens at the prostate cellular level and cause the prostate gland to shrink.\textsuperscript{43} By shrinking the prostate, these drugs have been shown to improve BPH-related symptoms and reduce the risk of future urinary retention and BPH-related surgery. $\alpha_1$-Adrenergic blockers do not affect PSA and have no effect on prostate cancer risk; however, antiandrogen agents lower PSA by 50% after 6 months of therapy.\textsuperscript{44} Newer, minimally invasive treatments include interstitial laser treatment, transurethral radiofrequency procedures (such as transurethral needle ablation [TUNA]), and Cooled ThermoTherapy™.

**Prostatitis**

Prostatitis is an inflammation of the prostate. The incidence and prevalence of prostatitis is not known. Inflammation is usually limited to a few of the gland's excretory ducts.

Prostatitis syndromes have been classified by the National Institutes of Health as (1) acute bacterial prostatitis (ABP), (2) chronic bacterial prostatitis (CBP), (3) chronic pelvic pain syndrome (CPPS), and (4) asymptomatic inflammatory
Prostatitis (Box 34-4). ABP and CBP are mostly caused by gram-negative Enterobacteriaceae and Enterococci species that originate in the gastrointestinal flora. The most common organism is *Escherichia coli*, which is identified in the majority of infections. Klebsiella species, *Pseudomonas aeruginosa*, and *Serratia* species are common gram-negative cultured microorganisms. Nonbacterial prostatitis (CP/CPPS) syndromes are caused by a cascade of inflammatory, immunologic, neuroendocrine, and neuropathic mechanisms whereby the initiating cause is unknown.

**Box 34-4**

**NIH Classification of Prostatitis Syndrome**

This system, developed for clinical research purposes, can be simplified for use in primary care practice (see text).

*Category I*, or acute bacterial prostatitis (ABP), is an acute infection of the prostate and is manifested by systemic signs of infection and positive urine culture.

*Category II*, or chronic bacterial prostatitis (CBP), is a chronic bacterial infection in which bacteria are received in significant numbers from a purulent prostatic fluid. These bacteria are thought to be the most common cause of recurrent urinary tract infection in men.

*Category III*, or chronic pelvic pain syndrome (CPPS), is diagnosed when no pathologic bacteria can be localized to the prostate (culture of expressed prostatic fluid or postprostatic massage urine specimen) and is further divided into IIIa and IIIb. Category IIIa refers to the inflammatory CPPS where a significant number of white blood cells (WBCs) are localized to the prostate, whereas category IIIb is noninflammatory.

*Category IV* refers to asymptomatic inflammatory prostatitis in which bacteria or WBCs are localized to the prostate, but individuals are asymptomatic.

**Bacterial prostatitis.**

Acute bacterial prostatitis (ABP, category I) is an ascending infection of the urinary tract that tends to occur in men between the ages of 30 and 50 years but is also associated with BPH in older men. Infection stimulates an inflammatory response in which the prostate becomes enlarged, tender, firm, or boggy. The onset of prostatitis may be acute and unrelated to previous illnesses, or it may follow
catheterization or cystoscopy.

Clinical manifestations of acute bacterial prostatitis are those of urinary tract infection or pyelonephritis. Sudden onset of malaise, low back and perineal pain, high fever (up to 40°C [104°F]), and chills is common, as are dysuria, inability to empty the bladder, nocturia, and urinary retention. The individual also may have symptoms of lower urinary tract obstruction, such as slow, small, “narrowed” urinary stream, which may be a medical emergency. Acute inflammatory prostatic edema can compress the urethra, causing urinary obstruction. Systemic signs of infection include sudden onset of a high fever, fatigue, arthralgia, and myalgia. Prostatic pain may occur, especially when the individual is in an upright position, because the pelvic floor muscles tighten with standing and compression of the prostate gland occurs. Some individuals experience low back pain, painful ejaculation, and rectal or perineal pain. Palpation discloses an enlarged, extremely tender and swollen prostate that is firm, indurated, and warm to the touch.

Because acute bacterial prostatitis is usually associated with a bladder infection caused by the same microorganism, urine cultures disclose its identity. Prostatic massage may express enough secretions from the urethra for direct bacterial examination, but massage may be painful and increases the risk that the infection will ascend to adjacent structures or enter the bloodstream and cause septicemia.

To resolve the infection and control its spread, individuals may require antibiotics. In severe cases, the individual is hospitalized and treated with intravenous antibiotics, followed by oral antibiotics. Analgesics, antipyretics, bed rest, and adequate hydration are also therapeutic. Complications include urinary retention that resolves with antibiotic therapy; prostatic abscess that may rupture into the urethra, rectum, or perineum; epididymitis; bacteremia; and septic shock. Urinary retention requiring drainage is best managed with a suprapubic catheter; Foley catheterization is contraindicated during acute infection.

**Chronic bacterial prostatitis (CBP, category II)*** is characterized by recurrent urinary tract symptoms and persistence of pathogenic bacteria (usually gram negative) in urine or prostatic fluid. This form of prostatitis is the most common recurrent urinary tract infection in men. Symptoms may be similar to those of an acute bladder infection: frequency, urgency, dysuria, perineal discomfort, low back pain, myalgia, arthralgia, and sexual dysfunction. The prostate may be only slightly enlarged or boggy, but it may be fibrotic because repeated infections can cause it to be firm and irregular in shape.

When the initial urine sample is bacteria-free, prostatic massage is used to express secretions. Subsequently, the first 10 ml of voided urine is collected and examined microscopically. Prostatic secretions showing more than 10 white blood cells (WBCs) per high-power field (hpf) and macrophages containing fat are
indicative of bacterial infection; diagnosis is confirmed by culture. A pelvic x-ray or transurethral ultrasound (TRUS) may show prostatic calculi.

