Introduction to Pathophysiology

## Part One Basic Concepts of Pathophysiology

## Unit 1 The Cell

1 Cellular Biology
2 Genes and Genetic Diseases

DNA, RNA, and Proteins: Heredity at the Molecular Level

Chromosomes

Elements of Formal Genetics

Transmission of Genetic Diseases

Linkage Analysis and Gene Mapping

Multifactorial Inheritance

Did You Understand?

Key Terms

References

3 Epigenetics and Disease

Epigenetic Mechanisms

Epigenetics and Human Development

Genomic Imprinting

Long-Term and Multigenerational Persistence of Epigenetic States Induced by Stochastic and
Environmental Factors
Epigenetics and Cancer
Future Directions
Did You Understand?
Key Terms

Notices
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary. Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and
knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

ABOUT THE COVER
Microbiome. This colored scanning electron micrograph of *Escherichia coli* bacteria (red rods) was taken from the small intestine of a child. *E. coli* are part of the normal flora or microbiota of the human gut and many normal flora are essential for health. The terms microbiota or microbiome refer to the community of microbes that normally reside on and within the human body. The microbiome also means the full collection of genes of all the microbes in the community. DNA-sequencing tools have helped define the microbiome and they outnumber our own cells by about 10 to 1. These resident microbes are highly skilled and provide crucial functions—they sense what food is present, if pathogens are lurking, and the inflammatory state of the gut. Shifts in the bacterial composition of the gut microbiota have been correlated with intestinal dysfunctions such as inflammatory bowel disease, antibiotic-associated diarrhea and metabolic dysfunction including obesity. Gut microflora have protective, metabolic, growth, and immunologic functions because the microbiota interact with both innate and adaptive immune systems. If the overall interaction is flawed autoimmune or inflammatory diseases may occur. We acquire our microbiomes from the environment at birth. Our microbial profiles change with aging because microbial populations shift with changes in the environment. Credit: STEPHANIE SCHULLER/SCIENCE PHOTO LIBRARY

The sixth edition of *Understanding Pathophysiology*, like other editions, has been rigorously updated and revised with consideration of the rapid advances in molecular and cell biology. Many sections have been rewritten or reorganized to provide a foundation for better understanding of the mechanisms of disease. Integrated throughout the text are concepts from the basic sciences, including genetics, epigenetics, gene–environment interaction, immunity, and inflammation. The text has been written to assist students with the translation of the concepts and processes of pathophysiology into clinical practice and to promote lifelong learning.

Although the primary focus of the text is pathophysiology, we continue to include discussions of the following interconnected topics to highlight their importance for clinical practice:

- A life-span approach that includes special sections on aging and separate chapters on children
- Epidemiology and incidence rates showing regional and worldwide differences that reflect the importance of environmental and lifestyle factors on disease initiation and progression
- Sex differences that affect epidemiology and pathophysiology
- Molecular biology—mechanisms of normal cell function and how their alteration leads to disease
- Clinical manifestations, summaries of treatment, and health promotion/risk reduction
Organization and Content: What's New in the Sixth Edition

The book is organized into two parts: Part One, Basic Concepts of Pathophysiology, and Part Two, Body Systems and Diseases. Two new chapters have been added.

Part One: Basic Concepts of Pathophysiology

Part One introduces basic principles and processes that are important for a contemporary understanding of the pathophysiology of common diseases. The concepts include descriptions of cellular communication; forms of cell injury; genes and genetic disease; epigenetics; fluid and electrolytes and acid and base balance; immunity and inflammation; mechanisms of infection; stress, coping, and illness; and tumor biology. A new chapter, Epigenetics and Disease (Chapter 3), has been added since significant progress is emerging that explains the way heritable changes in gene expression—phenotype without a change in genotype—are influenced by several factors, including age, environment/lifestyle, and disease state.

Significant revisions to Part One also include new or updated information on the following topics:

• Updated content on cell membranes, cell junctions, intercellular communication, transport by vesicles, and stem cells (Chapter 1)
• New chapter on epigenetics and disease (Chapter 3)
• Updated content on cellular adaptations, oxidative stress, chemical injury, types of cell death, and aging (Chapter 4)
• Updates regarding mechanisms of human defense—characteristics of innate and adaptive immunity (Chapters 6 and 7)
• Updated content on mechanisms of infection, antibiotic-resistant disease, and alterations in immune defense (Chapter 8)
• Updated content on stress, inflammation, hormones, and disease (Chapter 9)
• Extensive entire chapter revisions and reorganization of tumor biology (Chapter 10)
• Extensive entire chapter revisions and updated epidemiology of cancer (Chapter 11)
Part Two: Body Systems and Diseases

Part Two presents the pathophysiology of the most common alterations according to body system. To promote readability and comprehension, we have used a logical sequence and uniform approach in presenting the content of the units and chapters. Each unit focuses on a specific organ system and contains chapters related to anatomy and physiology, the pathophysiology of the most common diseases, and common alterations in children. The anatomy and physiology content is presented as a review to enhance the learner's understanding of the structural and functional changes inherent in pathophysiology. A brief summary of normal aging effects is included at the end of these review chapters. The general organization of each disease/disorder discussion includes an introductory paragraph on relevant risk factors and epidemiology, a significant focus on pathophysiology and clinical manifestations, and then a brief review of evaluation and treatment.

The information on reproductive pathophysiology is now presented in two chapters, with a new chapter, Alterations of the Male Reproductive System. Other significant revisions to Part Two include new and/or updated information on the following topics:

• Mechanisms of pain transmission, pain syndromes, and categories of sleep disorders (Chapter 14)
• Alterations in levels of consciousness, seizure disorders, and delirium. Pathogenesis of degenerative brain diseases, the dementias, movement disorders, traumatic brain and spinal cord injury, stroke syndromes, headache, and infections and structural malformations of the CNS (Chapters 15, 16, 17)
• The pathogenesis of type 2 diabetes mellitus (Chapter 19)
• Platelet function and coagulation; anemias, alterations of leukocyte function and myeloid and lymphoid tumors (Chapters 20 and 21)
• Extensive chapter revisions of alterations of hematologic function in children (Chapter 22)
• Extensive chapter revisions on structure and function of the cardiovascular and lymphatic systems (Chapter 23)
• Mechanisms of atherosclerosis, hypertension, coronary artery disease, heart failure, and shock (Chapter 24)
• Pediatric valvular disorders, heart failure, hypertension, obesity, and heart disease (Chapter 25)
• Pathophysiology of acute lung injury, asthma, pneumonia, lung cancer, respiratory distress in the newborn, and cystic fibrosis (Chapters 27 and 28)
• Mechanisms of kidney stone formation, immune processes of glomerulonephritis, and acute and chronic kidney injury (Chapters 30 and 31)

• Female and male reproductive disorders, female and male reproductive cancers, breast diseases and mechanisms of breast cancer, prostate cancer, male breast cancer, and sexually transmitted infections (Chapters 33 and 34)

• Gastroesophageal reflux, nonalcoholic liver disease, inflammatory bowel disease, viral hepatitis, obesity, gluten-sensitive enteropathy, and necrotizing enterocolitis (Chapters 36 and 37)

• Bone cells, bone remodeling, joint and tendon diseases, osteoporosis, rheumatoid arthritis, and osteoarthritis (Chapters 38 and 39)

• Congenital and acquired musculoskeletal disorders, and muscular dystrophies in children (Chapter 40)

• Psoriasis, discoid lupus erythematosus, and atopic dermatitis (Chapters 41 and 42)

Cancer of the various organ systems was updated for all of the chapters.
Features to Promote Learning

A number of features are incorporated into this text that guide and support learning and understanding, including:

- *Chapter Outlines* including page numbers for easy reference
- *Quick Check* questions strategically placed throughout each chapter to help readers confirm their understanding of the material; answers are included on the textbook's Evolve website
- *Health Alerts* with concise discussions of the latest research
- *Risk Factors* boxes for selected diseases
- End-of-chapter *Did You Understand?* summaries that condense the major concepts of each chapter into an easy-to-review list format; printable versions of these are available on the textbook's Evolve website
- *Key Terms* set in blue boldface in text and listed, with page numbers, at the end of each chapter
- Special boxes for *Aging* and *Pediatrics* content that highlight discussions of life-span alterations
Art Program

All of the figures and photographs have been carefully reviewed, revised, or updated. This edition features approximately 100 new or heavily revised illustrations and photographs with a total of approximately 1000 images. The figures are designed to help students visually understand sometimes difficult and complex material. Hundreds of high-quality photographs show clinical manifestations, pathologic specimens, and clinical imaging techniques. Micrographs show normal and abnormal cellular structure. The combination of illustrations, algorithms, photographs, and use of color for tables and boxes allows a more precise understanding of essential information.
Teaching/Learning Package

For Students

The free electronic Student Resources on Evolve include review questions and answers, numerous animations, answers to the Quick Check questions in the book, printable key points, and bonus case studies with questions and answers. A comprehensive Glossary for the textbook of more than 600 terms helps students with the often difficult terminology related to pathophysiology; this is available both on Evolve and in the electronic version of the textbook. These electronic resources enhance learning options for students. Go to http://evolve.elsevier.com/Huether.

The newly rewritten Study Guide includes many different question types, aiming to help the broad spectrum of student learners. Question types include the following:

• Choose the Correct Words
• Complete These Sentences
• Categorize These Clinical Examples
• Explain the Pictures
• Teach These People about Pathophysiology
• Plus many more…

Answers are found in the back of the Study Guide for easy reference for students.

For Instructors

The electronic Instructor Resources on Evolve are available free to instructors with qualified adoptions of the textbook and include the following: TEACH Lesson Plans with case studies to assist with clinical application; a Test Bank of more than 1200 items; PowerPoint Presentations for each chapter, with integrated images, audience response questions, and case studies; and an Image Collection of approximately 1000 key figures from the text. All of these teaching resources are also available to instructors on the book's Evolve site. Plus the Evolve Learning System provides a comprehensive suite of course communication and organization tools that allow you to upload your class calendar and syllabus, post scores and announcements, and more. Go to http://evolve.elsevier.com/Huether.

The most exciting part of the learning support package is Pathophysiology Online, a complete set of online modules that provide thoroughly developed lessons
on the most important and difficult topics in pathophysiology supplemented with illustrations, animations, interactive activities, interactive algorithms, self-assessment reviews, and exams. Instructors can use it to enhance traditional classroom lecture courses or for distance and online-only courses. Students can use it as a self-guided study tool.
Acknowledgments

This book would not be possible without the knowledge and expertise of our contributors, both those who have worked with us through previous editions and the new members of our team. Their reviews and synthesis of the evidence and clear concise presentation of information is a strength of the text. We thank them.

Nancy Kline, PhD, RN was a highly respected colleague, researcher, nurse, and contributor to our textbooks. We dedicate this edition to her memory and the many contributions she made to nursing research, medicine, patient services, and children’s health. We will miss her.

The reviewers for this edition provided excellent recommendations for focus of content and revisions. We appreciate their insightful work.

For more than 30 years Sue Meeks has been the rock of our manuscript preparation. She is masterful at managing details of the numerous revisions, maintains the correct formatting, provides helpful recommendations, and manages the complexity and chaos—all with a wonderful sense of humor. We cannot thank her enough.

Tina Brashers, MD, and Neal Rote, PhD, continued to serve as section editors and contributing authors. Tina is a distinguished teacher and has received numerous awards for her teaching and work with nursing and medical students and faculty. She is nationally known for her leadership and development in promoting and teaching interprofessional collaboration. Tina brings innovation and clarity to the subject of pathophysiology. Her contributions to the online course continue to be intensive and creative, and a significant learning enhancement for students. Thank you, Tina, for the outstanding quality of your work. Neal has major expertise, passion, and hard-to-find precision in the topics of immunity, reproductive biology, and human defenses. His expertise was well placed to rewrite and update the challenging tumor biology chapter. Neal has held many appointments, including department chair, associate dean, and professor in both reproductive biology and pathology. He is a top-notch researcher and reviewer of grants and has received numerous awards and recognition for his teaching. Neal has a gift for creating images that bring clarity to the complex content of immunology. He also completely updated the glossary. Thank you, Neal, for your persistence in promoting understanding and for your continuing devotion to students.

Karen Turner was our excellent Senior Content Development Specialist. Always gracious and efficient, Karen guided us through the hardest times and even the redo times. Thank you, Karen, especially for another set of “eagle eyes.” Jeanne Genz
retired as the Project Manager during the preparation of this edition and we will miss her expertise. Always dedicated and an amazing “can do” attitude, we thank you, Jeanne. Tracey Schriefer picked up the reins without missing a step. Thank you, Tracey, for such diligence—finding and correcting obscure errors. We also thank Beth Welch, who has copyedited our last four editions. Kellie White was our Executive Content Strategist and was responsible for overseeing the entire project. Very organized and a delightful sense of humor, we thank you Kellie. The internal layout, selection of colors, and design of the cover highlight the pedagogy and were done by our Designer, Margaret Reid. Thanks to the team from Graphic World, who created many new images and managed the cleanup and scanning of artwork obtained from many resources.

We thank the Department of Dermatology at the University of Utah School of Medicine, which provided numerous photos of skin lesions. Thank you to our many colleagues and friends at the University of Utah College of Nursing, School of Medicine, Eccles Medical Library, and College of Pharmacy for their helpfulness, suggestions, and critiques.

We extend gratitude to those who contributed to the book supplements. Linda Felver has created an all new inventive and resourceful Study Guide. Thank you, Linda, for your very astute edits. Additional thanks to the reviewers of the Study Guide, Janie Corbitt, Kathleen Murtaugh, and Linda Turchin. A special thanks to Linda Turchin, Joanna Cain, Stephen Krau, and Melanie Cole for their thorough approach in preparing the materials for the Evolve website, and to Linda Turchin, Kim Webb, and Lauren Mussig for the valuable reviews of these resources. Tina Brashers, Nancy Burruss, Mandi Counters, Joe Gordon, Melissa Geist, Kay Gaehle, Stephen Krau, Jason Mott, and Kim Webb also updated the interactive online lessons and activities for *Pathophysiology Online*.

Special thanks to faculty and nursing students and other health science students for your questions and suggestions. It is because of you, the future clinicians, that we are so motivated to put our best efforts into this work.

Sincerely and with great affection we thank our families, especially Mae and John. Always supportive, you make the work possible!

*Sue E. Huether*

*Kathryn L. McCance*
Introduction to Pathophysiology

The word root “patho” is derived from the Greek word *pathos*, which means suffering. The Greek word root “logos” means discourse or, more simply, system of formal study, and “physio” refers to functions of an organism. Altogether, pathophysiology is the study of the underlying changes in body physiology (molecular, cellular, and organ systems) that result from disease or injury. Important, however, is the inextricable component of suffering and the psychological, spiritual, social, cultural, and economic implications of disease.

The science of pathophysiology seeks to provide an understanding of the mechanisms of disease and to explain how and why alterations in body structure and function lead to the signs and symptoms of disease. Understanding pathophysiology guides healthcare professionals in the planning, selection, and evaluation of therapies and treatments.

Knowledge of human anatomy and physiology and the interrelationship among the various cells and organ systems of the body is an essential foundation for the study of pathophysiology. Review of this subject matter enhances comprehension of pathophysiologic events and processes. Understanding pathophysiology also entails the utilization of principles, concepts, and basic knowledge from other fields of study including pathology, genetics, epigenetics, immunology, and epidemiology. A number of terms are used to focus the discussion of pathophysiology; they may be used interchangeably at times, but that does not necessarily indicate that they have the same meaning. Those terms are reviewed here for the purpose of clarification.

**Pathology** is the investigation of structural alterations in cells, tissues, and organs, which can help identify the cause of a particular disease. Pathology differs from **pathogenesis**, which is the pattern of tissue changes associated with the development of disease. **Etiology** refers to the study of the cause of disease. Diseases may be caused by infection, heredity, gene–environment interactions, alterations in immunity, malignancy, malnutrition, degeneration, or trauma. Diseases that have no identifiable cause are termed **idiopathic**. Diseases that occur as a result of medical treatment are termed **iatrogenic** (for example, some antibiotics can injure the kidney and cause renal failure). Diseases that are acquired as a consequence of being in a hospital environment are called **nosocomial**. An infection that develops as a result of a person's immune system being depressed after receiving cancer treatment during a hospital stay would be defined as a nosocomial infection.

**Diagnosis** is the naming or identification of a disease. A diagnosis is made from
an evaluation of the evidence accumulated from the presenting signs and symptoms, health and medical history, physical examination, laboratory tests, and imaging. A **prognosis** is the expected outcome of a disease. **Acute disease** is the sudden appearance of signs and symptoms that last only a short time. **Chronic disease** develops more slowly and the signs and symptoms last for a long time, perhaps for a lifetime. Chronic diseases may have a pattern of remission and exacerbation. **Remissions** are periods when symptoms disappear or diminish significantly. **Exacerbations** are periods when the symptoms become worse or more severe. A **complication** is the onset of a disease in a person who is already coping with another existing disease (for example, a person who has undergone surgery to remove a diseased appendix may develop the complication of a wound infection or pneumonia). **Sequelae** are unwanted outcomes of having a disease or are the result of trauma, such as paralysis resulting from a stroke or severe scarring resulting from a burn.

**Clinical manifestations** are the signs and symptoms or **evidence** of disease. **Signs** are objective alterations that can be observed or measured by another person, measures of bodily functions such as pulse rate, blood pressure, body temperature, or white blood cell count. Some signs are **local**, such as redness or swelling, and other signs are **systemic**, such as fever. **Symptoms** are subjective experiences reported by the person with disease, such as pain, nausea, or shortness of breath; and they vary from person to person. The **prodromal period** of a disease is the time during which a person experiences vague symptoms such as fatigue or loss of appetite before the onset of specific signs and symptoms. The term **insidious symptoms** describes vague or nonspecific feelings and an awareness that there is a change within the body. Some diseases have a **latent period**, a time during which no symptoms are readily apparent in the affected person, but the disease is nevertheless present in the body; an example is the incubation phase of an infection or the early growth phase of a tumor. A **syndrome** is a group of symptoms that occur together and may be caused by several interrelated problems or a specific disease; severe acute respiratory syndrome (SARS), for example, presents with a set of symptoms that include headache, fever, body aches, an overall feeling of discomfort, and sometimes dry cough and difficulty breathing. A **disorder** is an abnormality of function; this term also can refer to an illness or a particular problem such as a bleeding disorder.

**Epidemiology** is the study of tracking patterns or disease occurrence and transmission among populations and by geographic areas. **Incidence** of a disease is the number of new cases occurring in a specific time period. **Prevalence** of a disease is the number of existing cases within a population during a specific time period.
**Risk factors**, also known as **predisposing factors**, increase the probability that disease will occur, but these factors are not the *cause* of disease. Risk factors include heredity, age, gender, race, environment, and lifestyle. A **precipitating factor** is a condition or event that *does* cause a pathologic event or disorder. For example, asthma is precipitated by exposure to an allergen, or angina (pain) is precipitated by exertion.

Pathophysiology is an exciting field of study that is ever-changing as new discoveries are made. Understanding pathophysiology empowers healthcare professionals with the knowledge of how and why disease develops and informs their decision making to ensure optimal healthcare outcomes. Embedded in the study of pathophysiology is understanding that suffering is a personal, individual experience and a major component of disease.

All body functions depend on the integrity of cells. Therefore an understanding of cellular biology is increasingly necessary to comprehend disease processes. An overwhelming amount of information reveals how cells behave as a multicellular “social” organism. At the heart of it all is cellular communication (cellular “crosstalk”)—how messages originate and are transmitted, received, interpreted, and used by the cell. Streamlined conversation between, among, and within cells maintains cellular function and specialization. Cells must demonstrate a “chemical fondness” for other cells to maintain the integrity of the entire organism. When they no longer tolerate this fondness, the conversation breaks down, and cells either adapt (sometimes altering function) or become vulnerable to isolation, injury, or disease.
Prokaryotes and Eukaryotes

Living cells generally are divided into eukaryotes and prokaryotes. The cells of higher animals and plants are eukaryotes, as are the single-celled organisms, fungi, protozoa, and most algae. Prokaryotes include cyanobacteria (blue-green algae), bacteria, and rickettsiae. Prokaryotes traditionally were studied as core subjects of molecular biology. Today, emphasis is on the eukaryotic cell; much of its structure and function have no counterpart in bacterial cells.

Eukaryotes (eu = good; karyon = nucleus; also spelled eucaryotes) are larger and have more extensive intracellular anatomy and organization than prokaryotes. Eukaryotic cells have a characteristic set of membrane-bound intracellular compartments, called organelles, that includes a well-defined nucleus. The prokaryotes contain no organelles, and their nuclear material is not encased by a nuclear membrane. Prokaryotic cells are characterized by lack of a distinct nucleus.

Besides having structural differences, prokaryotic and eukaryotic cells differ in chemical composition and biochemical activity. The nuclei of prokaryotic cells carry genetic information in a single circular chromosome, and they lack a class of proteins called histones, which in eukaryotic cells bind with deoxyribonucleic acid (DNA) and are involved in the supercoiling of DNA. Eukaryotic cells have several or many chromosomes. Protein production, or synthesis, in the two classes of cells also differs because of major structural differences in ribonucleic acid (RNA)–protein complexes. Other distinctions include differences in mechanisms of transport across the outer cellular membrane and in enzyme content.
Cellular Functions

Cells become specialized through the process of differentiation, or maturation, so that some cells eventually perform one kind of function and other cells perform other functions. Cells with a highly developed function, such as movement, often lack some other property, such as hormone production, which is more highly developed in other cells.

The eight chief cellular functions are as follows:

1. Movement. Muscle cells can generate forces that produce motion. Muscles that are attached to bones produce limb movements, whereas those muscles that enclose hollow tubes or cavities move or empty contents when they contract (e.g., the colon).

2. Conductivity. Conduction as a response to a stimulus is manifested by a wave of excitation, an electrical potential that passes along the surface of the cell to reach its other parts. Conductivity is the chief function of nerve cells.

3. Metabolic absorption. All cells can take in and use nutrients and other substances from their surroundings.

4. Secretion. Certain cells, such as mucous gland cells, can synthesize new substances from substances they absorb and then secrete the new substances to serve as needed elsewhere.

5. Excretion. All cells can rid themselves of waste products resulting from the metabolic breakdown of nutrients. Membrane-bound sacs (lysosomes) within cells contain enzymes that break down, or digest, large molecules, turning them into waste products that are released from the cell.

6. Respiration. Cells absorb oxygen, which is used to transform nutrients into energy in the form of adenosine triphosphate (ATP). Cellular respiration, or oxidation, occurs in organelles called mitochondria.

7. Reproduction. Tissue growth occurs as cells enlarge and reproduce themselves. Even without growth, tissue maintenance requires that new cells be produced to replace cells that are lost normally through cellular death. Not all cells are capable of continuous division (see Chapter 4).

8. Communication. Communication is vital for cells to survive as a society of cells.
Appropriate communication allows the maintenance of a dynamic steady state.
Structure and Function of Cellular Components

Figure 1-1, A, shows a “typical” eukaryotic cell, which consists of three components: an outer membrane called the plasma membrane, or plasmalemma; a fluid “filling” called cytoplasm (Figure 1-1, B); and the “organs” of the cell—the membrane-bound intracellular organelles, among them the nucleus.
Nucleus

The nucleus, which is surrounded by the cytoplasm and generally is located in the
center of the cell, is the largest membrane-bound organelle. Two pliable membranes compose the **nuclear envelope** (Figure 1-2, A). The nuclear envelope is pockmarked with pits, called **nuclear pores**, which allow chemical messages to exit and enter the nucleus (see Figure 1-2). The outer membrane is continuous with membranes of the endoplasmic reticulum (see Figure 1-1). The nucleus contains the **nucleolus** (a small dense structure composed largely of ribonucleic acid), most of the cellular DNA, and the DNA-binding proteins (i.e., the histones) that regulate its activity. The DNA “chain” in eukaryotic cells is so long that it is easily broken. Therefore the histones that bind to DNA cause DNA to fold into chromosomes (Figure 1-2, C), which decreases the risk of breakage and is essential for cell division in eukaryotes.
The primary functions of the nucleus are cell division and control of genetic information. Other functions include the replication and repair of DNA and the transcription of the information stored in DNA. Genetic information is transcribed into ribonucleic acid (RNA), which can be processed into messenger, transport, and ribosomal RNAs and introduced into the cytoplasm, where it directs cellular activities. Most of the processing of RNA occurs in the nucleolus. (The roles of DNA and RNA in protein synthesis are discussed in Chapter 2.)

**Cytoplasmic Organelles**

Cytoplasm is an aqueous solution (cytosol) that fills the cytoplasmic matrix—the
space between the nuclear envelope and the plasma membrane. The cytosol represents about half the volume of a eukaryotic cell. It contains thousands of enzymes involved in intermediate metabolism and is crowded with ribosomes making proteins (see Figure 1-1, B). Newly synthesized proteins remain in the cytosol if they lack a signal for transport to a cell organelle. The organelles suspended in the cytoplasm are enclosed in biologic membranes, so they can simultaneously carry out functions requiring different biochemical environments. Many of these functions are directed by coded messages carried from the nucleus by RNA. The functions include synthesis of proteins and hormones and their transport out of the cell, isolation and elimination of waste products from the cell, performance of metabolic processes, breakdown and disposal of cellular debris and foreign proteins (antigens), and maintenance of cellular structure and motility. The cytosol is a storage unit for fat, carbohydrates, and secretory vesicles. Table 1-1 lists the principal cytoplasmic organelles.

Quick Check 1-1

1. Why is the process of differentiation essential to specialization? Give an example.

2. Describe at least two cellular functions.

Plasma Membranes

Every cell is contained within a membrane with gates, channels, and pumps. Membranes surround the cell or enclose an intracellular organelle and are exceedingly important to normal physiologic function because they control the composition of the space, or compartment, they enclose. Membranes can allow or exclude various molecules and, because of selective transport systems, they can move molecules in or out of the space (Figure 1-3). By controlling the movement of substances from one compartment to another, membranes exert a powerful influence on metabolic pathways. Directional transport is facilitated by polarized domains, distinct apical and basolateral domains. **Cell polarity**, the direction of cellular transport, maintains normal cell and tissue structure for numerous functions (for example, movement of nutrients in and out of the cell) and becomes altered with diseases (Figure 1-4). The plasma membrane also has an important role in cell-to-cell recognition. Other functions of the plasma membrane include cellular mobility and the maintenance of cellular shape (Table 1-2).

## Membrane Composition

The basic structure of cell membranes is the **lipid bilayer**, composed of two apposing leaflets and proteins that span the bilayer or interact with the lipids on either side of the two leaflets (*Figure 1-5*). Lipid research is growing and principles of membrane organization are being overhauled. In short, the main constituents of cell membranes are lipids and proteins. Historically, the plasma membrane was described as a fluid lipid bilayer (fluid mosaic model) composed of a uniform lipid distribution with inserted moving proteins. It now appears that the lipid bilayer is a much more complex structure where lipids and proteins are not uniformly distributed but can separate into discrete units called microdomains, differing in their protein and lipid compositions. Different membranes have varying percentages of lipids and proteins. Intracellular membranes may have a higher percentage of proteins than do plasma membranes, presumably because most enzymatic activity occurs within organelles. The membrane organization is achieved through noncovalent bonds that allow different physical states called phases. The lipid bilayer can be structured in three main phases: solid gel phase, fluid liquid-crystalline phase, and liquid-ordered phase (*Figure 1-5, B*). These phases can change under physiologic factors such as temperature and pressure.
fluctuations. Carbohydrates are mainly associated with plasma membranes, in which they are chemically combined with lipids, forming glycolipids, and with proteins, forming glycoproteins (see Figure 1-5).
FIGURE 1-5 Lipid Bilayer Membranes. A, Concepts of biologic membranes have markedly changed in the last two decades, from the classic fluid mosaic model to the current model that lipids and proteins are not evenly distributed but can isolate into microdomains, differing in their protein and lipid composition. B, An example of a microdomain is lipid rafts (yellow). Rafts are dynamic domain structures composed of cholesterol, sphingolipids, and membrane proteins important in different cellular processes. Various models exist to clarify the functions of domains. The three major phases of lipid bilayer organization include a solid gel phase (e.g., with low temperatures), a liquid-ordered phase (high temperatures), and a fluid liquid-crystalline (or liquid-disordered) phase. Some membrane-associated proteins are integrated into the lipid bilayer; other proteins are loosely attached to the outer and inner surfaces of the membrane. Transmembrane proteins protrude through the entire outer and inner surfaces of the membrane, and they can be attracted to microdomains through specific interactions with lipids. Interaction of the membrane proteins with distinct lipids depends on the hydrophobic thickness of the membrane, the lateral pressures of the membrane (mechanical force may shift protein channels from an open to closed state), the polarity or electrical charges at the lipid-protein interface, and the presence on the protein side of amino acid side chains. Important for pathophysiology is the proposal that protein-lipid interactions can be critical for correct insertion, folding, and orientation of membrane proteins. For example, diseases related to lipids that interfere with protein folding are becoming more prevalent. C, The cell membrane is not static but is always moving. Observed for the first time from measurements taken at the National Institute of Standards and Technology (NIST) and France’s Institut Laue-Langevin (ILL). (Adapted from Bagatolli LA et al: Prog Lipid Res 49[4]:378-389, 2010; Contreras FX et al: Cold Spring Harb Perspect Biol 3[6]: pii a004705,
The outer surface of the plasma membrane in many types of cells, especially endothelial cells and adipocytes, is not smooth but dimpled with flask-shaped invaginations known as caveolae (“tiny caves”). Caveolae serve as a storage site for many receptors, provide a route for transport into the cell, and act as the initiator for relaying signals from several extracellular chemical messengers into the cell's interior (see p. 24).

**Lipids.**

Each lipid molecule is said to be polar, or amphipathic, which means that one part is hydrophobic (uncharged, or “water hating”) and another part is hydrophilic (charged, or “water loving”) (Figure 1-6). The membrane spontaneously organizes itself into two layers because of these two incompatible solubilities. The hydrophobic region (hydrophobic tail) of each lipid molecule is protected from water, whereas the hydrophilic region (hydrophilic head) is immersed in it. The bilayer serves as a barrier to the diffusion of water and hydrophilic substances, while allowing lipid-soluble molecules, such as oxygen ($O_2$) and carbon dioxide ($CO_2$), to diffuse through the membrane readily.

A major component of the plasma membrane is a bilayer of lipid molecules—glycerophospholipids, sphingolipids, and sterols (for example, cholesterol). The
most abundant lipids are phospholipids. **Phospholipids** have a phosphate-containing hydrophilic head connected to a hydrophobic tail. Phospholipids and glycolipids form self-sealing lipid bilayers. Lipids along with protein assemblies act as “molecular glue” for the structural integrity of the membrane. Investigators are studying the concept of lipid rafts. **Membrane lipid rafts (MLRs)** appear to be structurally and functionally distinct regions of the plasma membrane and consist of cholesterol and sphingolipid-dependent microdomains that form a network of lipid-lipid, protein-protein, and protein-lipid interactions (Figures 1-5, B, and 1-7) Although discrepancies between experimental results exist, two main types of MLRs are hypothesized: those that contain the cholesterol-binding protein caveolin (see p. 24) and those that do not. Researchers hypothesized there are lipid rafts that have several functions, including (1) providing cellular polarity and organization of signaling trafficking; (2) acting as platforms for extracellular matrix (ECM) adhesion and intracellular cytoskeletal tethering to the plasma membrane through cellular adhesion molecules (CAMs, see p. 8); (3) enabling signaling across the membrane, which can rearrange cytoskeletal architecture and regulate cell growth, migration, and other functions; and (4) allowing entry of viruses, bacteria, toxins, and nanoparticles.

![FIGURE 1-7 Lipid Rafts](Lipid Rafts.png)

**Proteins.**

A **protein** is made from a chain of amino acids known as **polypeptides**. There are 20 types of amino acids in proteins and each type of protein has a unique sequence
of amino acids. Proteins are the major workhorses of the cell. After translation (the synthesis of protein from RNA, see Chapter 2) of a protein, posttranslational modifications (PTMs) are the methods used to diversify the limited numbers of proteins generated. These modifications alter the activity and functions of proteins and have become very important in understanding diseases. Researchers have known for decades that pathogens interfere with the host's PTMs.\(^6\) New approaches are being used to understand changes in proteins—a field called proteomics is the study of the proteome, or entire set of proteins expressed by a genome from synthesis, translocation, and modification (e.g., folding), and the analysis of the roles of proteomes in a staggering number of diseases.

Membrane proteins associate with the lipid bilayer in different ways (Figure 1-8), including (1) transmembrane proteins that extend across the bilayer and exposed to an aqueous environment on both sides of the membrane (see Figure 1-8, A); (2) proteins located almost entirely in the cytosol and associated with the cytosolic half of the lipid bilayer by an α helix exposed on the surface of the protein (see Figure 1-8, B); (3) proteins that exist outside the bilayer, on one side or the other, and attached to the membrane by one or more covalently attached lipid groups (see Figure 1-8, C); and (4) proteins bound indirectly to one or the other bilayer membrane face and held in place by their interactions with other proteins (see Figure 1-8, D).\(^1\)

![Figure 1-8](image)

Proteins directly attached to the membrane bilayer can be removed by dissolving the bilayer with detergents called integral membrane proteins. The remaining
proteins that can be removed by gentler procedures that interfere with protein-protein interactions but do not dissolve the bilayer are known as **peripheral membrane proteins**.

Proteins exist in densely folded molecular configurations rather than straight chains; so most hydrophilic units are at the surface of the molecule and most hydrophobic units are inside. Membrane proteins, like other proteins, are synthesized by the ribosome and then make their way, called **trafficking**, to different membrane locations of a cell. **Trafficking** places unique demands on membrane proteins for folding, translocation, and stability. Thus, much research is now being done to understand misfolded proteins (for example, as a cause of disease; **Box 1-1**).

### Box 1-1

**Endoplasmic Reticulum, Protein Folding, and ER Stress**

Protein folding in the endoplasmic reticulum (ER) is critical for us. As the biologic workhorses, proteins perform vital functions in every cell. To do these tasks proteins must fold into complex three-dimensional structures (see figure). Most secreted proteins **fold** and are modified in an error-free manner, but ER or cell stress, mutations, or random (stochastic) errors during protein synthesis can decrease the folding amount or the rate of folding. Pathophysiologic processes, such as viral infections, environmental toxins, and mutant protein expression, can perturb the sensitive ER environment. Natural processes also can perturb the environment, such as the large protein-synthesizing load placed on the ER. These perturbations cause the accumulation of immature and abnormal proteins in cells, leading to **ER stress**. Fortunately, the ER is loaded with protective ways to help folding; for example, protein **chaperones** facilitate folding and prevent the formation of off-pathway types. Because specialized cells produce large amounts of secreted proteins, the movement or flux through the ER is tremendous. Therefore misfolded proteins not repaired in the ER are observed in some diseases and can initiate apoptosis or cell death. It has recently been shown that the endoplasmic reticulum mediates intracellular signaling pathways in response to the accumulation of unfolded or misfolded proteins; collectively, the pathways are known as the **unfolded-protein response (UPR)**. Investigators are studying UPR-associated inflammation and how the UPR is coupled to inflammation in health and disease. Specific diseases include Alzheimer disease, Parkinson disease, prion disease, amyotrophic lateral sclerosis, and diabetes mellitus. Additionally being
studied is ER stress and how it may accelerate age-related dysfunction.