Treatment of chronic bacterial prostatitis is difficult because it is often caused by prostatic calculi. Calculi are silent and are found in up to 50% of men with prostatitis, and infected calculi can serve as a source of bacterial persistence and relapsing urinary tract infection. Calculi harbor pathogens within the stone and, consequently, pathogens cannot be eradicated from the urinary tract. Permanent cure is achieved by surgical intervention.46

**Chronic prostatitis/chronic pelvic pain syndrome.**

**Chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS, category III)** is diagnosed when no pathogenic bacteria can be localized to the prostate, and is further subdivided into categories IIIa and IIIb (see Box 34-4). Category IIIa refers to inflammatory chronic pelvic pain syndrome in which white blood cell count is elevated and localized to the prostate. Compared with category III, symptoms tend to be milder but are persistent and annoying. Presumably, noninfectious prostatitis or pain is caused by reflux of sterile urine into the ejaculatory ducts because of high-pressure voiding.46 Reflux may be triggered by spasms of the external or internal sphincters. Category IIIb is noninflammatory. Category IV exists when individuals are asymptomatic but have an increase in bacteria and white blood cells localized to the prostate. Microorganisms suspected of causing CP/CPPS include *Escherichia coli*, *Enterobacter*, *Pseudomonas aeruginosa*, and, a new suspect, *Helicobacter pylori*.47

Men with nonbacterial prostatitis may complain of pain or a dull ache that is continuous or spasmodic in the suprapubic, infrapubic, scrotal, penile, or inguinal area. Other symptoms are pain on ejaculation and urinary symptoms, such as frequency of urination. The prostate gland generally feels normal on palpation.

Nonbacterial prostatitis is a diagnosis of exclusion. Digital examination of the prostate, bacterial cultures of the urogenital tract, microscopic examination of expressed prostatic fluid, urethroscopy, and urodynamic studies are used to verify the diagnosis of nonbacterial prostatitis.

There is no generally accepted treatment for nonbacterial prostatitis. Hot sitz baths, bed rest, and pharmacologic therapies, including anti-inflammatory drugs, can relieve symptoms.

**Cancer of the Prostate**

Prostate cancer is the most commonly diagnosed, nonskin cancer in men in the United States with a lifetime risk for diagnosis currently estimated at 15.9%.48 The
incidence varies greatly worldwide (Figure 34-13) but it is still considered to be the second most frequently diagnosed cancer in men and the sixth leading cause of death worldwide.\textsuperscript{49} An estimated 1.1 million cases of prostate cancer were diagnosed worldwide in 2012, accounting for 15% of the cancers diagnosed in men. Almost 70% of diagnosed cases of prostate cancer (759,000) were found to occur in more developed regions.\textsuperscript{50} Importantly, incidence rates vary by more than 25-fold worldwide, with the highest rates recorded mostly in developed countries, such as Oceania, Europe, and North America, largely because of wide use or overuse of PSA testing. Screening with PSA can amplify the incidence of prostate cancer by allowing detection of prostate lesions that, although meeting the pathologic criteria for malignancy, may have low potential (e.g., latent, indolent, preclinical) for growth and metastasis. In countries with higher use of PSA testing, such as United States, Canada, Australia, and the Nordic countries, trends in incidence rates follow similar patterns.\textsuperscript{50}

Different from Western countries, incidence and death rates are rising in several Asian and Central and Eastern European countries, including Japan. Death rates
have been decreasing in several countries, including Australia, Canada, the United Kingdom, the United States, Italy, and Norway, in part because of improved treatment. Males of African descent in the Caribbean region have the highest mortality from prostate cancer in the world.\textsuperscript{50} Most cases of prostate cancer have a good prognosis even without treatment, but some cases are aggressive; the lifetime risk for dying of prostate cancer is 2.8%. Prostate cancer is rare before age 50 years and very few men die from this cancer before 60 years of age. Indeed, more than 75\% of all prostate cancer is diagnosed in men older than 65.\textsuperscript{48} With aging, most of the androgen-metabolizing enzymes undergo significant alteration and older age, race (black), and family history remain the well-established risk factors.

**Dietary factors.**

Although evidence exists for a dietary role in prostate cancer, the epidemiologic evidence is inconsistent.\textsuperscript{51} The problem has been confounded by the lack of biomarkers for certain nutrients, difficulties in measuring and quantifying diet, and a limitation of clinical trials to study diet over time. Important are the effects of diet on signaling pathways, hormones, oxidative stress, and reactive oxygen species (ROS). The nutrients in the epidemiology of prostate cancer that have received the most attention include carotenoids, fat, vitamin E, vitamin D/calcium, and selenium. Less studied are isoflavones, curcumin, lycopene, green tea, omega-3 polyunsaturated fats, and sulforaphane (Box 34-5). Associations between obesity and prostate cancer are not clear because there are some inconsistencies, but obesity seems to be negatively associated with more indolent prostate cancer and positively associated with more aggressive disease and a worse outcome.\textsuperscript{52} Since adipose tissue is increasingly being regarded as hormonally active tissue, high body fat and obesity need in-depth exploration to understand the associated risk of prostate problems. Adipose tissue is now known to affect circulating levels of several bioactive messengers and therefore could affect the risk of developing prostate problems in addition to several other well-recognized health problems.\textsuperscript{53} High-energy intake (consumption of excess calories) indicates that this may indeed increase insulin levels and levels of IGF-1, a powerful carcinogenic agent.