Although membrane structure is determined by the lipid bilayer, membrane functions are determined largely by proteins. Proteins act as (1) recognition and binding units (receptors) for substances moving into and out of the cell; (2) pores or transport channels for various electrically charged particles, called ions or electrolytes, and specific carriers for amino acids and monosaccharides; (3) specific enzymes that drive active pumps to promote concentration of certain ions, particularly potassium (K⁺), within the cell while keeping concentrations of other ions (for example, sodium, Na⁺), less than concentrations found in the extracellular environment; (4) cell surface markers, such as glycoproteins (proteins attached to carbohydrates), that identify a cell to its neighbor; (5) cell adhesion molecules (CAMs), or proteins that allow cells to hook together and form attachments of the cytoskeleton for maintaining cellular shape; and (6) catalysts of chemical reactions (for example, conversion of lactose to glucose; see Figure 1-3). Membrane proteins are key components of energy transduction, converting chemical energy into electrical energy, or electrical energy into either mechanical energy or synthesis of ATP. Investigators are studying ATP enzymes and the changes in shape of biologic membranes, particularly mitochondrial membranes, and their relationship to aging and disease.8-10
In animal cells, the plasma membrane is stabilized by a meshwork of proteins attached to the underside of the membrane called the cell cortex. Human red blood cells have a cell cortex that maintains their flattened biconcave shape.¹

Protein regulation in a cell: protein homeostasis.

The cellular protein pool is in constant change or flux. The number of copies of a protein in a cell depends on how quickly it is made and how long it survives or is broken down. This adaptable system of protein homeostasis is defined by the “proteostasis” network comprised of ribosomes (makers); chaperones (helpers); and two protein breakdown systems or proteolytic systems—lysosomes and the ubiquitin-proteasome system (UPS). These systems regulate protein homeostasis under a large variety of conditions, including variations in nutrient supply, the existence of oxidative stress or cellular differentiation, changes in temperature, and the presence of heavy metal ions and other sources of stress.¹¹ Malfunction or failure of the proteostasis network is associated with human disease¹² (Figure 1-9).

**FIGURE 1-9** Protein Homeostasis System and Outcomes. A main role of the protein homeostasis network (proteostasis) is to minimize protein misfolding and protein aggregation. The network includes ribosome-mediated protein synthesis, chaperone (folding helpers in the ER) and enzyme mediated folding, breakdown systems of lysosome and proteasome-mediated protein degradation, and vesicular trafficking. The network integrates biologic pathways that balance folding, trafficking, and protein degradation depicted by arrows b, d, e, f, g, h, and i. ER, Endoplasmic reticulum. (Adapted from Lindquist SL, Kelly JW: Cold Spring Harb Perspect Biol 3[12]:pii: a004907, 2011.)
Carbohydrates.

The short chains of sugars or carbohydrates (oligosaccharides) contained within the plasma membrane are generally bound to membrane proteins (glycoproteins) and lipids (glycolipids). Long polysaccharide chains attached to membrane proteins are called proteoglycans. All of the carbohydrate on the glycoproteins, proteoglycans, and glycolipids is located on the outside of the plasma membrane and the carbohydrate coating is called the glycocalyx. The glycocalyx helps protect the cell from mechanical damage. Additionally, the layer of carbohydrate gives the cell a slimy surface that assists the mobility of other cells, like leukocytes, to squeeze through the narrow spaces. The functions of carbohydrates are more than protection and lubrication and include specific cell-cell recognition and adhesion. Intercellular recognition is an important function of membrane oligosaccharides; for example, the transmembrane proteins called lectins, which bind to a particular oligosaccharide, recognize neutrophils at the site of bacterial infection. This recognition allows the neutrophil to adhere to the blood vessel wall and migrate from the blood into the infected tissue to help eliminate the invading bacteria.

Cellular Receptors

Cellular receptors are protein molecules on the plasma membrane, in the cytoplasm, or in the nucleus that can recognize and bind with specific smaller molecules called ligands (from the Latin ligare, “to bind”) (Figure 1-10). The region of a protein that associates with a ligand is called its binding site. Hormones, for example, are ligands. Recognition and binding depend on the chemical configuration of the receptor and its smaller ligand, which must fit together somewhat like pieces of a jigsaw puzzle (see Chapter 18). Binding selectively to a protein receptor with high affinity to a ligand depends on formation of weak, noncovalent interactions—hydrogen bonds, electrostatic attractions, and van der Waals attractions—and favorable hydrophobic forces. Numerous receptors are found in most cells, and ligand binding to receptors activates or inhibits the receptor's associated signaling or biochemical pathway (see p. 12).
FIGURE 1-10 Cellular Receptors. (A) 1. Plasma membrane receptor for a ligand (here, a hormone molecule) on the surface of an integral protein. A neurotransmitter can exert its effect on a postsynaptic cell by means of two fundamentally different types of receptor proteins: 2, channel-linked receptors, and 3, non–channel-linked receptors. Channel-linked receptors are also known as ligand-gated channels. (B) Example of ligand-receptor interaction. Insulin-like growth factor 1 (IGF-1) is a ligand and binds to the insulin-like growth factor 1 receptor (IGF-1R). With binding at the cell membrane the intracellular signaling pathway is activated, causing translation of new proteins to act as intracellular communicators. This pathway is important for cancer growth. Researchers are developing pharmacologic strategies to reduce signaling at and downstream of the insulin-like growth factor 1 receptor (IGF-1R), hoping this will lead to compounds useful in cancer treatment.
**Plasma membrane receptors** protrude from or are exposed at the external surface of the membrane and are important for cellular uptake of ligands (see Figure 1-10). The ligands that bind with membrane receptors include hormones, neurotransmitters, antigens, complement components, lipoproteins, infectious agents, drugs, and metabolites. Many new discoveries concerning the specific interactions of cellular receptors with their respective ligands have provided a basis for understanding disease.

Although the chemical nature of ligands and their receptors differs, receptors are classified based on their location and function. Cellular type determines overall cellular function, but plasma membrane receptors determine which ligands a cell will bind with and how the cell will respond to the binding. Specific processes also control intracellular mechanisms.

Receptors for different drugs are found on the plasma membrane, in the cytoplasm, and in the nucleus. Membrane receptors have been found for certain anesthetics, opiates, endorphins, enkephalins, antibiotics, cancer chemotherapeutic agents, digitalis, and other drugs. Membrane receptors for endorphins, which are opiate-like peptides isolated from the pituitary gland, are found in large quantities in pain pathways of the nervous system (see Chapters 13 and 14). With binding to the receptor, the endorphins (or drugs such as morphine) change the cell's permeability to ions, increase the concentration of molecules that regulate intracellular protein synthesis, and initiate molecular events that modulate pain perception.

Receptors for infectious microorganisms, or antigen receptors, bind bacteria, viruses, and parasites to the cell membrane. Antigen receptors on white blood cells (lymphocytes, monocytes, macrophages, granulocytes) recognize and bind with antigenic microorganisms and activate the immune and inflammatory responses (see Chapter 6).
Cell-to-Cell Adhesions

Cells are small and squishy, not like bricks. They are enclosed only by a flimsy membrane, yet the cell depends on the integrity of this membrane for its survival. How can cells be connected strongly, with their membranes intact, to form a muscle that can lift this textbook? Plasma membranes not only serve as the outer boundaries of all cells but also allow groups of cells to be held together robustly, in cell-to-cell adhesions, to form tissues and organs. Once arranged, cells are linked by three different means: (1) cell adhesion molecules in the cell's plasma membrane (see p. 8), (2) the extracellular matrix, and (3) specialized cell junctions.

Extracellular Matrix

Cells can be united by attachment to one another or through the extracellular matrix (including the basement membrane), which the cells secrete around themselves. The extracellular matrix is an intricate meshwork of fibrous proteins embedded in a watery, gel-like substance composed of complex carbohydrates (Figure 1-11). The matrix is similar to glue; however, it provides a pathway for diffusion of nutrients, wastes, and other water-soluble substances between the blood and tissue cells. Interwoven within the matrix are three groups of macromolecules: (1) fibrous structural proteins, including collagen and elastin; (2) adhesive glycoproteins, such as fibronectin; and (3) proteoglycans and hyaluronic acid.

1. **Collagen** forms cablelike fibers or sheets that provide tensile strength or resistance to longitudinal stress. Collagen breakdown, such as occurs in osteoarthritis, destroys the fibrils that give cartilage its tensile strength.

2. **Elastin** is a rubber-like protein fiber most abundant in tissues that must be capable of stretching and recoiling, such as found in the lungs.

3. **Fibronectin**, a large glycoprotein, promotes cell adhesion and cell anchorage. Reduced amounts have been found in certain types of cancerous cells; this allows cancer cells to travel, or metastasize, to other parts of the body. All of these macromolecules occur in intercellular junctions and cell surfaces and may assemble into two different components: interstitial matrix and basement membrane (BM) (see Figure 1-11).
FIGURE 1-11  Extracellular Matrix. A, Tissues are not just cells but also extracellular space. The extracellular space is an intricate network of macromolecules called the extracellular matrix (ECM). The macromolecules that constitute the ECM are secreted locally (by mostly fibroblasts) and assembled into a meshwork in close association with the surface of the cell that produced them. Two main classes of macromolecules include proteoglycans, which are bound to polysaccharide chains called glycosaminoglycans, and fibrous proteins (e.g., collagen, elastin, fibronectin, and laminin), which have structural and adhesive properties. Together the proteoglycan molecules form a gel-like ground substance in which the fibrous proteins are embedded. The gel permits rapid diffusion of nutrients, metabolites, and hormones between the blood and the tissue cells. Matrix proteins modulate cell-matrix interactions, including normal tissue remodeling (which can become abnormal, for example, with chronic inflammation). Disruptions of this balance result in serious diseases such as arthritis, tumor growth, and other pathologic conditions. B, Scanning electron micrograph of a chick embryo where a portion of the epithelium has been removed, exposing the curtain-like extracellular matrix. (A, adapted from Kumar V et al: Robbins and Cotran pathologic basis of disease, ed 9, Philadelphia, 2015, Saunders; B, © Robert L Trelstad; from Gartner LP, Hiatt JL: Color textbook of histology, ed 3, St Louis, 2006, Saunders/Elsevier.)

The basement membrane is a thin, tough layer of extracellular matrix (connective tissue) underlying the epithelium of many organs and is also called the basal lamina (see Figure 1-11, B).

The extracellular matrix is secreted by fibroblasts (“fiber formers”) (Figure 1-12), local cells that are present in the matrix. The matrix and the cells within it are known collectively as connective tissue because they interconnect cells to form
tissues and organs. Human connective tissues are enormously varied. They can be hard and dense, like bone; flexible, like tendons or the dermis of the skin; resilient and shock absorbing, like cartilage; or soft and transparent, similar to the jelly-like substance that fills the eye. In all these examples, the majority of the tissue is composed of extracellular matrix, and the cells that produce the matrix are scattered within it like raisins in a pudding (see Figure 1-12).

![Figure 1-12](image)

**FIGURE 1-12** Fibroblasts in Connective Tissue. This micrograph shows tissue from the cornea of a rat. The extracellular matrix surrounds the fibroblasts (F). (From Nishida T et al. The extracellular matrix of animal connective tissues, Invest Ophthalmol Vis Sci 29:1877-1880, 1998.)

The matrix is not just passive scaffolding for cellular attachment but also helps regulate the function of the cells with which it interacts. The matrix helps regulate such important functions as cell growth and differentiation.

**Specialized Cell Junctions**
Cells in direct physical contact with neighboring cells are often interconnected at specialized plasma membrane regions called **cell junctions**. Cell junctions are classified by their function: (1) some hold cells together and form a tight seal (tight junctions); (2) some provide strong mechanical attachments (adherens junctions, desmosomes, hemidesmosomes); (3) some provide a special type of chemical communication (for example, inorganic ions and small water-soluble molecules to move from the cytosol of one cell to the cytosol of another cell), such as those causing an electrical wave (gap junctions); and (4) some maintain apico-basal polarity of individual epithelial cells (tight junctions) (Figure 1-13). Overall, cell junctions make the epithelium leak-proof and mediate mechanical attachment of one cell to another, allow communicating tunnels and maintaining cell polarity.
Cell junctions can be classified as symmetric and asymmetric. Symmetric junctions include tight junctions, the belt desmosome (zonula adherens), desmosomes (macula adherens), and gap junctions (also called intercellular channel...
or communicating junctions).\textsuperscript{13} An asymmetric junction is the hemidesmosome (see Figure 1-13). Together they form the \textbf{junctional complex}. \textbf{Desmosomes} unite cells either by forming continuous bands or belts of epithelial sheets or by developing button-like points of contact. Desmosomes also act as a system of braces to maintain structural stability. \textbf{Tight junctions} are barriers to diffusion, prevent the movement of substances through transport proteins in the plasma membrane, and prevent the leakage of small molecules between the plasma membranes of adjacent cells. \textbf{Gap junctions} are clusters of communicating tunnels or connexons that allow small ions and molecules to pass directly from the inside of one cell to the inside of another. \textbf{Connexons} are hemichannels that extend outward from each of the adjacent plasma membranes (Figure 1-13, C).

Multiple factors regulate gap junction intercellular communication, including voltage across the junction, intracellular pH, intracellular Ca\textsuperscript{++} concentration, and protein phosphorylation. The most abundant human connexin is connexin 43 (Cx43).\textsuperscript{14} Investigators recently showed that loss of Cx43 expression in colorectal tumors is correlated with a shorter cancer-free survival rate.\textsuperscript{15} This study is the first evidence that Cx43 acts as a tumor suppressor for colorectal cancer (enhances apoptosis) and therefore may be an important prognostic marker and target for therapy.\textsuperscript{15} Investigators also recently reported that glycyrrhizic acid (GA), a glycoside of licorice root extracts, may be a strong chemopreventive agent against carcinogens; induced colon cancer in rats and Cx43 is one target.\textsuperscript{16} Too much GA often in humans may lead to hypokalemia and hypertension.\textsuperscript{17}

The junctional complex is a highly permeable part of the plasma membrane. Its permeability is controlled by a process called \textbf{gating}. Increased levels of cytoplasmic calcium cause decreased permeability at the junctional complex. Gating enables uninjured cells to protect themselves from injured neighbors. Calcium is released from injured cells.
Cellular Communication and Signal Transduction

Cells need to communicate with each other to maintain a stable internal environment, or homeostasis; to regulate their growth and division; to oversee their development and organization into tissues; and to coordinate their functions. Cells communicate by using hundreds of kinds of signal molecules, for example, insulin (see Figure 1-10, B). Cells communicate in three main ways: (1) they display plasma membrane–bound signaling molecules (receptors) that affect the cell itself and other cells in direct physical contact (Figure 1-14, A); (2) they affect receptor proteins inside the target cell and the signal molecule has to enter the cell to bind to them (Figure 1-14, B); and (3) they form protein channels (gap junctions) that directly coordinate the activities of adjacent cells (Figure 1-14, C). Alterations in cellular communication affect disease onset and progression. In fact, if a cell cannot perform gap junctional intercellular communication, normal growth control and cell differentiation is compromised, thereby favoring cancerous tumor development (see Chapter 10). (Communication through gap junctions was discussed earlier, and contact signaling by plasma membrane–bound molecules is discussed on this page and on p. 15.) Secreted chemical signals involve communication locally and at a distance. Primary modes of intercellular signaling are contact-dependent, paracrine, hormonal, neurohormonal, and neurotransmitter. Autocrine stimulation occurs when the secreting cell targets itself (Figure 1-15).

**FIGURE 1-14** Cellular Communication. Three primary ways cells communicate with one another. (B adapted from Alberts B et al: Molecular biology of the cell, ed 5, New York, 2008, Garland.)
Contact-dependent signaling requires cells to be in close membrane-membrane contact. In paracrine signaling, cells secrete local chemical mediators that are quickly taken up, destroyed, or immobilized. Paracrine signaling usually involves different cell types; however, cells also can produce signals to which they alone respond, called autocrine signaling (see Figure 1-15). For example, cancer cells use this form of signaling to stimulate their survival and proliferation. The mediators act only on nearby cells. Hormonal signaling involves specialized endocrine cells that secrete chemicals called hormones; hormones are released by one set of cells and travel through the bloodstream to produce a response in other sets of cells (see Chapter 18). In neurohormonal signaling hormones are released into the blood by neurosecretory neurons. Like endocrine cells, neurosecretory neurons release blood-borne chemical messengers, whereas ordinary neurons secrete short-range neurotransmitters into a small discrete space (i.e., synapse). Neurons communicate directly with the cells they innervate by releasing chemicals or neurotransmitters at specialized junctions called chemical synapses; the neurotransmitter diffuses across the synaptic cleft and acts on the postsynaptic target cell (see Figure 1-15). Many of these same signaling molecules are receptors used in hormonal, neurohormonal, and paracrine signaling. Important differences lie in

**Figure 1-15** Primary Modes of Chemical Signaling. Five forms of signaling mediated by secreted molecules. Hormones, paracines, neurotransmitters, and neurohormones are all intercellular messengers that accomplish communication between cells. Autoclines bind to receptors on the same cell. Not all neurotransmitters act in the strictly synaptic mode shown; some act in a contact-dependent mode as local chemical mediators that influence multiple target cells in the area.
the speed and selectivity with which the signals are delivered to their targets.¹

Plasma membrane receptors belong to one of three classes that are defined by the signaling (transduction) mechanism used. Table 1-3 summarizes these classes of receptors. Cells respond to external stimuli by activating a variety of **signal transduction pathways**, which are communication pathways, or signaling cascades (Figure 1-16, C). Signals are passed between cells when a particular type of molecule is produced by one cell—the **signaling cell**—and received by another—the **target cell**—by means of a **receptor protein** that recognizes and responds specifically to the signal molecule (Figure 1-16, A and B). In turn, the signaling molecules activate a pathway of intracellular protein kinases that results in various responses, such as grow and reproduce, die, survive, or differentiate (Figure 1-16, D). If deprived of appropriate signals, most cells undergo a form of cell suicide known as **programmed cell death**, or **apoptosis** (see p. 104).

Like a telephone receiver that converts an electrical signal into a sound signal, a cell converts an extracellular signal, A, into an intracellular signal, B. C, An extracellular signal molecule (ligand) bonds to a receptor protein located on the plasma membrane, where it is transduced into an intracellular signal. This process initiates a signaling cascade that relays the signal into the cell interior, amplifying and distributing it during transit. Amplification is often achieved by stimulating enzymes. Steps in the cascade can be modulated by other events in the cell. D, Different cell behaviors rely on multiple extracellular signals.
Cellular Metabolism

All of the chemical tasks of maintaining essential cellular functions are referred to as cellular metabolism. The energy-using process of metabolism is called anabolism (ana = upward), and the energy-releasing process is known as catabolism (kata = downward). Metabolism provides the cell with the energy it needs to produce cellular structures.

Dietary proteins, fats, and starches (i.e., carbohydrates) are hydrolyzed in the intestinal tract into amino acids, fatty acids, and glucose, respectively. These constituents are then absorbed, circulated, and incorporated into the cell, where they may be used for various vital cellular processes, including the production of ATP. The process by which ATP is produced is one example of a series of reactions called a metabolic pathway. A metabolic pathway involves several steps whose end products are not always detectable. A key feature of cellular metabolism is the directing of biochemical reactions by protein catalysts or enzymes. Each enzyme has a high affinity for a substrate, a specific substance converted to a product of the reaction.

Role of Adenosine Triphosphate

Best known about ATP is its role as a universal “fuel” inside living cells. This fuel or energy drives biologic reactions necessary for cells to function. For a cell to function, it must be able to extract and use the chemical energy in organic molecules. When 1 mole (mol) of glucose metabolically breaks down in the presence of oxygen into carbon dioxide and water, 686 kilocalories (kcal) of chemical energy are released. The chemical energy lost by one molecule is transferred to the chemical structure of another molecule by an energy-carrying or energy-transferring molecule, such as ATP. The energy stored in ATP can be used in various energy-requiring reactions and in the process is generally converted to adenosine diphosphate (ADP) and inorganic phosphate (Pi). The energy available as a result of this reaction is about 7 kcal/mol of ATP. The cell uses ATP for muscle contraction and active transport of molecules across cellular membranes. ATP not only stores energy but also transfers it from one molecule to another. Energy stored by carbohydrate, lipid, and protein is catabolized and transferred to ATP.

Emerging understandings are the role of ATP outside cells—as a messenger. In animal studies, using the newly developed ATP probe, ATP has been measured in pericellular spaces. New research is clarifying the role of ATP as an extracellular messenger and its role in many physiologic processes, including inflammation.
Food and Production of Cellular Energy

Catabolism of the proteins, lipids, and polysaccharides found in food can be divided into the following three phases (Figure 1-17):

**Phase 1: Digestion.** Large molecules are broken down into smaller subunits: proteins into amino acids, polysaccharides into simple sugars (i.e., monosaccharides), and fats into fatty acids and glycerol. These processes occur outside the cell and are activated by secreted enzymes.

**Phase 2: Glycolysis and oxidation.** The most important part of phase 2 is glycolysis, the splitting of glucose. Glycolysis produces two molecules of ATP per glucose molecule through oxidation, or the removal and transfer of a pair of electrons. The total process is called oxidative cellular metabolism and involves ten biochemical reactions (Figure 1-18).

**Phase 3: Citric acid cycle (Krebs cycle, tricarboxylic acid cycle).** Most of the ATP is generated during this final phase, which begins with the citric acid cycle and ends with oxidative phosphorylation. About two thirds of the total oxidation of carbon compounds in most cells is accomplished during this phase. The major end products are carbon dioxide (CO₂) and two dinucleotides—reduced nicotinamide adenine dinucleotide (NADH) and the reduced form of flavin adenine dinucleotide (FADH₂)—both of which transfer their electrons into the electron-transport chain.
FIGURE 1-17 Three Phases of Catabolism, Which Lead from Food to Waste Products. These reactions produce adenosine triphosphate (ATP), which is used to power other processes in the cell.
Oxidative Phosphorylation

Oxidative phosphorylation occurs in the mitochondria and is the mechanism by which the energy produced from carbohydrates, fats, and proteins is transferred to ATP. During the breakdown (catabolism) of foods, many reactions involve the removal of electrons from various intermediates. These reactions generally require a coenzyme (a nonprotein carrier molecule), such as nicotinamide adenine dinucleotide (NAD), to transfer the electrons and thus are called transfer reactions.

Molecules of NAD and flavin adenine dinucleotide (FAD) transfer electrons they have gained from the oxidation of substrates to molecular oxygen, $O_2$. The
electrons from reduced NAD and FAD, NADH and FADH$_2$, respectively, are transferred to the **electron-transport chain** on the inner surfaces of the mitochondria with the release of hydrogen ions. Some carrier molecules are brightly colored, iron-containing proteins known as cytochromes that accept a pair of electrons. These electrons eventually combine with molecular oxygen.

If oxygen is not available to the electron-transport chain, ATP will not be formed by the mitochondria. Instead, an anaerobic (without oxygen) metabolic pathway synthesizes ATP. This process, called **substrate phosphorylation** or **anaerobic glycolysis**, is linked to the breakdown (glycolysis) of carbohydrate (see Figure 1-18). Because glycolysis occurs in the cytoplasm of the cell, it provides energy for cells that lack mitochondria. The reactions in anaerobic glycolysis involve the conversion of glucose to pyruvic acid (pyruvate) with the simultaneous production of ATP. With the glycolysis of one molecule of glucose, two ATP molecules and two molecules of pyruvate are liberated. If oxygen is present, the two molecules of pyruvate move into the mitochondria, where they enter the citric acid cycle (Figure 1-19).
What Happens to Pyruvate, the Product of Glycolysis? In the presence of oxygen, pyruvate is oxidized to acetyl coenzyme A (Acetyl CoA) and enters the citric acid cycle. In the absence of oxygen, pyruvate instead is reduced, accepting the electrons extracted during glycolysis and carried by reduced nicotinamide adenine dinucleotide (NADH). When pyruvate is reduced directly, as it is in muscles, the product is lactic acid. When CO₂ is first removed from pyruvate and the remainder is reduced, as it is in yeasts, the resulting product is ethanol.

If oxygen is absent, pyruvate is converted to lactic acid, which is released into the extracellular fluid. The conversion of pyruvic acid to lactic acid is reversible; therefore once oxygen is restored, lactic acid is quickly converted back to either pyruvic acid or glucose. The anaerobic generation of ATP from glucose through glycolysis is not as efficient as the aerobic generation process. Adding an oxygen-requiring stage to the catabolic process (phase 3; see Figure 1-17) provides cells with a much more powerful method for extracting energy from food molecules.
Membrane Transport: Cellular Intake and Output

Cell survival and growth depend on the constant exchange of molecules with their environment. Cells continually import nutrients, fluids, and chemical messengers from the extracellular environment and expel metabolites, or the products of metabolism, and end products of lysosomal digestion. Cells also must regulate ions in their cytosol and organelles. Simple diffusion across the lipid bilayer of the plasma membrane occurs for such important molecules as O$_2$ and CO$_2$. However, the majority of molecular transfer depends on specialized membrane transport proteins that span the lipid bilayer and provide private conduits for select molecules.\(^1\) Membrane transport proteins occur in many forms and are present in all cell membranes.\(^1\) Transport by membrane transport proteins is sometimes called mediated transport. Most of these transport proteins allow selective passage (for example, Na$^+$ but not K$^+$ or K$^+$ but not Na$^+$). Each type of cell membrane has its own transport proteins that determine which solute can pass into and out of the cell or organelle.\(^1\) The two main classes of membrane transport proteins are transporters and channels. These transport proteins differ in the type of solute—small particles of dissolved substances—they transport. A transporter is specific, allowing only those ions that fit the unique binding sites on the protein (Figure 1-20, A). A transporter undergoes conformational changes to enable membrane transport. A channel, when open, forms a pore across the lipid bilayer that allows ions and selective polar organic molecules to diffuse across the membrane (see Figure 1-20, B). Transport by a channel depends on the size and electrical charge of the molecule. Some channels are controlled by a gate mechanism that determines which solute can move into it. Ion channels are responsible for the electrical excitability of nerve and muscle cells and play a critical role in the membrane potential.
Inorganic ions and small, polar organic molecules can cross a cell membrane through either a transporter or a channel. (Adapted from Alberts B: Essential cell biology, ed 4, New York, 2014, Garland.)

The mechanisms of membrane transport depend on the characteristics of the substance to be transported. In **passive transport**, water and small, electrically uncharged molecules move easily through pores in the plasma membrane's lipid bilayer (see Figure 1-20). This process occurs naturally through any semipermeable barrier. Molecules will easily flow “downhill” from a region of high concentration to a region of low concentration; this movement is called passive because it does not require expenditure of energy or a driving force. It is driven by osmosis, hydrostatic pressure, and diffusion, all of which depend on the laws of physics and do not require life.

Other molecules are too large to pass through pores or are ligands bound to receptors on the cell's plasma membrane. Some of these molecules are moved into and out of the cell by **active transport**, which requires life, biologic activity, and the cell's expenditure of metabolic energy (see Figure 1-20). Unlike passive transport, active transport occurs across only living membranes that have to drive the flow “uphill” by coupling it to an energy source (see p. 21). Movement of a solute against its concentration gradient occurs by special types of transporters called **pumps** (see Figure 1-20). These transporter pumps must harness an energy source to power the transport process. Energy can come from ATP hydrolysis, a transmembrane ion gradient, or sunlight (Figure 1-21). The best-known energy source is the Na⁺-K⁺–dependent adenosine triphosphatase (ATPase) pump (see Figure 1-26). It continuously regulates the cell's volume by controlling leaks through pores or protein channels and maintaining the ionic concentration gradients needed for cellular excitation and membrane conductivity (see p. 24). The maintenance of intracellular K⁺ concentrations is required also for enzyme activity, including enzymes involved in protein synthesis (see Figure 1-21). Large molecules (macromolecules), along with fluids, are transported by endocytosis (taking in) and
exocytosis (expelling) (see p. 21). Receptor-macromolecule complexes enter the cell by means of receptor-mediated endocytosis (see p. 24).

**FIGURE 1-21** Pumps Carry Out Active Transport in Three Ways. 1, *Coupled pumps* link the uphill transport of one solute to the downhill transport of another solute. 2, *ATP-driven pumps* drive uphill transport from hydrolysis of ATP. 3, *Light-driven pumps* are mostly found in bacteria and use energy from sunlight to drive uphill transport. (Adapted from Alberts B: *Essential cell biology*, ed 4, New York, 2014, Garland.)

Mediated transport systems can move solute molecules singly or two at a time. Two molecules can be moved simultaneously in one direction (a process called *symport*; for example, sodium-glucose in the digestive tract) or in opposite directions (called *antiport*; for example, the sodium-potassium pump in all cells), or a single molecule can be moved in one direction (called *uniport*; for example, glucose) (Figure 1-22).
**Electrolytes as Solutes**

Body fluids are composed of **electrolytes**, which are electrically charged and dissociate into constituent **ions** when placed in solution, and nonelectrolytes, such as glucose, urea, and creatinine, which do not dissociate. Electrolytes account for approximately 95% of the solute molecules in body water. Electrolytes exhibit **polarity** by orienting themselves toward the positive or negative pole. Ions with a positive charge are known as **cations** and migrate toward the negative pole, or cathode, if an electrical current is passed through the electrolyte solution. **Anions** carry a negative charge and migrate toward the positive pole, or anode, in the presence of electrical current. Anions and cations are located in both the intracellular fluid (ICF) and the extracellular fluid (ECF) compartments, although their concentration depends on their location. (Fluid and electrolyte balance between body compartments is discussed in Chapter 5.) For example, sodium (Na\(^+\)) is the predominant extracellular cation, and potassium (K\(^+\)) is the principal intracellular cation. The difference in ICF and ECF concentrations of these ions is important to the transmission of electrical impulses across the plasma membranes of nerve and muscle cells.

Electrolytes are measured in milliequivalents per liter (mEq/L) or milligrams per deciliter (mg/dl). The term **milliequivalent** indicates the chemical-combining
activity of an ion, which depends on the electrical charge, or **valence**, of its ions. In abbreviations, valence is indicated by the number of plus or minus signs. One milliequivalent of any cation can combine chemically with 1 mEq of any anion: one monovalent anion will combine with one monovalent cation. Divalent ions combine more strongly than monovalent ions. To maintain electrochemical balance, one divalent ion will combine with two monovalent ions (e.g., \( \text{Ca}^{++} + 2\text{Cl}^- \rightleftharpoons \text{CaCl}_2 \)).

**Passive Transport: Diffusion, Filtration, and Osmosis**

**Diffusion.**

**Diffusion** is the movement of a solute molecule from an area of greater solute concentration to an area of lesser solute concentration. This difference in concentration is known as a **concentration gradient**. Although particles in a solution move randomly in any direction, if the concentration of particles in one part of the solution is greater than that in another part, the particles distribute themselves evenly throughout the solution. According to the same principle, if the concentration of particles is greater on one side of a **permeable membrane** than on the other side, the particles diffuse spontaneously from the area of greater concentration to the area of lesser concentration until equilibrium is reached. The higher the concentration on one side, the greater the diffusion rate.

The diffusion rate is influenced by differences of electrical potential across the membrane (see p. 24). Because the pores in the lipid bilayer are often lined with \( \text{Ca}^{++} \), other cations (e.g., \( \text{Na}^+ \) and \( \text{K}^+ \)) diffuse slowly because they are repelled by positive charges in the pores.

The rate of diffusion of a substance depends also on its size (diffusion coefficient) and its lipid solubility (**Figure 1-23**). Usually, the smaller the molecule and the more soluble it is in oil, the more hydrophobic or nonpolar it is and the more rapidly it will diffuse across the bilayer. Oxygen, carbon dioxide, and steroid hormones (for example, androgens and estrogens) are all nonpolar molecules. Water-soluble substances, such as glucose and inorganic ions, diffuse very slowly, whereas uncharged lipophilic (“lipid-loving”) molecules, such as fatty acids and steroids, diffuse rapidly. Ions and other polar molecules generally diffuse across cellular membranes more slowly than lipid-soluble substances.
Water readily diffuses through biologic membranes because water molecules are small and uncharged. The dipolar structure of water allows it to rapidly cross the regions of the bilayer containing the lipid head groups. The lipid head groups constitute the two outer regions of the lipid bilayer.

**Filtration: hydrostatic pressure.**

Filtration is the movement of water and solutes through a membrane because of a greater pushing pressure (force) on one side of the membrane than on the other side. Hydrostatic pressure is the mechanical force of water pushing against cellular membranes (Figure 1-24, A). In the vascular system, hydrostatic pressure is the blood pressure generated in vessels when the heart contracts. Blood reaching the capillary bed has a hydrostatic pressure of 25 to 30 mm Hg, which is sufficient force to push water across the thin capillary membranes into the interstitial space. Hydrostatic pressure is partially balanced by osmotic pressure, whereby water moving out of the capillaries is partially balanced by osmotic forces that tend to pull water into the capillaries (Figure 1-24, B). Water that is not osmotically attracted back into the capillaries moves into the lymph system (see the discussion of Starling forces in Chapter 5).
Osmosis.

Osmosis is the movement of water “down” a concentration gradient—that is, across a semipermeable membrane from a region of higher water concentration to one of lower concentration. For osmosis to occur, (1) the membrane must be more permeable to water than to solutes and (2) the concentration of solutes on one side of the membrane must be greater than that on the other side so that water moves more easily. Osmosis is directly related to both hydrostatic pressure and solute concentration but not to particle size or weight. For example, particles of the plasma protein albumin are small but are more concentrated in body fluids than the larger and heavier particles of globulin. Therefore albumin exerts a greater osmotic force than does globulin.

Osmolality controls the distribution and movement of water between body
compartments. The terms osmolality and osmolality often are used interchangeably in reference to osmotic activity, but they define different measurements. Osmolality measures the number of milliosmoles per kilogram (mOsm/kg) of water, or the concentration of molecules per weight of water. Osmolarity measures the number of milliosmoles per liter of solution, or the concentration of molecules per volume of solution.

In solutions that contain only dissociable substances, such as sodium and chloride, the difference between the two measurements is negligible. When considering all the different solutes in plasma (e.g., proteins, glucose, lipids), however, the difference between osmolality and osmolarity becomes more significant. Less of plasma's weight is water, and the overall concentration of particles is therefore greater. The osmolality will be greater than the osmolarity because of the smaller proportion of water. Osmolality is thus preferred in human clinical assessment.

The normal osmolality of body fluids is 280 to 294 mOsm/kg. The osmolalities of intracellular and extracellular fluids tend to equalize, providing a measure of body fluid concentration and thus the body's hydration status. Hydration is affected also by hydrostatic pressure because the movement of water by osmosis can be opposed by an equal amount of hydrostatic pressure. The amount of hydrostatic pressure required to oppose the osmotic movement of water is called the osmotic pressure of the solution. Factors that determine osmotic pressure are the type and thickness of the plasma membrane, the size of the molecules, the concentration of molecules or the concentration gradient, and the solubility of molecules within the membrane.

Effective osmolality is sustained osmotic activity and depends on the concentration of solutes remaining on one side of a permeable membrane. If the solutes penetrate the membrane and equilibrate with the solution on the other side of the membrane, the osmotic effect will be diminished or lost.