**Box 34-5**

**Summary of Diet for Prostate Cancer**

- Lower rates of prostate cancer are found in countries whose residents consume a low fat and high vegetable diet. When men from a low-risk country move to the
United States and eat a Western diet, their rates of prostate cancer increase significantly. Inconclusive are the exact culprits that increase this risk, including fat and sugar intake.

- Obesity is linked to advanced and aggressive prostate cancer.

- High body mass index (BMI) is associated with more aggressive disease and a worse outcome.

- Calorie-dense or excessive carbohydrate intake and obesity, independent of dietary fat intake, may increase the risk of developing prostate cancer.

- Dietary fat may increase levels of androgens, increase oxidative stress, and increase reactive oxygen species (ROS).

- Monounsaturated fats may decrease the risk of prostate cancer.

- High levels of linoleic acid (found in corn oil) act as a proinflammatory eicosanoid, which is implicated in promotion of cell proliferation and angiogenesis as well as inhibition of apoptosis.

- The Western diet has increased omega-6 to omega-3 ratios and therefore is proinflammatory. Carcinogenic nitrosamines are formed after consumption of processed meat that contains nitrites and from heme iron present in large quantities of red meat.

- Even given the above knowledge, it is important to realize that studies showing an association between meat intake and prostate cancers have been largely inconclusive. Some studies reveal red meat is positively associated with increased prostate cancer risk with an association with more aggressive disease states. Despite some studies showing a 43% elevation in prostate cancer risk with high consumption of red meat, others show no association with prostate cancer risk.

- Although the role of red meat in prostate and breast cancer remains inconclusive, one explanation for the possible associations reported is the accumulation of carcinogens during the cooking process. Cooking meat at high temperatures produces heterocyclic amines and aromatic hydrocarbons that are carcinogenic.

- Vitamin E has long been considered a candidate for prostate cancer prevention from in vitro and in vivo animal studies. Vitamin E belongs to the family of
tocopherols and tocotrienols that exist as α, β, γ, and δ isoforms. Among these, δ-tocopherol is the major dietary isoform, whereas supplements contain α-tocopherol. Vitamin E is a fat-soluble vitamin obtained from vegetable oils, nuts, and egg yolk. It is a potent intracellular antioxidant known to inhibit peroxidation and DNA damage. The Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study (ATBC) showed that supplementation with vitamin E could reduce the incidence of prostate cancer among men who smoked. In vitro studies demonstrate that α-tocopherol succinate induces cell cycle arrest in human prostate cancer cells (i.e., induces apoptosis) and inhibits the androgen receptor. Mouse studies show vitamin E can inhibit the growth-promoting effects of a high-fat diet; however, vitamin E in combination with selenium does not reduce the incidence of prostate cancer in Lady mice models. A prospective large clinical trial, the Selenium and Vitamin E Cancer Prevention Trial (SELECT), showed no reduction in prostate cancer period prevalence but an increased risk of prostate cancer with vitamin E alone.

• Selenium is a trace mineral and exists in food as selenomethionine and selenocysteine. It is essential for the functioning of many antioxidant enzymes and proteins in the body. Humans receive selenium in their diet through plant (dependent on soil concentrations) and animal products. The SELECT trial showed that neither selenium nor vitamin E, taken alone or together, helped to prevent prostate cancer.

• Vitamin D may play an important role in prostate cancer prevention.

• Soy anticancer properties include inhibition of cell proliferation and angiogenesis and reduction in PSA and androgen receptor levels. Countries whose residents have a high intake of soy have much lower rates of prostate cancer.

• Tomatoes or tomato products ingested daily seem to reduce prostate cancer risk. In vitro studies show lycopene found in tomatoes inhibits DNA strand breaks. Unresolved is whether lycopene itself or a metabolic product is responsible for its biologic effect. In clinical studies tomato paste, which is high in lycopene, reduced plasma PSA levels in those men with benign prostatic hyperplasia. Lycopene administration is associated with cell cycle arrest (apoptosis) and growth factor signaling. In 2007 the FDA evaluated 13 available studies and found the relationship between lycopene and reduced risk of prostate cancer inadequate.

• Vegetables including broccoli, cabbage, cauliflower, brussels sprouts, Chinese cabbage, and turnips (all crucifers) may be protective (several epidemiologic
studies) against prostate cancer. In particular, a diet high in broccoli reduced cancer risk. By contrast, four studies revealed no cancer preventive effects. Crucifoms have anticancer properties mediated by the phytochemicals phenethyl isothiocyanate, sulforaphane, and indole-3-carbinol. Sulforaphane is a naturally occurring isothiocyanate that was first isolated in broccoli. It protects against carcinogen-induced cancer in many rodents. Mice given 240 mg of broccoli sprouts per day showed a significant reduction in growth of prostate cancer cells. Sulforaphane treatment lowered androgen receptor protein and gene expression.

• Green tea contains polyphenols, including epigallocatechin gallate (EGCG). Green tea consumption has been associated with a reduced incidence of several cancers including prostate cancer. Green tea consumed within a balanced controlled diet in humans improved overall antioxidant potential. The anticancer effect potential of green tea from in vitro and experimental studies shows these compounds bind directly to carcinogens and induce phase II enzymes that inhibit heterocyclic amines. EGCG administration decreased NF-κB activity. Green tea was shown to inhibit IGF-1 and increase IGFBP3, leading to inhibition of prostate cancer development and progression. Yet, in two small randomized studies in individuals with high-grade prostatic neoplasia, it showed no effects. However, treatment with a mixture of bioactive compounds that share molecular anticarcinogenic targets may enhance the effect on these targets at low concentrations of individual compounds.

• Epidemiologic studies have consistently shown that regular consumption of fruits and vegetables is strongly associated with reduced risk of developing chronic diseases, such as cancer. It is now accepted that the actions of any specific phytonutrient alone do not explain the observed health benefits of diets rich in fruits and vegetables; also, clinical trials demonstrated that consumption of phytonutrients did not show consistent preventive effects. Synergistic inhibition of prostate cancer cell growth has been evident when using combinations of low concentrations of various carotenoids or carotenoids with retinoic acid and the active metabolite of vitamin D. Combinations of several carotenoids (e.g., lycopene, phytoene, and phytofluene) or carotenoids and polyphenols (e.g., carnosic acid and curcumin) and/or other compounds (e.g., vitamin E) synergistically inhibit the androgen receptor activity and activate the electrophile/antioxidant response element (EpRE/ARE) transcription system. The activation of EpRE/ARE is up to fourfold higher than the sum of activities of single ingredients.
• Examples of important potential processes that can be targeted in the regulation of tumorigenesis include cholesterol synthesis and metabolites, reactive oxygen species and hypoxia, macrophage activation and conversion, indoleamine 2,3-dioxygenase regulation of dendritic cells, vascular endothelial growth factor regulation of angiogenesis, fibrosis inhibition, and endoglin and Janus kinase signaling.

• Curcumin has anticarcinogenic potential with well-characterized anti-inflammatory, antiangiogenic, and antioxidant properties. Recent studies report curcumin modulates the Wingless signaling pathway (Wnt) that supports its antiproliferative potential. Curcumin is characteristic of regulating multiple targets, a desirable feature in current drug design and drug development. Together with its potential in treating castration-resistant prostate cancer and its safety profile, this feature enables curcumin to serve as an ideal compound for the design and syntheses of agents with improved potential for enhancing clinical therapies used to treat prostate cancer.

• Overall, multiple signaling pathways are involved in prostate cancer development and progression, many of which are affected by dietary and lifestyle factors.

Hormones.

Prostate cancer develops in an androgen-dependent epithelium and is usually androgen sensitive. Androgens are synthesized not only in the testis, accounting for 50% to 60% of the total testosterone in the prostate, but also in the prostate gland itself. In a process called **intraprostatic conversion**, the hormone dehydroepiandrosterone (DHEA) produced by the adrenal glands is converted to testosterone and then into dihydrotestosterone (DHT) in the prostate (Figure 34-14). Additionally, prostate cancer cells have been reported to make androgens from cholesterol (i.e., de novo). However, these overall relative contributions from intratumoral sources remain to be determined. Population studies have not, however, provided clear and convincing patterns involving associations between circulating (e.g., not tissue concentrations) hormone concentrations and prostate cancer risk. Thus, there is universal agreement that androgens are important for prostatic growth, development, and maintenance of tissue balance; however, their role in cancer is controversial. Evidence in support of the involvement of androgens in prostate cancer development is derived from clinical trials with 5α-reductase inhibitors. However, the involvement of 5α-reductase, which is critical in androgen activity in the prostate, is contradictory and inconsistent (see Figure 34-14). A prevention study has provided some of the strongest hormonal data with the drug finasteride, which inhibits 5α-reductase. The 7-year intervention study
reduced prostate cancer risk in healthy men by about 25%.\textsuperscript{58} Important, however, was that more high-grade tumors were found in those men who developed prostate cancer while on the drug. In men younger than 50 years, circulating levels of androgens and estrogens appear to be higher in men of African descent than in European-American men.

Despite the well-documented importance of androgens, their pathophysiologic process in prostate diseases is incomplete.\textsuperscript{59} Androgens also are metabolized to estrogens (see Figure 34-14, B) through the action of the enzyme aromatase, and a growing body of evidence implicates estrogens in the etiology of prostate disease (see \textit{Pathogenesis} section).
**Vasectomy.**

Vasectomy has been identified as a possible risk factor for prostate cancer in both case-controlled studies and cohort studies.\(^6^0,^6^1\) Three mechanisms by which vasectomy could increase risk are (1) elevation of circulating androgens; (2) activation of immunologic mechanisms involving antisperm antibodies; and (3) reduction of seminal fluid levels of 5α-dihydrotestosterone, the active metabolite of testosterone in the prostate, in vasectomized men. These results suggest an elevation of circulating free testosterone level following vasectomy. However, with these combined mechanisms it is unlikely that vasectomy plays a causal role.\(^6^2\)

**Chronic inflammation.**

The results of a 5-year longitudinal study of the influence of chronic inflammation and prostate cancer have been reported.\(^6^3\) The study included 144 men, 33 of whom presented with chronic inflammation in their initial biopsy. Biopsies revealed prostatic hyperplasia and proliferative inflammatory atrophy in those with chronic inflammation. Upon repeat biopsy, 29 new cancers were diagnosed, representing a new cancer incidence of 20%.\(^6^3\) In contrast, of the 33 men initially showing no inflammation, 2 (6%) were found to have adenocarcinoma. Certain metabolic comorbidities, including obesity, diabetes, sleep apnea, and erectile dysfunction, may be linked to both BPH and inflammation.\(^6^4\) The causes of chronic inflammation are emerging (possible causes are shown in Figure 34-15). Thus, chronic inflammation may be an important risk factor for prostatic adenocarcinoma.\(^6^5\) Chronic inflammation involves autocrine/paracrine growth-stimulating and growth-inhibiting factors. These factors include insulin-like growth factors (IGFs), epidermal growth factors, fibroblast factors, and transforming growth factor-beta (TGF-β) as well as several others. Recent data show that human prostate stromal cells can actively contribute to the inflammatory process from the induction of inflammatory cytokines and chemokines.\(^3^6,^6^6\) Importantly, a continuous input from TGF-β and IGF in the tumor microenvironment or stroma will result in cancer progression. Understanding of these events can help prevention, diagnosis, and therapy of prostate cancer.\(^6^6\) (Figure 34-16).
FIGURE 34-15  Possible Causes of Prostate Inflammation. A, Infection, including viruses, bacteria, fungi, and parasites. B, Hormones, for example, estrogen at key times during development. C, Physical trauma, any type of blunt physical injury. D, Urine reflex. E, Certain dietary factors (see text).
Genetic and epigenetic factors.