Plasma proteins influence osmolality because they have a negative charge (see Figure 1-24, B). The principle involved is known as Gibbs-Donnan equilibrium; it occurs when the fluid in one compartment contains small, diffusible ions, such as Na⁺ and chloride (Cl⁻), together with large, nondiffusible, charged particles, such as plasma proteins. Because the body tends to maintain an electrical equilibrium, the nondiffusible protein molecules cause asymmetry in the distribution of small ions. Anions such as Cl⁻ are thus driven out of the cell or plasma, and cations such as Na⁺ are attracted to the cell. The protein-containing compartment maintains a state of electroneutrality, but the osmolality is higher. The overall osmotic effect of colloids, such as plasma proteins, is called the oncotic pressure, or colloid osmotic pressure.
**Tonicity** describes the effective osmolality of a solution. (The terms osmolality and tonicity may be used interchangeably.) Solutions have relative degrees of tonicity. An isotonic solution (or isosmotic solution) has the same osmolality or concentration of particles (285 mOsm) as the ICF or ECF. A hypotonic solution has a lower concentration and is thus more dilute than body fluids (Figure 1-25). A hypertonic solution has a concentration of more than 285 to 294 mOsm/kg. The concept of tonicity is important when correcting water and solute imbalances by administering different types of replacement solutions (see Figure 1-25) (see Chapter 5).

**Quick Check 1-2**

1. What does glycolysis produce?
2. Define membrane transport proteins.
3. What are the differences between passive and active transport?
4. Why do water and small, electrically charged molecules move easily through pores in the plasma membrane?

---

**Active Transport of Na⁺ and K⁺**
The active transport system for Na⁺ and K⁺ is found in virtually all mammalian cells. The Na⁺-K⁺-antiport system (i.e., Na⁺ moving out of the cell and K⁺ moving into the cell) uses the direct energy of ATP to transport these cations. The transporter protein is ATPase, which requires Na⁺, K⁺, and magnesium (Mg²⁺) ions. The concentration of ATPase in plasma membranes is directly related to Na⁺-K⁺-transport activity. Approximately 60% to 70% of the ATP synthesized by cells, especially muscle and nerve cells, is used to maintain the Na⁺-K⁺-transport system. Excitable tissues have a high concentration of Na⁺-K⁺ ATPase, as do other tissues that transport significant amounts of Na⁺. For every ATP molecule hydrolyzed, three molecules of Na⁺ are transported out of the cell, whereas only two molecules of K⁺ move into the cell. The process leads to an electrical potential and is called electrogenic, with the inside of the cell more negative than the outside. Although the exact mechanism for this transport is uncertain, it is possible that ATPase induces the transporter protein to undergo several conformational changes, causing Na⁺ and K⁺ to move short distances (Figure 1-26). The conformational change lowers the affinity for Na⁺ and K⁺ to the ATPase transporter, resulting in the release of the cations after transport.
FIGURE 1-26 Active Transport and the Sodium-Potassium Pump. 1, Three Na\(^+\) ions bind to sodium-binding sites on the carrier’s inner face. 2, At the same time, an energy-containing...
adenosine triphosphate (ATP) molecule produced by the cell's mitochondria binds to the carrier. The ATP dissociates, transferring its stored energy to the carrier. 3 and 4. The carrier then changes shape, releases the three Na+ ions to the outside of the cell, and attracts two potassium (K+) ions to its potassium-binding sites. 5. The carrier then returns to its original shape, releasing the two K+ ions and the remnant of the ATP molecule to the inside of the cell. The carrier is now ready for another pumping cycle.

Table 1-4 summarizes the major mechanisms of transport through pores and protein transporters in the plasma membranes. Many disease states are caused or manifested by loss of these membrane transport systems.

**NOTE:** The known transport systems are listed here; others have been proposed. Most transport systems have been studied in only a few tissues and their sites of activity may be more limited than indicated.

ADP, Adenosine diphosphate; ATP, adenosine triphosphate.

**Transport by Vesicle Formation**

**Endocytosis and Exocytosis**

The active transport mechanisms by which the cells move large proteins,
polynucleotides, or polysaccharides (macromolecules) across the plasma membrane are very different from those that mediate small solute and ion transport. Transport of macromolecules involves the sequential formation and fusion of membrane-bound vesicles.

In **endocytosis**, a section of the plasma membrane enfolds substances from outside the cell, invaginates (folds inward), and separates from the plasma membrane, forming a vesicle that moves into the cell (Figure 1-27, A). Two types of endocytosis are designated based on the size of the vesicle formed. **Pinocytosis** (cell drinking) involves the ingestion of fluids, bits of the plasma membrane, and solute molecules through formation of small vesicles; and **phagocytosis** (cell eating) involves the ingestion of large particles, such as bacteria, through formation of large vesicles (vacuoles).

Because most cells continually ingest fluid and solutes by pinocytosis, the terms **pinocytosis** and **endocytosis** often are used interchangeably. In pinocytosis, the vesicle containing fluids, solutes, or both fuses with a lysosome, and lysosomal enzymes digest the vesicle's contents for use by the cell. Vesicles that bud from
membranes have a particular protein coat on their cytosolic surface and are called **coated vesicles**. The best studied are those that have an outer coat of bristlelike structures—the protein **clathrin**. Pinocytosis occurs mainly by the clathrin-coated pits and vesicles (Figure 1-28). After the coated pits pinch off from the plasma membrane, they quickly shed their coats and fuse with an endosome. An **endosome** is a vesicle pinched off from the plasma membrane from which its contents can be recycled to the plasma membrane or sent to lysosomes for digestion. In phagocytosis, the large molecular substances are engulfed by the plasma membrane and enter the cell so that they can be isolated and destroyed by lysosomal enzymes (see Chapter 6). Substances that are not degraded by lysosomes are isolated in residual bodies and released by exocytosis. Both pinocytosis and phagocytosis require metabolic energy and often involve binding of the substance with plasma membrane receptors before membrane invagination and fusion with lysosomes in the cell. New data are revealing that endocytosis has an even larger and more important role than previously known (Box 1-2).

**Box 1-2**

**The New Endocytic Matrix**
An explosion of new data is disclosing a much more involved role for endocytosis than just a simple way to internalize nutrients and membrane-associated molecules. These new data show that endocytosis not only is a master organizer of signaling pathways but also has a major role in managing signals in time and space. Endocytosis appears to control signaling; therefore it determines the net output of biochemical pathways. This occurs because endocytosis modulates the presence of receptors and their ligands as well as effectors at the plasma membrane or at intermediate stations of the endocytic route. The overall processes and anatomy of these new functions are sometimes called the “endocytic matrix.” All of these functions ultimately have a large impact on almost every cellular process, including the nucleus.

In eukaryotic cells, secretion of macromolecules almost always occurs by exocytosis (see Figure 1-27). **Exocytosis** has two main functions: (1) replacement of portions of the plasma membrane that have been removed by endocytosis and (2) release of molecules synthesized by the cells into the extracellular matrix.

### Receptor-Mediated Endocytosis

The internalization process, called **receptor-mediated endocytosis (ligand internalization)**, is rapid and enables the cell to ingest large amounts of receptor-macromolecule complexes in clathrin-coated vesicles without ingesting large volumes of extracellular fluid (see Figure 1-28). The cellular uptake of cholesterol, for example, depends on receptor-mediated endocytosis. Additionally, many essential metabolites (for example, vitamin B$_{12}$ and iron) depend on receptor-mediated endocytosis and, unfortunately, the influenza flu virus.

### Caveolae

The outer surface of the plasma membrane is dimpled with tiny flask-shaped pits (cavelike) called **caveolae**. Caveolae are thought to form from membrane microdomains or lipid rafts. Caveolae are cholesterol- and glycosphingolipid-rich microdomains where the protein **caveolin** is thought to be involved in several processes, including clathrin-independent endocytosis, cellular cholesterol regulation and transport, and cellular communication. Many proteins, including a variety of receptors, cluster in these tiny chambers.

Caveolae are not only uptake vehicles but also important sites for signal transduction, a tedious process in which extracellular chemical messages or **signals** are communicated to the cell's interior for execution. For example, in vitro evidence now exists that plasma membrane estrogen receptors can localize in caveolae, and
crosstalk with estradiol facilitates several intracellular biologic actions.\textsuperscript{21}

**Movement of Electrical Impulses: Membrane Potentials**

All body cells are electrically polarized, with the inside of the cell more negatively charged than the outside. The difference in electrical charge, or voltage, is known as the **resting membrane potential** and is about −70 to −85 millivolts (mV). The difference in voltage across the plasma membrane results from the differences in ionic composition of ICF and ECF. Sodium ions are more concentrated in the ECF, and potassium ions are in greater concentration in the ICF. The concentration difference is maintained by the active transport of Na\textsuperscript{+} and K\textsuperscript{+} (the sodium-potassium pump), which transports sodium outward and potassium inward (Figure 1-29). Because the resting plasma membrane is more permeable to K\textsuperscript{+} than to Na\textsuperscript{+}, K\textsuperscript{+} diffuses easily from the ICF to the ECF. Because both sodium and potassium are cations, the net result is an excess of anions inside the cell, resulting in the resting membrane potential.
Nerve and muscle cells are excitable and can change their resting membrane potential in response to electrochemical stimuli. Changes in resting membrane potential convey messages from cell to cell. When a nerve or muscle cell receives a stimulus that exceeds the membrane threshold value, a rapid change occurs in the resting membrane potential, known as the action potential. The action potential carries signals along the nerve or muscle cell and conveys information from one cell to another in a domino-like fashion. Nerve impulses are described in Chapter 13. When a resting cell is stimulated through voltage-regulated channels, the cell membranes become more permeable to sodium, so a net movement of sodium into the cell occurs and the membrane potential decreases, or moves forward, from a negative value (in millivolts) to zero. This decrease is known as depolarization. The depolarized cell is more positively charged, and its polarity is neutralized.

To generate an action potential and the resulting depolarization, the threshold potential must be reached. Generally this occurs when the cell has depolarized by 15 to 20 millivolts. When the threshold is reached, the cell will continue to depolarize with no further stimulation. The sodium gates open, and sodium rushes into the cell, causing the membrane potential to drop to zero and then become positive (depolarization). The rapid reversal in polarity results in the action potential.
During **repolarization**, the negative polarity of the resting membrane potential is reestablished. As the voltage-gated sodium channels begin to close, voltage-gated potassium channels open. Membrane permeability to sodium decreases and potassium permeability increases, so potassium ions leave the cell. The sodium gates close, and with the loss of potassium the membrane potential becomes more negative. The Na⁺, K⁺ pump then returns the membrane to the resting potential by pumping potassium back into the cell and sodium out of the cell.

During most of the action potential, the plasma membrane cannot respond to an additional stimulus. This time is known as the **absolute refractory period** and is related to changes in permeability to sodium. During the latter phase of the action potential, when permeability to potassium increases, a stronger-than-normal stimulus can evoke an action potential; this time is known as the **relative refractory period**.

When the membrane potential is more negative than normal, the cell is in a **hyperpolarized state** (less excitable: decreased K⁺ levels within the cell). A stronger-than-normal stimulus is then required to reach the threshold potential and generate an action potential. When the membrane potential is more positive than normal, the cell is in a **hypopolarized state** (more excitable than normal: increased K⁺ levels within the cell) and a weaker-than-normal stimulus is required to reach the threshold potential. Changes in the intracellular and extracellular concentrations of ions or a change in membrane permeability can cause these alterations in membrane excitability.

**Quick Check 1-3**

1. Identify examples of molecules transported in one direction (symport) and opposite directions (antiport).

2. If oxygen is no longer available to make ATP, what happens to the transport of Na⁺?

3. Define the differences between pinocytosis, phagocytosis, and receptor-mediated endocytosis.
Cellular Reproduction: the Cell Cycle

Human cells are subject to wear and tear, and most do not last for the lifetime of the individual. In most tissues, new cells are created as fast as old cells die. Cellular reproduction is therefore necessary for the maintenance of life. Reproduction of gametes (sperm and egg cells) occurs through a process called meiosis, described in Chapter 2. The reproduction, or division, of other body cells (somatic cells) involves two sequential phases—mitosis, or nuclear division, and cytokinesis, or cytoplasmic division. Before a cell can divide, however, it must double its mass and duplicate all its contents. Separation for division occurs during the growth phase, called interphase. The alternation between mitosis and interphase in all tissues with cellular turnover is known as the cell cycle.

The four designated phases of the cell cycle (Figure 1-30) are (1) the S phase (S = synthesis), in which DNA is synthesized in the cell nucleus; (2) the G2 phase (G = gap), in which RNA and protein synthesis occurs, namely, the period between the completion of DNA synthesis and the next phase (M); (3) the M phase (M = mitosis), which includes both nuclear and cytoplasmic division; and (4) the G1 phase, which is the period between the M phase and the start of DNA synthesis.
Phases of Mitosis and Cytokinesis

Interphase (the G₁, S, and G₂ phases) is the longest phase of the cell cycle. During interphase, the chromatin consists of very long, slender rods jumbled together in the nucleus. Late in interphase, strands of chromatin (the substance that gives the nucleus its granular appearance) begin to coil, causing shortening and thickening.

The M phase of the cell cycle, mitosis and cytokinesis, begins with prophase, the first appearance of chromosomes. As the phase proceeds, each chromosome is seen as two identical halves called chromatids, which lie together and are attached by a spindle site called a centromere. (The two chromatids of each chromosome, which are genetically identical, are sometimes called sister chromatids.) The nuclear membrane, which surrounds the nucleus, disappears. Spindle fibers are microtubules formed in the cytoplasm. They radiate from two centrioles located at opposite poles of the cell and pull the chromosomes to opposite sides of the cell, beginning metaphase. Next, the centromeres become aligned in the middle of the spindle, which is called the equatorial plate (or metaphase plate) of the cell. In this
stage, chromosomes are easiest to observe microscopically because they are highly condensed and arranged in a relatively organized fashion.

**Anaphase** begins when the centromeres split and the sister chromatids are pulled apart. The spindle fibers shorten, causing the sister chromatids to be pulled, centromere first, toward opposite sides of the cell. When the sister chromatids are separated, each is considered to be a chromosome. Thus the cell has 92 chromosomes during this stage. By the end of anaphase, there are 46 chromosomes lying at each side of the cell. Barring mitotic errors, each of the 2 groups of 46 chromosomes is identical to the original 46 chromosomes present at the start of the cell cycle.

During **telophase**, the final stage, a new nuclear membrane is formed around each group of 46 chromosomes, the spindle fibers disappear, and the chromosomes begin to uncoil. Cytokinesis causes the cytoplasm to divide into almost equal parts during this phase. At the end of telophase, two identical diploid cells, called **daughter cells**, have been formed from the original cell.

### Rates of Cellular Division

Although the complete cell cycle lasts 12 to 24 hours, about 1 hour is required for the four stages of mitosis and cytokinesis. All types of cells undergo mitosis during formation of the embryo, but many adult cells—such as nerve cells, lens cells of the eye, and muscle cells—lose their ability to replicate and divide. The cells of other tissues, particularly epithelial cells (e.g., cells of the intestine, lung, or skin), divide continuously and rapidly, completing the entire cell cycle in less than 10 hours.

The difference between cells that divide slowly and cells that divide rapidly is the length of time spent in the $G_1$ phase of the cell cycle. Once the $S$ phase begins, however, progression through mitosis takes a relatively constant amount of time.

The mechanisms that control cell division depend on the integrity of genetic, epigenetic (heritable changes in genome function that occur without alterations in the DNA sequence; see Chapter 3), and protein growth factors. Protein growth factors govern the proliferation of different cell types. Individual cells are members of a complex cellular society in which survival of the entire organism is key—not survival or proliferation of just the individual cells. When a need arises for new cells, as in repair of injured cells, previously nondividing cells must be triggered rapidly to reenter the cell cycle. With continual wear and tear, the cell birth rate and the cell death rate must be kept in balance.

### Growth Factors
**Growth factors**, also called **cytokines**, are peptides (protein fractions) that transmit signals within and between cells. They have a major role in the regulation of tissue growth and development (**Table 1-5**). Having nutrients is not enough for a cell to proliferate; it must also receive stimulatory chemical signals (growth factors) from other cells, usually its neighbors or the surrounding supporting tissue called **stroma**. These signals act to overcome intracellular braking mechanisms that tend to restrain cell growth and block progress through the cell cycle (**Figure 1-31**).

</table>

An example of a brake that regulates cell proliferation is the retinoblastoma (Rb) protein, first identified through studies of a rare childhood eye tumor called retinoblastoma, in which the Rb protein is missing or defective. The Rb protein is abundant in the nucleus of all vertebrate cells. It binds to gene regulatory proteins, preventing them from stimulating the transcription of genes required for cell proliferation (see Figure 1-31). Extracellular signals, such as growth factors, activate intracellular signaling pathways that inactivate the Rb protein, leading to cell proliferation.

Different types of cells require different growth factors; for example, platelet-derived growth factor (PDGF) stimulates the production of connective tissue cells. Table 1-5 summarizes the most significant growth factors. Evidence shows that some growth factors also regulate other cellular processes, such as cellular differentiation. In addition to growth factors that stimulate cellular processes, there are factors that inhibit these processes; these factors are not well understood. Cells that are starved of growth factors come to a halt after mitosis and enter the arrested (resting) (G₀) state of the cell cycle (see p. 25 for cell cycle).¹
Tissues

Cells of one or more types are organized into tissues, and different types of tissues compose organs. Finally, organs are integrated to perform complex functions as tracts or systems.

All cells are in contact with a network of extracellular macromolecules known as the extracellular matrix (see p. 10). This matrix not only holds cells and tissues together but also provides an organized latticework within which cells can migrate and interact with one another.