Other possible causes are those of genetic predisposition (familial and hereditary forms). Genetic studies suggest that strong familial predisposition may be responsible for 5% to 10% of prostate cancers. Compared with men with no family history, those with one first-degree relative with prostate cancer have twice the risk and those with two first-degree relatives have five times the risk. Germline mutations in the breast cancer predisposition gene 2 (BRCA2) are the genetic events known to date that confer the highest risk of prostate cancer (8.6-fold in men ≤65 years). Although the role of BRCA2 and BRCA1 in prostate tumorigenesis remains unrevealed, deleterious mutations in both genes have been associated with more
aggressive disease and poor clinical outcomes.\textsuperscript{68,69} Men with \textit{BRCA2} (tumor suppressor) germline mutations have a 20-fold increase in risk of prostate cancer. Using previously estimated population carrier frequencies, investigators have recently found that deleterious \textit{BRCA1} mutations confer a relative risk of prostate cancer of \(\approx3.75\)-fold, translating to 8.6\% cumulative risk by age 65.\textsuperscript{70} A common type of somatic mutation that develops into chromosomal rearrangements is the \textit{ETS} gene. The most common epigenetic alteration in prostate cancer is hypermethylation of the glutathione S-transferase (\textit{GSTP1}) gene located on chromosome 11. More than 30 independent, peer-reviewed studies have reported a consistently high sensitivity and specificity of \textit{GSTP1} hypermethylation in prostatectomy or biopsy tissue.\textsuperscript{71} There is no clear evidence of a causal link between BPH and prostate cancer, even though they may often occur together. Variations in several other genes related to inflammatory pathways might affect the probability of developing prostate cancer.

\textbf{Pathogenesis}

More than 95\% of prostatic neoplasms are adenocarcinomas\textsuperscript{72} and most occur in the periphery of the prostate (see \textbf{Figures 34-12} and \textbf{34-17}). Prostatic adenocarcinoma is a heterogeneous group of tumors with a diverse spectrum of molecular and pathologic characteristics and, therefore, diverse clinical behaviors and challenges.\textsuperscript{73} The biologic aggressiveness of the neoplasm appears to be related to the degree of differentiation rather than the size of the tumor (\textbf{Box 34-6}). Several genetic alterations have been found for prostate carcinoma, including acquired genomic structural changes, somatic mutations, and epigenetic alterations.\textsuperscript{74}
Box 34-6

Determining the Grade of Prostate Cancer with the Gleason Score

Grade 1. The cancer cells closely resemble normal cells. They are small, uniform in shape, evenly spaced, and well differentiated (i.e., they remain separate from one another).

Grade 2. The cancer cells are still well differentiated, but they are arranged more loosely and are irregular in shape and size. Some of the cancer cells have invaded the neighboring prostate tissue.

Grade 3. This is the most common grade. The cells are less well differentiated (some have fused into clumps) and are more variable in shape.

Grade 4. The cells are poorly differentiated and highly irregular in shape. Invasion of the neighboring prostate tissue has progressed further.
Hormonal factors.

Just as the testicles are the male equivalent of the female ovaries, the prostate is the male equivalent of the female uterus; in both situations they originate from the same embryonic cells. This may be important in understanding the role of the associated hormones testosterone (T), dihydrotestosterone (DHT), and estrogens in prostate cancer development. Testicular testosterone synthesis and serum testosterone levels fall as men age, but the levels of estradiol do not decline, remaining unchanged or increasing with age. The relationship between hormones and the pathophysiology of prostate carcinogenesis is incomplete and controversial. The main issues and controversies include (1) sources of androgen production outside of the testes, or extratesticular sources (e.g., from adrenal DHEA and from prostate tissue cholesterol [de novo] itself); (2) the role of prostatic androgen receptor (AR); (3) the role of estrogens, aromatase enzyme, and the estrogen receptors ERα and ERβ; and (4) the role of the surrounding microenvironment or stroma.

Prostate cancer is considered a hormone-dependent disease; cell growth and survival of early stage prostate cancer can respond to androgens and this is the background evidence for androgen-deprivation therapy (ADT). However, evidence thus far is lacking to associate plasma androgens with prostate cancer progression. Prostatic tissue has the ability to produce its own steroids, including androgens and estrogens. Therefore, the local tissue levels of sex steroids have become a major focus of intraprostatic hormonal profiles. Prostate tissue contains many metabolizing enzymes for the local production of active androgens and estrogens. Carcinogenesis can alter these intraprostatic enzymes and alter the normal balance.

The androgenic hormone responses in the normal prostate and prostate cancer are mediated by androgen receptor (AR) signaling. Exactly how AR drives the growth of prostate cancer cells is not fully known. Several mechanisms have been suggested and specific pathways of signaling are important because they can provide novel therapeutic targets. A recent study using animal models found that loss of androgen receptor function prevented prostatic carcinogenesis, malignant transformation, and metastasis. Tissue-specific evaluation of androgen hormone action demonstrated that epithelial androgen receptor was not necessary for prostate cancer progression, whereas the stromal androgen receptor was essential for prostate cancer progression, malignant transformation, and metastasis.

Testicular testosterone provides the main source of androgens in the prostate (see
Figure 34-14) and is the major circulating androgen, whereas DHT predominates in prostate tissue and binds to the androgen receptor (AR) with greater affinity than does T. The adrenal cortex contributes the far less potent dehydroepiandrosterone (DHEA) that promotes synthesis of androgens in the prostate. In the target tissues and, to a lesser extent, in the testes themselves, testosterone is converted to dihydrotestosterone (DHT) by the enzyme 5α-reductase (Figure 34-18). Thus, DHT is the most potent intraprostatic androgen.

![Diagram](https://via.placeholder.com/150)

Figure 34-18 Testosterone and Conversion to Dihydrotestosterone (DHT).

Normally, a small amount of estrogen is produced daily—estrone and estradiol—by the aromatization of androstenedione and testosterone, respectively. This reaction is catalyzed by the enzyme aromatase. A small quantity of estradiol is released by the testes (see Figure 34-18); the rest of the estrogens in males are produced by adipose tissue, liver, skin, brain, and other nonendocrine tissue. Thus, testosterone is a precursor of two hormones—DHT and estradiol.

Recent studies show aromatase is expressed in stromal tissue in the benign human prostate gland. Thus it appears that both normal prostate and benign prostate have the capacity to locally metabolize androgens to estrogens through aromatase. This leads to the following question: How does aromatase gene expression contribute to the etiology and progression of prostate cancer? Investigators have demonstrated altered aromatase expression in prostate cancer (see Figure 34-14, B, p. 869).

Accumulating evidence shows that estrogens participate in the pathogenesis and development of benign prostatic hyperplasia and prostate cancer by activating estrogen receptor α (ER-α). In contrast, estrogen receptor β (ER-β) is involved in the differentiation and maturation of prostatic epithelial cells, and thus possesses antitumor effects in prostate cancer. The effect of estrogen is determined by the two receptors ER-α and ER-β. ER-α leads to abnormal proliferation, inflammation, and the development of premalignant lesions. In contrast, ER-β leads to antiproliferative, anti-inflammatory, and potentially anticarcinogenic effects that act
in concert or balance the actions of ER-α and androgens. Increased expression of ER-α has been found to be associated with prostate cancer progression, metastasis, and the so-called castration-resistant (medical treatment that suppresses androgens) phenotype. A specific oncogene is regulated by ERs, and those hormones that stimulate the ER-α receptor-like (i.e., agonists) endogenous estrogens can stimulate oncogene expression.

Most of the androgen-metabolizing enzymes undergo a significant age-dependent alteration. In epithelium, both the blood levels of 5α-reductase activity and the DHT level decrease with age, whereas in stroma (prostate), not only the 5α-reductase activity but also the stromal DHT level is rather constant over the lifetime. In contrast to the relatively unaltered DHT level over time, the estrogen concentration follows an age-dependent increase. Thus the age-dependent decrease of the DHT accumulation in epithelium and the concomitant increase of the estrogen accumulation in stroma lead to a tremendous increase with age of the estrogen/androgen ratio in the human prostate. In animal studies, chronic exposure to testosterone plus estradiol is strongly carcinogenic, whereas testosterone alone is weakly carcinogenic. In mice studies, elevated testosterone level in the absence of estrogen leads to the development of hypertrophy and hyperplasia but not malignancy. High estrogen and low testosterone levels have been shown to lead to inflammation with aging and the emergence of precancerous lesions. The mechanism is not clearly understood and may involve estrogen-generated oxidative stress and DNA toxicity, and it requires androgen-mediated and estrogen receptor–mediated processes, such as changes in sex steroid metabolism and receptor status. In addition, there are changes in the balance between autocrine/paracrine growth-stimulatory and growth-inhibitory factors, such as the insulin growth factors (IGFs).

Investigators have summarized the following key findings on hormones and prostate cancer: (1) androgens are clearly involved in the progression of prostate cancer; (2) it is only with the addition of estrogen to testosterone in rats that cancer can be reliably induced; (3) in vivo and in vitro studies have identified multiple mechanisms involving hormonal involvement with genotoxicity, epigenetic toxicity, hyperprolactinemia, chronic inflammation, and estrogen receptor–mediated changes.

**Prostate epithelial neoplasia.**

A precursor lesion, **prostatic epithelial neoplasia (PIN)**, has been described. PIN may be more concentrated in prostates containing cancer and is noted in proximity to cancer. However, the final fate of PIN is unknown, including the possibilities of
latency, invasion, and even regression. The current working model of prostate carcinogenesis suggests that repeated cycles of injury and cell death occur to the prostate epithelium as a result of damage (i.e., from oxidative stress) from inflammatory responses.\textsuperscript{88} The direct injury is hypothesized as a response to infections; autoimmune disease; circulating carcinogens or toxins, or both, from the diet; or urine that has refluxed into the prostate (see Figure 34-15). The resultant manifestation of this injury is focal atrophy or prostate intraepithelial atrophy (PIA). Biologic responses cause an increase in proliferation and a massive increase in epithelial cells that possess a phenotype intermediate between basal cells and mature luminal cells (Figure 34-19).\textsuperscript{88} In a small subset of cells, some may contain “stem cell” or tumor-initiating properties and telomere shortening (see Chapter 10). A subset of PIN cells may activate telomerase enzyme, causing the cells to become immortal.\textsuperscript{89} Molecular genetic and epigenetic changes can increase genetic instability that might progress to high-grade PIN and early prostate cancer formation. This model of prostate carcinogenesis needs much more research.