Tissue Formation

To form tissues, cells must exhibit intercellular recognition and communication, adhesion, and memory. Specialized cells sense their environment through signals, such as growth factors, from other cells. This type of communication ensures that new cells are produced only when and where they are required. Different cell types have different adhesion molecules in their plasma membranes, sticking selectively to other cells of the same type. They can also adhere to extracellular matrix components. Because cells are tiny and squishy and enclosed by a flimsy membrane, it is remarkable that they form a strong human being. Strength can occur because of the extracellular matrix and the strength of the cytoskeleton with cell-cell adhesions to neighboring cells. Cells have memory because of specialized patterns of gene expression evoked by signals that acted during embryonic development. Memory allows cells to autonomously preserve their distinctive character and pass it on to their progeny.¹

Fully specialized or **terminally differentiated** cells that are lost are regenerated from proliferating **precursor cells**. These precursor cells have been derived from a smaller number of stem cells.¹ **Stem cells** are cells with the potential to develop into many different cell types during early development and growth. In many tissues, stem cells serve as an internal repair and maintenance system, dividing indefinitely. These cells can maintain themselves over very long periods of time, called **self-renewal**, and can generate all the differentiated cell types of the tissue or **multipotency**. This stem cell–driven tissue renewal is very evident in the epithelial lining of the intestine, stomach, blood cells, and skin, which is continuously exposed to environmental factors. A class of extracellular signaling proteins, known as **Wnt signals**, sustain tissue renewal and enable tissue to be continuously replenished and maintained over a lifetime.²² When a stem cell divides, each daughter cell has a choice: it can remain as a stem cell or it can follow a pathway that results in terminal differentiation (Figure 1-32).
1. A **stem cell** can self-renew and give rise to either cell precursors or cells entering a terminal differentiation pathway. Depending on tissue requirements, a stem cell can remain transiently dormant or undergo steady-state cycling.

2. **Proliferation**

3. A **precursor cell** can undergo several rounds of cell divisions. As a precursor cell differentiates, it acquires distinctive features characteristic of each lineage.

4. **Differentiated cells** are nonmitotic with a finite life span.

5. Differentiating cells of a lineage follow a unique maturation sequence.

Stem cells are maintained in microenvironmental niches consisting of stromal cells.
Types of Tissues

The four basic types of tissues are nerve, epithelial, connective, and muscle. The structure and function of these four types underlie the structure and function of each organ system. Neural tissue is composed of highly specialized cells called neurons, which receive and transmit electrical impulses rapidly across junctions called synapses (see Figure 13-1). Different types of neurons have special characteristics that depend on their distribution and function within the nervous system. Epithelial, connective, and muscle tissues are summarized in Tables 1-6, 1-7, and 1-8, respectively.

Did You Understand?

Cellular Functions

1. Cells become specialized through the process of differentiation or maturation.

2. The eight specialized cellular functions are movement, conductivity, metabolic absorption, secretion, excretion, respiration, reproduction, and communication.

Structure and Function of Cellular Components

1. The eukaryotic cell consists of three general components: the plasma membrane, the cytoplasm, and the intracellular organelles.

2. The nucleus is the largest membrane-bound organelle and is found usually in the cell's center. The chief functions of the nucleus are cell division and control of genetic information.

3. Cytoplasm, or the cytoplasmic matrix, is an aqueous solution (cytosol) that fills the space between the nucleus and the plasma membrane.

4. The organelles are suspended in the cytoplasm and are enclosed in biologic membranes.

5. The endoplasmic reticulum is a network of tubular channels (cisternae) that extend throughout the outer nuclear membrane. It specializes in the synthesis and transport of protein and lipid components of most of the organelles.

6. The Golgi complex is a network of smooth membranes and vesicles located near the nucleus. The Golgi complex is responsible for processing and packaging proteins into secretory vesicles that break away from the Golgi complex and migrate to a variety of intracellular and extracellular destinations, including the plasma membrane.

7. Lysosomes are saclike structures that originate from the Golgi complex and contain digestive enzymes. These enzymes are responsible for digesting most cellular substances to their basic form, such as amino acids, fatty acids, and carbohydrates (sugars).

8. Cellular injury leads to a release of the lysosomal enzymes, causing cellular self-
digestion.

9. Peroxisomes are similar to lysosomes but contain several enzymes that either produce or use hydrogen peroxide.

10. Mitochondria contain the metabolic machinery necessary for cellular energy metabolism. The enzymes of the respiratory chain (electron-transport chain), found in the inner membrane of the mitochondria, generate most of the cell’s ATP.

11. The cytoskeleton is the “bone and muscle” of the cell. The internal skeleton is composed of a network of protein filaments, including microtubules and actin filaments (microfilaments).

12. The plasma membrane encloses the cell and, by controlling the movement of substances across it, exerts a powerful influence on metabolic pathways. Principles of membrane structure are being overhauled.

13. Proteins are the major workhorses of the cell. Membrane proteins, like other proteins, are synthesized by the ribosome and then make their way, called trafficking, to different locations in the cell. Trafficking places unique demands on membrane proteins for folding, translocation, and stability. Misfolded proteins are emerging as an important cause of disease.

14. Protein regulation in a cell is called protein homeostasis and is defined by the proteostasis network. This network is composed of ribosomes (makers), chaperones (helpers), and protein breakdown or proteolytic systems. Malfunction of these systems is associated with disease.

15. Carbohydrates contained within the plasma membrane are generally bound to membrane proteins (glycoproteins) and lipids (glycolipids).

16. Protein receptors (recognition units) on the plasma membrane enable the cell to interact with other cells and with extracellular substances.

17. Membrane functions are determined largely by proteins. These functions include recognition by protein receptors and transport of substances into and out of the cell.

Cell-to-Cell Adhesions

1. Cell-to-cell adhesions are formed on plasma membranes, thereby allowing the
formation of tissues and organs. Cells are held together by three different means: (1) the extracellular membrane, (2) cell adhesion molecules in the cell's plasma membrane, and (3) specialized cell junctions.

2. The extracellular matrix includes three groups of macromolecules: (1) fibrous structural proteins (collagen and elastin), (2) adhesive glycoproteins, and (3) proteoglycans and hyaluronic acid. The matrix helps regulate cell growth, movement, and differentiation.

3. The basement membrane is a tough layer of extracellular matrix underlying the epithelium of many organs; it is also called the basal lamina.

4. Cell junctions can be classified as symmetric and asymmetric. Symmetric junctions include tight junctions, the belt desmosome, desmosomes, and gap junctions. An asymmetric junction is the hemidesmosome.

**Cellular Communication and Signal Transduction**

1. Cells communicate in three main ways: (1) they form protein channels (gap junctions); (2) they display receptors that affect intracellular processes or other cells in direct physical contact; and (3) they use receptor proteins inside the target cell.

2. Primary modes of intercellular signaling include contact-dependent, paracrine, hormonal, neurohormonal, and neurotransmitter.

3. Signal transduction involves signals or instructions from extracellular chemical messengers that are conveyed to the cell's interior for execution. If deprived of appropriate signals, cells undergo a form of cell suicide known as programmed cell death or apoptosis.

**Cellular Metabolism**

1. The chemical tasks of maintaining essential cellular functions are referred to as cellular metabolism. Anabolism is the energy-using process of metabolism, whereas catabolism is the energy-releasing process.

2. Adenosine triphosphate (ATP) functions as an energy-transferring molecule. It is fuel for cell survival. Energy is stored by molecules of carbohydrate, lipid, and
protein, which, when catabolized, transfers energy to ATP.

3. Oxidative phosphorylation occurs in the mitochondria and is the mechanism by which the energy produced from carbohydrates, fats, and proteins is transferred to ATP.

**Membrane Transport: Cellular Intake and Output**

1. Cell survival and growth depends on the constant exchange of molecules with their environment. The two main classes of membrane transport proteins are transporters and channels. The majority of molecular transfer depends on specialized membrane transport proteins.

2. Water and small, electrically uncharged molecules move through pores in the plasma membrane's lipid bilayer in the process called *passive transport*.

3. Passive transport does not require the expenditure of energy; rather, it is driven by the physical effect of osmosis, hydrostatic pressure, and diffusion.

4. Larger molecules and molecular complexes are moved into the cell by active transport, which requires the cell to expend energy (by means of ATP).

5. The largest molecules (macromolecules) and fluids are transported by the processes of endocytosis (ingestion) and exocytosis (expulsion). Endocytosis, or vesicle formation, is when the substance to be transported is engulfed by a segment of the plasma membrane, forming a vesicle that moves into the cell.

6. Pinocytosis is a type of endocytosis in which fluids and solute molecules are ingested through formation of small vesicles.

7. Phagocytosis is a type of endocytosis in which large particles, such as bacteria, are ingested through formation of large vesicles, called *vacuoles*.

8. In receptor-mediated endocytosis, the plasma membrane receptors are clustered, along with bristlelike structures, in specialized areas called *coated pits*.

10. Inside the cell, lysosomal enzymes process and digest material ingested by
endocytosis.

11. Two types of solutes exist in body fluids: electrolytes and nonelectrolytes. Electrolytes are electrically charged and dissociate into constituent ions when placed in solution. Nonelectrolytes do not dissociate when placed in solution.

12. Diffusion is the passive movement of a solute from an area of higher solute concentration to an area of lower solute concentration.

13. Filtration is the measurement of water and solutes through a membrane because of a greater pushing pressure.

14. Hydrostatic pressure is the mechanical force of water pushing against cellular membranes.

15. Osmosis is the movement of water across a semipermeable membrane from a region of lower solute concentration to a region of higher solute concentration.

16. The amount of hydrostatic pressure required to oppose the osmotic movement of water is called the osmotic pressure of solution.

17. The overall osmotic effect of colloids, such as plasma proteins, is called the oncotic pressure or colloid osmotic pressure.

18. All body cells are electrically polarized, with the inside of the cell more negatively charged than the outside. The difference in voltage across the plasma membrane is the resting membrane potential.

19. When an excitable (nerve or muscle) cell receives an electrochemical stimulus, cations enter the cell and cause a rapid change in the resting membrane potential known as the action potential. The action potential “moves” along the cell's plasma membrane and is transmitted to an adjacent cell. This is how electrochemical signals convey information from cell to cell.

Cellular Reproduction: The Cell Cycle

1. Cellular reproduction in body tissues involves mitosis (nuclear division) and cytokinesis (cytoplasmic division).

2. Only mature cells are capable of division. Maturation occurs during a stage of
cellular life called *interphase (growth phase)*.

3. The cell cycle is the reproductive process that begins after interphase in all tissues with cellular turnover. There are four phases of the cell cycle: (1) the S phase, during which DNA synthesis takes place in the cell nucleus; (2) the G₂ phase, the period between the completion of DNA synthesis and the next phase (M); (3) the M phase, which involves both nuclear (mitotic) and cytoplasmic (cytokinetic) division; and (4) the G₁ phase (growth phase), after which the cycle begins again.

4. The M phase (mitosis) involves four stages: prophase, metaphase, anaphase, and telophase.

5. The mechanisms that control cellular division depend on the integrity of genetic, epigenetic, and protein growth factors.

**Tissues**

1. Cells of one or more types are organized into tissues, and different types of tissues compose organs. Organs are organized to function as tracts or systems.

2. Three key factors that maintain the cellular organization of tissues are (1) recognition and cell communication, (2) selective cell-to-cell adhesion, and (3) memory.

3. Fully specialized or terminally differentiated cells that are lost are generated from proliferating *precursor cells* and they, in turn, have been derived from a smaller number of stem cells. Stem cells are cells with the potential to develop into many different cell types during early development and growth. In many tissues, stem cells serve as an internal repair and maintenance system dividing indefinitely. These cells can maintain themselves over very long periods of time, called self-renewal, and can generate all the differentiated cell types of the tissue or multipotency.

4. Tissue cells are linked at cell junctions, which are specialized regions on their plasma membranes. Cell junctions attach adjacent cells and allow small molecules to pass between them.

5. The four basic types of tissues are epithelial, muscle, nerve, and connective tissues.
6. Neural tissue is composed of highly specialized cells called neurons that receive and transmit electrical impulses rapidly across junctions called synapses.

7. Epithelial tissue covers most internal and external surfaces of the body. The functions of epithelial tissue include protection, absorption, secretion, and excretion.

8. Connective tissue binds various tissues and organs together, supporting them in their locations and serving as storage sites for excess nutrients.

9. Muscle tissue is composed of long, thin, highly contractile cells or fibers called myocytes. Muscle tissue that is attached to bones enables voluntary movement. Muscle tissue in internal organs enables involuntary movement, such as the heartbeat.

Multifactorial Inheritance, 57
Genetics occupies a central position in the entire study of biology. An understanding of genetics is essential to study human, animal, plant, or microbial life. Genetics is the study of biologic inheritance. In the nineteenth century, microscopic studies of cells led scientists to suspect the nucleus of the cell contained the important mechanisms of inheritance. Scientists found chromatin, the substance giving the nucleus a granular appearance, is observable in nondividing cells. Just before the cell divides, the chromatin condenses to form discrete, dark-staining organelles, which are called chromosomes. (Cell division is discussed in Chapter 1.) With the rediscovery of Mendel's important breeding experiments at the turn of the twentieth century, it soon became apparent the chromosomes contained genes, the basic units of inheritance (Figure 2-1).

The primary constituent of chromatin is deoxyribonucleic acid (DNA). Genes are composed of sequences of DNA. By serving as the blueprints of proteins in the body, genes ultimately influence all aspects of body structure and function. Humans have approximately 20,000 protein-coding genes and an additional 9000 to 10,000 genes that encode various types of RNA (see below) that are not translated into proteins. An error in one of these genes often leads to a recognizable genetic
To date, more than 20,000 genetic traits and diseases have been identified and cataloged. As infectious diseases continue to be more effectively controlled, the proportion of beds in pediatric hospitals occupied by children with genetic diseases has risen. In addition to children, many common diseases primarily affecting adults, such as hypertension, coronary heart disease, diabetes, and cancer, are now known to have important genetic components.

Great progress is being made in the diagnosis of genetic diseases and in the understanding of genetic mechanisms underlying them. With the huge strides being made in molecular genetics, “gene therapy”—the utilization of normal genes to correct genetic disease—has begun.
DNA, RNA, and Proteins: Heredity at the Molecular Level

Definitions

Composition and Structure of DNA

Genes are composed of DNA, which has three basic components: the five-carbon monosaccharide deoxyribose; a phosphate molecule; and four types of nitrogenous bases. Two of the bases, cytosine and thymine, are single carbon-nitrogen rings called pyrimidines. The other two bases, adenine and guanine, are double carbon-nitrogen rings called purines. The four bases are commonly represented by their first letters: A (adenine), C (cytosine), T (thymine), and G (guanine).

Watson and Crick demonstrated how these molecules are physically assembled as DNA, proposing the double-helix model, in which DNA appears like a twisted ladder with chemical bonds as its rungs (Figure 2-2). The two sides of the ladder consist of deoxyribose and phosphate molecules, united by strong phosphodiester bonds. Projecting from each side of the ladder, at regular intervals, are the nitrogenous bases. The base projecting from one side is bound to the base projecting from the other by a weak hydrogen bond. Therefore the nitrogenous bases form the rungs of the ladder; adenine pairs with thymine, and guanine pairs with cytosine. Each DNA subunit—consisting of one deoxyribose molecule, one phosphate group, and one base—is called a nucleotide.
DNA as the Genetic Code

DNA directs the synthesis of all the body's proteins. Proteins are composed of one or more polypeptides (intermediate protein compounds), which in turn consist of sequences of amino acids. The body contains 20 different types of amino acids; they are specified by the 4 nitrogenous bases. To specify (code for) 20 different amino acids with only 4 bases, different combinations of bases, occurring in groups of 3 (triplets), are used. These triplets of bases are known as codons. Each codon specifies a single amino acid in a corresponding protein. Because there are 64 (4 × 4 × 4) possible codons but only 20 amino acids, there are many cases in which several codons correspond to the same amino acid.

The genetic code is universal: all living organisms use precisely the same DNA codes to specify proteins except for mitochondria, the cytoplasmic organelles in which cellular respiration takes place (see Chapter 1)—they have their own extranuclear DNA. Several codons of mitochondrial DNA encode different amino acids, as compared to the same nuclear DNA codons.

Replication of DNA

DNA replication consists of breaking the weak hydrogen bonds between the bases, leaving a single strand with each base unpaired (Figure 2-3). The consistent pairing of adenine with thymine and of guanine with cytosine, known as complementary base pairing, is the key to accurate replication. The unpaired base attracts a free nucleotide only if the nucleotide has the proper complementary base. When replication is complete, a new double-stranded molecule identical to the original is formed. The single strand is said to be a template, or molecule on which a complementary molecule is built, and is the basis for synthesizing the new double strand.
Several different proteins are involved in DNA replication. The most important of these proteins is an enzyme known as **DNA polymerase**. This enzyme travels along the single DNA strand, adding the correct nucleotides to the free end of the new strand and checking to ensure that its base is actually complementary to the template base. This mechanism of DNA proofreading substantially enhances the accuracy of DNA replication.

**Mutation**

A *mutation* is any inherited alteration of genetic material. One type of mutation is the **base pair substitution**, in which one base pair replaces another. This replacement *can* result in a change in the amino acid sequence. However, because of the redundancy of the genetic code, many of these mutations do not change the amino acid sequence and thus have no consequence. Such mutations are called **silent mutations**. Base pair substitutions altering amino acids consist of two basic types: **missense** mutations, which produce a change (i.e., the “sense”) in a single amino acid; and **nonsense** mutations, which produce one of the three stop codons (UAA, UAG, or UGA) in the messenger RNA (mRNA) (**Figure 2-4**). Missense mutations (see **Figure 2-4, A**) produce a single amino acid change, whereas nonsense mutations (see **Figure 2-4, B**) produce a premature stop codon in the mRNA. Stop codons terminate translation of the polypeptide.
The **frameshift mutation** involves the insertion or deletion of one or more base pairs of the DNA molecule. As Figure 2-5 shows, these mutations change the entire “reading frame” of the DNA sequence because the deletion or insertion is not a multiple of three base pairs (the number of base pairs in a codon). Frameshift mutations can thus greatly alter the amino acid sequence. (*In-frame* insertions or deletions, in which a multiple of three bases is inserted or lost, tend to have less severe disease consequences than do frameshift mutations.)
Agents known as mutagens increase the frequency of mutations. Examples include radiation and chemicals such as nitrogen mustard, vinyl chloride, alkylating agents, formaldehyde, and sodium nitrite.