\textbf{Stromal environment.}

The prostate gland is composed of secretory luminal epithelium, basal epithelium, neuroendocrine cells, and various cell types comprising supportive tissue or stroma. \textbf{Stroma}, or tissue microenvironment, produces autocrine/paracrine factors as well as structural supporting molecules that help regulate normal cell behavior and organ homeostasis.\textsuperscript{90} Stromal components in the tumor microenvironment are important contributions to tumor progression and metastasis.\textsuperscript{91} Reciprocal
interactions between tumor cells and stromal components influence the metastatic, dormancy-related, and stem cell–like potential of tumor cells. The stromal compartment of the tumor is complex and includes inflammatory/immune cells, vascular endothelial cells, pericytes, fibroblasts, adipocytes, and components of the extracellular matrix. Tumor-infiltrating inflammatory cells release a host of growth factors, chemokines, cytokines, and proinvasive matrix-degrading enzymes to promote tumor growth and progression. Angiogenesis occurs in response to factors secreted from tumor cells, resulting in continued growth and progression. Adipocytes in the tumor microenvironment produce adipokines, which are important for tumor growth. Fibroblasts in the tumor microenvironment provide the structural framework of the stroma; they remain quiet or dormant, but proliferate during wound healing, inflammation, and cancer. Tumor cells release paracrine factors that activate fibroblasts to become “cancer-associated fibroblasts” (CAFs). CAFs secrete factors that modulate tumor growth and modify the stroma to enhance metastasis and dampen responses to anticancer therapies. These findings suggest that alteration in the prostate microenvironment with therapeutic agents and approaches—in particular, natural products such as berberine, resveratrol, onionin A, epigallocatechin gallate, genistein, curcumin, naringenin, desoxyrhapontigenin, piperine, and zerumbone—warrants further investigation to target the tumor microenvironment for the treatment and prevention of cancer.

Epithelial-mesenchymal transition (EMT) was first described in embryonic development, and is observed in a number of solid tumors (see Chapter 10). Cells that undergo EMT become more migratory and invasive and gain access to vascular vessels. Numerous studies have shown that these transition states (EMT and mesenchymal-epithelial transition [MET]) are a consequence of tumor-stromal interactions. Investigators studying prostate cancer cells in vitro correlated EMT with increased growth, migration, and invasion. These investigators demonstrated that the microenvironment is a critical site for the transition of human prostate cancer cells from epithelial to mesenchymal structure, resulting in increased metastatic potential for bone and adrenal gland.

Prostate cancer is known to be diverse and composed of multiple genetically distinct cancer cell clones. Recent studies, however, indicate that most metastatic cancers arise from a single precursor cancer cell. From all of these observations, the following multifactorial general hypothesis of prostate carcinogenesis emerges: (1) androgens act as strong tumor promoters through androgen receptor–mediated mechanisms to enhance the carcinogenic activity of strong endogenous DNA toxic carcinogens, including reactive estrogen metabolites and estrogen, and prostate-generated reactive oxygen species; (2) reciprocal interactions between tumor cells and the stromal microenvironment
promote prostate cancer pathogenesis; and (3) possibly unknown environmental-lifestyle carcinogens may contribute to prostate cancer. All of these factors are modulated by diet and genetic determinants, such as hereditary susceptibility genes and polymorphic genes, which encode receptors and enzymes involved in the metabolism and action of steroid hormones.\textsuperscript{57}

The most common sites of distant metastasis are the lymph nodes, bones, lungs, liver, and adrenals. The pelvis, lumbar spine, femur, thoracic spine, and ribs are the most common sites of bone metastasis. Local extension is usually posterior, although late in the disease the tumor may invade the rectum or encroach on the prostatic urethra and cause bladder outlet obstruction (Figure 34-20). The spread of cancer through blood vessels is illustrated in Figure 34-21.
FIGURE 34-20 Carcinoma of Prostate. A, Schematic of carcinoma of the prostate. B, Carcinoma of the prostate extending into the rectum and urinary bladder. (B from Damjanov I, Linder J, editors: Pathology: a color atlas, St Louis, 2000, Mosby)
Clinical manifestations
Prostatic cancer often causes no symptoms until it is far advanced. The first manifestations of disease are those of bladder outlet obstruction: slow urinary stream, hesitancy, incomplete emptying, frequency, nocturia, and dysuria. Unlike the symptoms of obstruction caused by BPH, the symptoms of obstruction caused by prostatic cancer are progressive and do not remit. Local extension of prostatic cancer can obstruct the upper urinary tract ureters as well. Rectal obstruction also may occur, causing the individual to experience large bowel obstruction or difficulty in defecation. Symptoms of late disease include bone pain at sites of bone metastasis, edema of the lower extremities, enlargement of lymph nodes, liver enlargement, pathologic bone fractures, and mental confusion associated with brain metastases. Prostatic cancer and its treatment can affect sexual functioning.

Evaluation and treatment
Screening for prostatic cancer includes digital rectal examination (DRE) and prostate-specific antigen (PSA) blood tests. There is lack of evidence, however, whether screening with PSA or DRE reduces mortality from prostate cancer. It is unclear if detection of prostate cancer at an early stage leads to any change in the natural history or outcome. Observational studies in some countries show a trend toward lower mortality, but the relationship between the intensity and trends of screening is not clear and the associations with screening are inconsistent. The
observed trends may be a result of screening or improved treatment. Two randomized trials show no effect on mortality through 7 years and are inconsistent beyond 7 to 10 years.\textsuperscript{100} Strong evidence shows implementation of PSA or DRE detects some prostate cancers that would never have caused significant clinical problems.\textsuperscript{99} These screening tests lead to some degree of overtreatment. The screening tests can harm patients, including radical prostatectomy and radiation therapy that lead to irreversable side effects in many men.\textsuperscript{99} The most common side effects are erectile dysfunction and urinary incontinence. The screening process can cause considerable anxiety, especially in men who have a prostate biopsy but no identified prostate cancer. Screening can lead to biopsies, which are associated with complications including fever, pain, hematuria, hematospermia, positive urine cultures for bacteria, and, rarely, sepsis. About 20\% to 70\% of men who had no problems before radical prostatectomy or external-beam radiation therapy will have reduced sexual function or urinary problems, or both.