Mutations are rare events. The rate of spontaneous mutations (those occurring in the absence of exposure to known mutagens) in humans is about $10^{-4}$ to $10^{-7}$ per gene per generation. This rate varies from one gene to another. Some DNA sequences have particularly high mutation rates and are known as mutational hot spots.

From Genes to Proteins

DNA is formed and replicated in the cell nucleus, but protein synthesis takes place in the cytoplasm. The DNA code is transported from nucleus to cytoplasm, and
subsequent protein is formed through two basic processes: transcription and translation. These processes are mediated by ribonucleic acid (RNA), which is chemically similar to DNA except the sugar molecule is ribose rather than deoxyribose, and uracil rather than thymine is one of the four bases. The other bases of RNA, as in DNA, are adenine, cytosine, and guanine. Uracil is structurally similar to thymine, so it also can pair with adenine. Whereas DNA usually occurs as a double strand, RNA usually occurs as a single strand.

**Transcription**

In transcription, RNA is synthesized from a DNA template, forming messenger RNA (mRNA). RNA polymerase binds to a promoter site, a sequence of DNA that specifies the beginning of a gene. RNA polymerase then separates a portion of the DNA, exposing unattached DNA bases. One DNA strand then provides the template for the sequence of mRNA nucleotides.

The sequence of bases in the mRNA is thus complementary to the template strand, and except for the presence of uracil instead of thymine, the mRNA sequence is identical to that of the other DNA strand. Transcription continues until a termination sequence, codons that act as signals for the termination of protein synthesis, is reached. Then the RNA polymerase detaches from the DNA, and the transcribed mRNA is freed to move out of the nucleus and into the cytoplasm (Figures 2-6 and 2-7).
FIGURE 2-6 General Scheme of Ribonucleic Acid (RNA) Transcription. In transcription of messenger RNA (mRNA), a DNA molecule “unzips” in the region of the gene to be transcribed. RNA nucleotides already present in the nucleus temporarily attach themselves to exposed DNA bases along one strand of the unzipped DNA molecule according to the principle of complementary pairing. As the RNA nucleotides attach to the exposed DNA, they bind to each other and form a chainlike RNA strand called a messenger RNA (mRNA) molecule. Notice that the new mRNA strand is an exact copy of the base sequence on the opposite side of the DNA molecule. As in all metabolic processes, the formation of mRNA is controlled by an enzyme—in this case, the enzyme is called RNA polymerase. (From Ignatavicius DD, Workman LD: Medical-surgical nursing, ed 6, St Louis, 2010, Saunders.)
Gene Splicing

When the mRNA is first transcribed from the DNA template, it reflects exactly the base sequence of the DNA. In eukaryotes, many RNA sequences are removed by nuclear enzymes, and the remaining sequences are spliced together to form the functional mRNA that migrates to the cytoplasm. The excised sequences are called *introns* (intervening sequences), and the sequences that are left to code for proteins...
are called **exons**.

**Translation**

In **translation**, RNA directs the synthesis of a polypeptide (see Figure 2-7), interacting with **transfer RNA (tRNA)**, a cloverleaf-shaped strand of about 80 nucleotides. The tRNA molecule has a site where an amino acid attaches. The three-nucleotide sequence at the opposite side of the cloverleaf is called the **anticodon**. It undergoes complementary base pairing with an appropriate codon in the mRNA, which specifies the sequence of amino acids through tRNA.

The site of actual protein synthesis is in the **ribosome**, which consists of approximately equal parts of protein and **ribosomal RNA (rRNA)**. During translation, the ribosome first binds to an initiation site on the mRNA sequence and then binds to its surface, so that base pairing can occur between tRNA and mRNA. The ribosome then moves along the mRNA sequence, processing each codon and translating an amino acid by way of the interaction of mRNA and tRNA.

The ribosome provides an enzyme that catalyzes the formation of covalent peptide bonds between the adjacent amino acids, resulting in a growing polypeptide. When the ribosome arrives at a termination signal on the mRNA sequence, translation and polypeptide formation cease; the mRNA, ribosome, and polypeptide separate from one another; and the polypeptide is released into the cytoplasm to perform its required function.
Chromosomes

Human cells can be categorized into **gametes** (sperm and egg cells) and **somatic cells**, which include all cells other than gametes. Each somatic cell nucleus has 46 chromosomes in 23 pairs (**Figure 2-8**). These are **diploid cells**, and the individual’s father and mother each donate one chromosome per pair. New somatic cells are formed through **mitosis** and **cytokinesis**. Gametes are **haploid cells**: they have only 1 member of each chromosome pair, for a total of 23 chromosomes. Haploid cells are formed from diploid cells by **meiosis** (**Figure 2-9**).

**FIGURE 2-8** From Molecular Parts to the Whole Somatic Cell.
In 22 of the 23 chromosome pairs, the 2 members of each pair are virtually identical in microscopic appearance: thus they are homologous (Figure 2-10, B). These 22 chromosome pairs are homologous in both males and females and are termed autosomes. The remaining pair of chromosomes, the sex chromosomes, consists of two homologous X chromosomes in females and a nonhomologous pair, X and Y, in males.
Figure 2-10, A, illustrates a **metaphase spread**, which is a photograph of the chromosomes as they appear in the nucleus of a somatic cell during metaphase. (Chromosomes are easiest to visualize during this stage of mitosis.) In Figure 2-10, A, the chromosomes are arranged according to size, with the homologous chromosomes paired. The 22 autosomes are numbered according to length, with chromosome 1 being the longest and chromosome 22 the shortest. A **karyotype**, or **karyogram**, is an ordered display of chromosomes. Some natural variation in relative chromosome length can be expected from person to person, so it is not always possible to distinguish each chromosome by its length. Therefore the position of the centromere (region of DNA responsible for movement of the replicated chromosomes into the two daughter cells during mitosis and meiosis) also is used to classify chromosomes (**Figures 2-10, B** and 2-11).
The chromosomes in Figure 2-10 were stained with Giemsa stain, resulting in distinctive chromosome bands. These form various patterns in the different chromosomes so that each chromosome can be distinguished easily. Using banding techniques, researchers can number chromosomes and study individual variations. Missing or duplicated portions of chromosomes, which often result in serious diseases, also are readily identified. More recently, techniques have been devised permitting each chromosome to be visualized with a different color.

Chromosome Aberrations and Associated Diseases

Chromosome abnormalities are the leading known cause of intellectual disability and miscarriage. Estimates indicate that a major chromosome aberration occurs in at least 1 in 12 conceptions. Most of these fetuses do not survive to term; about 50% of all recovered first-trimester spontaneous abortuses have major chromosome aberrations. The number of live births affected by these abnormalities is, however, significant; approximately 1 in 150 has a major diagnosable chromosome abnormality.

Polyploidy
Cells with a multiple of the normal number of chromosomes are **euploid cells** (Greek *eu* = good or true). Because normal gametes are haploid and most normal somatic cells are diploid, they are both euploid forms. When a euploid cell has more than the diploid number of chromosomes, it is said to be a **polyploid cell**. Several types of body tissues, including some liver, bronchial, and epithelial tissues, are normally polyploid. A zygote that has three copies of each chromosome, rather than the usual two, has a form of polyploidy called **triploidy**. Nearly all triploid fetuses are spontaneously aborted or stillborn. The prevalence of triploidy among live births is approximately 1 in 10,000. **Tetraploidy**, a condition in which euploid cells have 92 chromosomes, has been found primarily in early abortuses, although occasionally affected infants have been born alive. Like triploid infants, however, they do not survive. Triploidy and tetraploidy are relatively common conditions, accounting for approximately 10% of all known miscarriages.²

**Aneuploidy**

A cell that does not contain a multiple of 23 chromosomes is an **aneuploid cell**. A cell containing three copies of one chromosome is said to be trisomic (a condition termed **trisomy**) and is aneuploid. Monosomy, the presence of only one copy of a given chromosome in a diploid cell, is the other common form of aneuploidy. Among the autosomes, monosomy of any chromosome is lethal, but newborns with trisomy of chromosomes 13, 18, 21, or X can survive. This difference illustrates an important principle: *in general, loss of chromosome material has more serious consequences than duplication of chromosome material.*

Aneuploidy of the sex chromosomes is less serious than that of the autosomes. Very little genetic material—only about 40 genes—is located on the Y chromosome. For the X chromosome, inactivation of extra chromosomes (see p. 54) largely diminishes their effect. A zygote bearing no X chromosome, however, will not survive.

Aneuploidy is usually the result of **nondisjunction**, an error in which homologous chromosomes or sister chromatids fail to separate normally during meiosis or mitosis (Figure 2-12). Nondisjunction produces some gametes that have two copies of a given chromosome and others that have no copies of the chromosome. When such gametes unite with normal haploid gametes, the resulting zygote is monosomic or trisomic for that chromosome. Occasionally, a cell can be monosomic or trisomic for more than one chromosome.
Autosomal aneuploidy.

Trisomy can occur for any chromosome, but fetuses with other trisomies of chromosomes (other than 13, 18, 21, or X) do not survive to term. Trisomy 16, for example, is the most common trisomy among abortuses, but it is not seen in live births.\(^3\)

Partial trisomy, in which only an extra portion of a chromosome is present in each cell, can occur also. The consequences of partial trisomies are not as severe as those of complete trisomies. Trisomies may occur in only some cells of the body. Individuals thus affected are said to be chromosomal mosaics, meaning that the body has two or more different cell lines, each of which has a different karyotype. Mosaics are often formed by early mitotic nondisjunction occurring in one embryonic cell but not in others.

The best-known example of aneuploidy in an autosome is trisomy of chromosome 21, which causes Down syndrome (named after J. Langdon Down, who first described the syndrome in 1866). Down syndrome is seen in
approximately 1 in 800 to 1 in 1000 live births; its principal features are shown and outlined in Figure 2-13 and Table 2-1.

| Turner Syndrome |  |
| (45,X) Monosomy of X Chromosome |  |
| IQ | Not considered to be intellectually disabled, although some impairment of spatial and mathematical reasoning ability is found |
| Male/female findings | Found only in females |
| Musculoskeletal system | Short stature common, characteristic webbing of neck, widely spaced nipples, reduced carrying angle at elbow |
| Systemic disorders | Coarctation (narrowing) of aorta, edema of feet in newborns, usually sterile and have gonadal streaks rather than ovaries; streaks are sometimes susceptible to cancer |
| Mortality | About 15-20% of spontaneous abortions with chromosome abnormalities have this karyotype, most common single-chromosome aberration; highly lethal during gestation, only about 0.5% of these conceptions survive to term |
| Causative factors | 75% inherit X chromosome from mother, thus caused by meiotic error in father; frequency low compared with other sex chromosome aneuploidies (1:5000 newborn females); 50% have simple monosomy of X chromosome; remainder have more complex abnormalities; combinations of 45; X cells with XX or XY cells common |

| Klinefelter Syndrome |  |
| (47,XXY) XYY Condition |  |
| IQ | Moderate degree of mental impairment may be present |
| Male/female findings | Have a male appearance but usually sterile; 50% develop female-like breasts (gynecomastia); occurs in 1:1000 male births |
| Face | Voice somewhat high pitched |
| Systemic disorders | Sparse body hair, sterile, small testicles |
| Causative factors | 50% of cases the result of nondisjunction of X chromosomes in mother, frequency rises with increasing maternal age; also involves XXY and XXXY karyotypes with degree of physical and mental impairment increasing with each added X chromosome; mosaicism fairly common with most prevalent combination of XXXY and XY cells |

The risk of having a child with Down syndrome increases greatly with maternal age. As Figure 2-14 demonstrates, women younger than 30 years have a risk ranging from about 1 in 1000 births to 1 in 2000 births. The risk begins to rise substantially after 35 years of age, and reaches 3% to 5% for women older than 45 years. This dramatic increase in risk is caused by the age of maternal egg cells, which are held in an arrested state of prophase I from the time they are formed in the female embryo until they are shed in ovulation. Thus an egg cell formed by a 45-year-old woman is itself 45 years old. This long suspended state may allow defects to accumulate in the cellular proteins responsible for meiosis, leading to nondisjunction. The risk of Down syndrome, as well as other trisomies, does not increase with paternal age.\(^4\)
Sex chromosome aneuploidy.

The incidence of sex chromosome aneuploidies is fairly high. Among live births, about 1 in 500 males and 1 in 900 females have a form of sex chromosome aneuploidy.\(^5\) Because these conditions are generally less severe than autosomal aneuploidies, all forms except complete absence of any X chromosome material allow at least some individuals to survive.

One of the most common sex chromosome aneuploidies, affecting about 1 in 1000 newborn females, is trisomy X. Instead of two X chromosomes, these females have three X chromosomes in each cell. Most of these females have no overt physical abnormalities, although sterility, menstrual irregularity, or intellectual disability is sometimes seen. Some females have four X chromosomes, and they are more often intellectually disabled. Those with five or more X chromosomes generally have more severe intellectual disability and various physical defects.

A condition that leads to somewhat more serious problems is the presence of a single X chromosome and no homologous X or Y chromosome, so that the individual has a total of 45 chromosomes. The karyotype is usually designated 45,X, and it causes a set of symptoms known as **Turner syndrome** (Figure 2-15; see Table 2-1). Individuals with at least two X chromosomes and one Y chromosome in each cell (47,XXY karyotype) have a disorder known as **Klinefelter syndrome** (Figure 2-16; see Table 2-1).
Abnormalities of Chromosome Structure

In addition to the loss or gain of whole chromosomes, parts of chromosomes can be lost or duplicated as gametes are formed, and the arrangement of genes on chromosomes can be altered. Unlike aneuploidy and polyploidy, these changes sometimes have no serious consequences for an individual's health. Some of them can even remain entirely unnoticed, especially when very small pieces of chromosomes are involved. Nevertheless, abnormalities of chromosome structure can also produce serious disease in individuals or their offspring.
During meiosis and mitosis, chromosomes usually maintain their structural integrity, but chromosome breakage occasionally occurs. Mechanisms exist to “heal” these breaks and usually repair them perfectly with no damage to the daughter cell. However, some breaks remain or heal in a way that alters the chromosome's structure. The risk of chromosome breakage increases with exposure to harmful agents called clastogens (e.g., ionizing radiation, viral infections, or some types of chemicals).

Deletions.

Broken chromosomes and lost DNA cause deletions (Figure 2-17). Usually, a gamete with a deletion unites with a normal gamete to form a zygote. The zygote thus has one chromosome with the normal complement of genes and one with some missing genes. Because many genes can be lost in a deletion, serious consequences result even though one normal chromosome is present. The most often cited example of a disease caused by a chromosomal deletion is the cri du chat syndrome. The term literally means “cry of the cat” and describes the characteristic cry of the affected child. Other symptoms include low birth weight, severe intellectual disability, microcephaly (smaller than normal head size), and heart defects. The disease is caused by a deletion of part of the short arm of chromosome 5.
Duplications.
A deficiency of genetic material is more harmful than an excess, so **duplications** usually have less serious consequences than deletions. For example, a deletion of a region of chromosome 5 causes cri du chat syndrome, but a duplication of the same region causes mental retardation but less serious physical defects.

Inversions.
An **inversion** occurs when two breaks take place on a chromosome, followed by the reinsertion of the missing fragment at its original site but in inverted order. Therefore a chromosome symbolized as ABCDEFG might become ABEDCFG after an inversion.

Unlike deletions and duplications, no loss or gain of genetic material occurs, so
inversions are “balanced” alterations of chromosome structure, and they often have no apparent physical effect. Some genes are influenced by neighboring genes, however, and this **position effect**, a change in a gene's expression caused by its position, sometimes results in physical defects in these persons. Inversions can cause serious problems in the offspring of individuals carrying the inversion because the inversion can lead to duplications and deletions in the chromosomes transmitted to the offspring.

**Translocations.**

The interchange of genetic material between nonhomologous chromosomes is called **translocation**. A **reciprocal translocation** occurs when breaks take place in two different chromosomes and the material is exchanged (Figure 2-18, A). As with inversions, the carrier of a reciprocal translocation is usually normal, but his or her offspring can have duplications and deletions.

![Normal and Abnormal Chromosome Translocation](image)

**Figure 2-18**  Normal and Abnormal Chromosome Translocation. A, Normal chromosomes and reciprocal translocation. B, Pairing at meiosis. C, Consequences of translocation in gametes; unbalanced gametes result in zygotes that are partially trisomic and partially monosomic and consequently develop abnormally.

A second and clinically more important type of translocation is **Robertsonian translocation**. In this disorder, the long arms of two nonhomologous chromosomes fuse at the centromere, forming a single chromosome. Robertsonian translocations are confined to chromosomes 13, 14, 15, 21, and 22 because the short
arms of these chromosomes are very small and contain no essential genetic material. The short arms are usually lost during subsequent cell divisions. Because the carriers of Robertsonian translocations lose no important genetic material, they are unaffected although they have only 45 chromosomes in each cell. Their offspring, however, may have serious monosomies or trisomies. For example, a common Robertsonian translocation involves the fusion of the long arms of chromosomes 21 and 14. An offspring who inherits a gamete carrying the fused chromosome can receive an extra copy of the long arm of chromosome 21 and develop Down syndrome. Robertsonian translocations are responsible for approximately 3% to 5% of Down syndrome cases. Parents who carry a Robertsonian translocation involving chromosome 21 have an increased risk for producing multiple offspring with Down syndrome.

**Fragile sites.**

A number of areas on chromosomes develop distinctive breaks and gaps (observable microscopically) when the cells are cultured. Most of these fragile sites do not appear to be related to disease. However, one fragile site, located on the long arm of the X chromosome, is associated with fragile X syndrome. The most important feature of this syndrome is intellectual disability. With a relatively high population prevalence (affecting approximately 1 in 4000 males and 1 in 8000 females), fragile X syndrome is the second most common genetic cause of intellectual disability (after Down syndrome).

In fragile X syndrome, females who inherit the mutation do not necessarily express the disease condition, but they can pass it on to descendants who do express it. Ordinarily, a male who inherits a disease gene on the X chromosome expresses the condition, because he has only one X chromosome. An uncommon feature of this disease is that about one third of carrier females are affected, although less severely than males. Unaffected transmitting males have been shown to have more than about 50 repeated DNA sequences near the beginning of the fragile X gene. These trinucleotide sequences, which consist of CGG sequences duplicated many times, cause fragile X syndrome when the number of copies exceeds 200. The number of these repeats can increase from generation to generation. More than 20 other genetic diseases, including Huntington disease and myotonic dystrophy, also are caused by this mechanism.

**Quick Check 2-1**

1. What is the major composition of DNA?
2. Define the terms mutation, autosomes, and sex chromosomes.

3. What is the significance of mRNA?

4. What is the significance of chromosomal translocation?
Elements of Formal Genetics

The mechanisms by which an individual's set of paired chromosomes produces traits are the principles of genetic inheritance. Mendel's work with garden peas first defined these principles. Later geneticists have refined Mendel's work to explain patterns of inheritance for traits and diseases that appear in families.

Analysis of traits that occur with defined, predictable patterns has helped geneticists to assemble the pieces of the human gene map. Current research focuses on determining the RNA or protein products of each gene and understanding the way they contribute to disease. Eventually, diseases and defects caused by single genes can be traced and therapies to prevent and treat such diseases can be developed.

Traits caused by single genes are called mendelian traits (after Gregor Mendel). Each gene occupies a position along a chromosome known as a locus. The genes at a particular locus can have different forms (i.e., they can be composed of different nucleotide sequences) called alleles. A locus that has two or more alleles that each occur with an appreciable frequency in a population is said to be polymorphic (or a polymorphism).

Because humans are diploid organisms, each chromosome is represented twice, with one member of the chromosome pair contributed by the father and one by the mother. At a given locus, an individual has one allele whose origin is paternal and one whose origin is maternal. When the two alleles are identical, the individual is homozygous at that locus. When the alleles are not identical, the individual is heterozygous at that locus.

Phenotype and Genotype

The composition of genes at a given locus is known as the genotype. The outward appearance of an individual, which is the result of both genotype and environment, is the phenotype. For example, an infant who is born with an inability to metabolize the amino acid phenylalanine has the single-gene disorder known as phenylketonuria (PKU) and thus has the PKU genotype. If the condition is left untreated, abnormal metabolites of phenylalanine will begin to accumulate in the infant's brain and irreversible intellectual disability will occur. Intellectual disability is thus one aspect of the PKU phenotype. By imposing dietary restrictions to exclude food that contains phenylalanine, however, intellectual disability can be prevented. Foods high in phenylalanine include proteins found in milk, dairy products, meat, fish, chicken, eggs, beans, and nuts. Although the child still has the PKU genotype, a modification of the environment (in this case, the child's diet) produces an
Dominance and Recessiveness

In many loci, the effects of one allele mask those of another when the two are found together in a heterozygote. The allele whose effects are observable is said to be dominant. The allele whose effects are hidden is said to be recessive (from the Latin root for "hiding"). Traditionally, for loci having two alleles, the dominant allele is denoted by an uppercase letter and the recessive allele is denoted by a lowercase letter. When one allele is dominant over another, the heterozygote genotype $Aa$ has the same phenotype as the dominant homozygote $AA$. For the recessive allele to be expressed, it must exist in the homozygote form, $aa$. When the heterozygote is distinguishable from both homozygotes, the locus is said to exhibit codominance.

A carrier is an individual who has a disease gene but is phenotypically normal. Many genes for a recessive disease occur in heterozygotes who carry one copy of the gene but do not express the disease. When recessive genes are lethal in the homozygous state, they are eliminated from the population when they occur in homozygotes. By "hiding" in carriers, however, recessive genes for diseases are passed on to the next generation.
Transmission of Genetic Diseases

The pattern in which a genetic disease is inherited through generations is termed the **mode of inheritance**. Knowing the mode of inheritance can reveal much about the disease-causing gene itself, and members of families with the disease can be given reliable genetic counseling.

Gregor Mendel systematically studied modes of inheritance and formulated two basic laws of inheritance. His **principle of segregation** states that homologous genes separate from one another during reproduction and that each reproductive cell carries only one copy of a homologous gene. Mendel's second law, the **principle of independent assortment**, states that the hereditary transmission of one gene does not affect the transmission of another. Mendel discovered these laws in the mid-nineteenth century by performing breeding experiments with garden peas, even though he had no knowledge of chromosomes. Early twentieth century geneticists found that chromosomal behavior essentially corresponds to Mendel's laws, which now form the basis for the **chromosome theory of inheritance**.

The known single-gene diseases can be classified into four major modes of inheritance: autosomal dominant, autosomal recessive, X-linked dominant, and X-linked recessive. The first two types involve genes known to occur on the 22 pairs of autosomes. The last two types occur on the X chromosome; very few disease-causing genes occur on the Y chromosome.

The **pedigree** chart summarizes family relationships and shows which members of a family are affected by a genetic disease (Figure 2-19). Generally, the pedigree begins with one individual in the family, the **proband**. This individual is usually the first person in the family diagnosed or seen in a clinic.
Normal female
Normal male
Sex not specified

Single bar indicates mating

Normal parents and normal offspring, two girls and a boy, in birth order indicated by the numbers; I and II indicate generations

Single parent as presented means partner is normal or of no significance to the analysis

Double bar indicates a consanguineous mating (mating between close relatives)

Fraternal twins (not identical)

Identical twins

Multiple individuals of each sex

Darkened square or circle means affected individual; arrow (when present) indicates the affected individual is the propositus (proband)

Autosomal heterozygous recessive

Carrier—not likely to manifest disease

Not to manifest disease

Dead

Stillbirth at 29 weeks gestation
Autosomal Dominant Inheritance

Characteristics of Pedigrees

Diseases caused by autosomal dominant genes are rare, with the most common occurring in fewer than 1 in 500 individuals. Therefore it is uncommon for two individuals who are both affected by the same autosomal dominant disease to produce offspring together. Figure 2-20, A, illustrates this unusual pattern. Affected offspring are usually produced by the union of a normal parent with an affected heterozygous parent. The Punnett square in Figure 2-20, B, illustrates this mating. The affected parent can pass either a disease-causing allele or a normal allele to the next generation. On average, half the children will be heterozygous and will express the disease, and half will be normal.
The pedigree in Figure 2-21 shows the transmission of an autosomal dominant allele. Several important characteristics of this pedigree support the conclusion that the trait is caused by an autosomal dominant gene:

1. The two sexes exhibit the trait in approximately equal proportions; males and females are equally likely to transmit the trait to their offspring.

2. No generations are skipped. If an individual has the trait, one parent must also have it. If neither parent has the trait, none of the children have it (with the exception of new mutations, as discussed later).

3. Affected heterozygous individuals transmit the trait to approximately half their children, and because gamete transmission is subject to chance fluctuations, all or none of the children of an affected parent may have the trait. When large numbers of matings of this type are studied, however, the proportion of affected children
closely approaches one half.

**Recurrence Risks**

Parents at risk for producing children with a genetic disease nearly always ask the question, “What is the *chance* that our child will have this disease?” The probability that an individual will develop a genetic disease is termed the **recurrence risk**. When one parent is affected by an autosomal dominant disease (and is a heterozygote) and the other is unaffected, the recurrence risk for each child is one half.

An important principle is that each birth is an independent event, much like a coin toss. Thus, even though parents may have already had a child with the disease, their recurrence risk remains one half. Even if they have produced several children, all affected (or all unaffected) by the disease, the law of independence dictates the probability their next child will have the disease is still one half. Parents' misunderstanding of this principle is a common problem encountered in genetic counseling.

If a child is born with an autosomal dominant disease and there is no history of the disease in the family, the child is probably the product of a new mutation. The gene transmitted by one of the parents has thus undergone a mutation from a normal to a disease-causing allele. The alleles at this locus in most of the parent's other germ cells are still normal. In this situation the recurrence risk for the parent's subsequent offspring is not greater than that of the general population. The offspring of the affected child, however, will have a recurrence risk of one half. Because these diseases often reduce the potential for reproduction, many autosomal dominant diseases result from new mutations.

Occasionally, two or more offspring have symptoms of an autosomal dominant
disease when there is no family history of the disease. Because mutation is a rare event, it is unlikely that this disease would be a result of multiple mutations in the same family. The mechanism most likely responsible is termed **germline mosaicism**. During the embryonic development of one of the parents, a mutation occurred that affected all or part of the germline. Few or none of the somatic cells of the embryo were affected. Thus the parent carries the mutation in his or her germline but does not actually express the disease. As a result, the unaffected parent can transmit the mutation to multiple offspring. This phenomenon, although relatively rare, can have significant effects on recurrence risks. 

**Delayed Age of Onset**

One of the best-known autosomal dominant diseases is Huntington disease, a neurologic disorder whose main features are progressive dementia and increasingly uncontrollable limb movements (chorea; discussed further in Chapter 15). A key feature of this disease is its **delayed age of onset**: symptoms usually are not seen until 40 years of age or later. Thus those who develop the disease often have borne children before they are aware they have the disease-causing mutation. If the disease was present at birth, nearly all affected persons would die before reaching reproductive age and the occurrence of the disease-causing allele in the population would be much lower. An individual whose parent has the disease has a 50% chance of developing it during middle age. He or she is thus confronted with a torturous question: Should I have children, knowing that there is a 50:50 chance that I may have this disease-causing gene and will pass it to half of my children? A DNA test can now be used to determine whether an individual has inherited the trinucleotide repeat mutation that causes Huntington disease.

**Penetrance and Expressivity**

The **penetrance** of a trait is the percentage of individuals with a specific genotype who also exhibit the expected phenotype. Incomplete penetrance means individuals who have the disease-causing genotype may not exhibit the disease phenotype at all, even though the genotype and the associated disease may be transmitted to the next generation. A pedigree illustrating the transmission of an autosomal dominant mutation with incomplete penetrance is provided in Figure 2-22. Retinoblastoma, the most common malignant eye tumor affecting children, typically exhibits incomplete penetrance. About 10% of the individuals who are **obligate carriers** of the disease-causing mutation (i.e., those who have an affected parent and affected children and therefore must themselves carry the mutation) do not have the disease. The penetrance of the disease-causing genotype is then said to be 90%.
The gene responsible for retinoblastoma is a **tumor-suppressor gene**: the normal function of its protein product is to regulate the cell cycle so cells do not divide uncontrollably. When the protein is altered because of a genetic mutation, its tumor-suppressing capacity is lost and a tumor can form\(^9\) (see Chapters 10 and 17).

**Expressivity** is the extent of variation in phenotype associated with a particular genotype. If the expressivity of a disease is variable, penetrance may be complete but the severity of the disease can vary greatly. A good example of variable expressivity in an autosomal dominant disease is neurofibromatosis type 1, or von Recklinghausen disease. As in retinoblastoma, the mutations that cause neurofibromatosis type 1 occur in a tumor-suppressor gene.\(^{10}\) The expression of this disease varies from a few harmless café-au-lait (light brown) spots on the skin to numerous neurofibromas, scoliosis, seizures, gliomas, neuromas, malignant peripheral nerve sheath tumors, hypertension, and learning disorders (Figure 2-23).
Several factors cause variable expressivity. Genes at other loci sometimes modify the expression of a disease-causing gene. Environmental factors also can influence expression of a disease-causing gene. Finally, different mutations at a locus can cause variation in severity. For example, a mutation that alters only one amino acid of the factor VIII gene usually produces a mild form of hemophilia A, whereas a “stop” codon (premature termination of translation) usually produces a more severe form of this blood coagulation disorder.

**Epigenetics and Genomic Imprinting**

Although this chapter focuses on DNA sequence variation and its consequence for disease, there is increasing evidence that the same DNA sequence can produce dramatically different phenotypes because of chemical modifications altering the expression of genes (these modifications are collectively termed **epigenetic**, Chapter 3). An important example of such a modification is **DNA methylation**, the attachment of a methyl group to a cytosine base followed by a guanine base in the DNA sequence (Figure 2-24). These sequences, which are common near many genes, are termed **CpG islands**. When the CpG islands located near a gene become
heavily methylated, the gene is less likely to be transcribed into mRNA. In other words, the gene becomes transcriptionally inactive. One study showed that identical (monozygotic) twins accumulate different methylation patterns in the DNA sequences of their somatic cells as they age, causing increasing numbers of phenotypic differences. Intriguingly, twins with more differences in their lifestyles (e.g., smoking versus nonsmoking) accumulated larger numbers of differences in their methylation patterns. The twins, despite having identical DNA sequences, become more and more different as a result of epigenetic changes, which in turn affect the expression of genes (see Figure 3-5).
Epigenetic alteration of gene activity can have important disease consequences. For example, a major cause of one form of inherited colon cancer (termed hereditary nonpolyposis colorectal cancer [HNPCC]) is the methylation of a gene whose protein product repairs damaged DNA. When this gene becomes inactive,
damaged DNA accumulates, eventually resulting in colon tumors. Epigenetic
changes are also discussed in Chapters 3, 10 and 11.

Approximately 100 human genes are thought to be methylated differently,
depending on which parent transmits the gene. This epigenetic modification,
characterized by methylation and other changes, is termed genomic imprinting. For
each of these genes, one of the parents imprints the gene (inactivates it) when it is
transmitted to the offspring. An example is the insulin-like growth factor 2 gene
(IGF2) on chromosome 11, which is transmitted by both parents, but the copy
inherited from the mother is normally methylated and inactivated (imprinted). Thus
only one copy of IGF2 is active in normal individuals. However, the maternal
imprint is occasionally lost, resulting in two active copies of IGF2. This causes
excess fetal growth and contributes to a condition known as Beckwith-Weidemann
syndrome (see p. 65).

A second example of genomic imprinting is a deletion of part of the long arm of
chromosome 15 (15q11-q13), which, when inherited from the father, causes the
offspring to manifest a disease known as Prader-Willi syndrome (short stature,
obesity, hypogonadism). When the same deletion is inherited from the mother, the
offspring develop Angelman syndrome (intellectual disability, seizures, atactic gait).
The two different phenotypes reflect the fact that different genes are normally active
in the maternally and paternally transmitted copies of this region of chromosome 15
(see p. 65).

**Autosomal Recessive Inheritance**

**Characteristics of Pedigrees**

Like autosomal dominant diseases, diseases caused by autosomal recessive genes
are rare in populations, although there can be numerous carriers. The most
common lethal recessive disease in white children, cystic fibrosis, occurs in about 1
in 2500 births. Approximately 1 in 25 whites carries a copy of a mutation that causes
cystic fibrosis (see Chapter 28). Carriers are phenotypically unaffected. Some
autosomal recessive diseases are characterized by delayed age of onset, incomplete
penetrance, and variable expressivity.

Figure 2-25 shows a pedigree for cystic fibrosis. The gene responsible for cystic
fibrosis encodes a chloride ion channel in some epithelial cells. Defective transport
of chloride ions leads to a salt imbalance that results in secretions of abnormally
thick, dehydrated mucus. Some digestive organs, particularly the pancreas, become
obstructed, causing malnutrition, and the lungs become clogged with mucus,
making them highly susceptible to bacterial infections. Death from lung disease or
heart failure occurs before 40 years of age in about half of persons with cystic
fibrosis.

The important criteria for discerning autosomal recessive inheritance include the following:

1. Males and females are affected in equal proportions.

2. Consanguinity (marriage between related individuals) is sometimes present, especially for rare recessive diseases.

3. The disease may be seen in siblings of affected individuals but usually not in their parents.

4. On average, one fourth of the offspring of carrier parents will be affected.

**Recurrence Risks**

In most cases of recessive disease, both of the parents of affected individuals are heterozygous carriers. On average, one fourth of their offspring will be normal homozygotes, half will be phenotypically normal carrier heterozygotes, and one fourth will be homozygotes with the disease (Figure 2-26). Thus the recurrence risk for the offspring of carrier parents is 25%. However, in any given family, there are chance fluctuations.
If two parents have a recessive disease, they each must be homozygous for the disease. Therefore all their children also must be affected. This distinguishes recessive from dominant inheritance because two parents both affected by a dominant gene are nearly always both heterozygotes and thus one fourth of their children will be unaffected.

Because carrier parents usually are unaware that they both carry the same recessive allele, they often produce an affected child before becoming aware of their condition. Carrier detection tests can identify heterozygotes by analyzing the DNA sequence to reveal a mutation. Some recessive diseases for which carrier detection tests are routinely used include phenylketonuria (PKU), sickle cell disease, cystic fibrosis, Tay-Sachs disease, hemochromatosis, and galactosemia.

**Consanguinity**

Consanguinity and inbreeding are related concepts. Consanguinity refers to the mating of two related individuals, and the offspring of such matings are said to be inbred. Consanguinity is sometimes an important characteristic of pedigrees for recessive diseases because relatives share a certain proportion of genes received from a common ancestor. The proportion of shared genes depends on the