Prostate cancer usually grows very slowly and is predominantly a tumor of older men with the median age at diagnosis of 72 years.\textsuperscript{99} Until recently, many physicians and organizations encouraged yearly PSA screening for men beginning at age 50; however, with more understanding about the benefits and detriments, a number of organizations have cautioned men against routine population screening (Figure 34-22). Some organizations continue to recommend PSA screening. Some tumors found through PSA screening do not cause symptoms, grow slowly, and are unlikely to threaten a man's life. The PSA screening test often suggests that prostate cancer may be present when there is no cancer. This is called a “false positive” result. False positive results lead to unnecessary follow-up tests. Detecting these tumors is called overdiagnosis.
Benefits and Harms of PSA Screening for Prostate Cancer

1,000 men ages 55–69 screened every 1–4 years for 10 years with a PSA test

Out of these:

100–120
Get false-positive results that may cause anxiety and lead to biopsy (possible side effects of biopsies include serious infections, pain, and bleeding).

Out of these:

At least 50
Will have treatment complications, such as infections, sexual dysfunction, or bladder or bowel control problems.

4–5
Die from prostate cancer (5 die among men who do not get screened).

0–1
Death from prostate cancer is avoided.

1,000 men screened

FIGURE 34-22 Benefits and Harms of PSA Screening for Prostate Cancer. The U.S. Preventive Services Task Force (USPSTF) recommends against PSA-based screenings for prostate cancer.
Across age ranges, black men and men with a family history of prostate cancer have an increased risk of developing and dying of prostate cancer. Black men are approximately twice as likely to die of prostate cancer compared with men of other races in the United States, and the reason for this disparity is unknown. Black men represent a very small minority of participants in randomized clinical trials of screening and thus no firm conclusions can be made about the balance of benefits and harms of PSA-based screening in this population. As such, it is questionable practice to selectively recommend PSA-based screening for black men in the absence of data that support a more favorable balance of risks and benefits. Because of this “overtreatment” phenomenon, active surveillance with delayed intervention is gaining traction as a viable management approach in contemporary practice.

Treatment of prostatic cancer depends on the stage of the neoplasm, the anticipated effects of treatment; and the age, general health, and life expectancy of the individual. Options include no treatment; surgical treatments, such as total prostatectomy, transurethral resection of the prostate (TURP), or cryotherapy; nonsurgical treatments, such as radiation therapy, hormone therapy, or chemotherapy; watchful waiting; and any combination of these treatment modalities. In addition, new approaches are using immunotherapy. Palliative treatment is aimed at relieving urinary, bladder outlet, or colon obstruction; spinal cord compression; and pain. Box 34-7 shows staging for prostate cancer. Prognosis and survival rates have improved steadily over the past 50 years. Over the past 25 years, the 5-year relative survival rate for all stages combined has increased from 68% to almost 100%. According to the most recent data, 10- and 15-year relative survival rates are 98% and 94%, respectively.

Box 34-7

Staging for Prostate Cancer

Stage I
In stage I, cancer is found in the prostate only. The cancer:

- Is found by performing a needle biopsy (done for a high PSA level) or by examining a small amount of tissue during surgery for other reasons (such as benign prostatic hyperplasia). The PSA level is lower than 10 and the Gleason score is 6 or lower; or

- Is found on half or less of one lobe of the prostate. The PSA level is lower than 10 and the Gleason scores is 6 or lower; or

- Cannot be felt during a digital rectal exam and cannot be seen in imaging tests. Cancer is found in half or less of one lobe of the prostate. The PSA level and the Gleason score are not known.

**Stage II**

In stage II, cancer is more advanced than in stage I, but has not spread outside the prostate. Stage II is divided into stages IIA and IIB.

**Stage IIA**
• Is found by performing a needle biopsy (done for a high PSA level) or by examining a small amount of tissue during surgery for other reasons (such as benign prostatic hyperplasia). The PSA level is lower than 20 and the Gleason score is 7; or
• Is found by performing a needle biopsy (done for a high PSA level) or by examining a small amount of tissue during surgery for other reasons (such as benign prostatic hyperplasia). The PSA level is at least 10 but lower than 20 and the Gleason score is 6 or lower; or
• Is found in half or less of one lobe of the prostate. The PSA level is lower than 20 and the Gleason score is 7; or
• Is found in more than half of one lobe of the prostate.

Stage IIB

• Is found on opposite sides of the prostate. The PSA can be any level and the Gleason score can range from 2 to 10; or
• Cannot be felt during a digital rectal examination and cannot be seen in imaging tests. The PSA level is 20 or higher and the Gleason score can range from 2 to 10; or
• Cannot be felt during a digital rectal examination and cannot be seen in imaging tests. The PSA can be any level and the Gleason score is 8 or higher.

Stage III
• In stage III, cancer has spread beyond the outer layer of the prostate and may have spread to the seminal vesicles. The PSA can be any level and the Gleason score can range from 2 to 10.

Stage IV

In stage IV, the PSA can be any level and the Gleason score can range from 2 to 10. Also, cancer:
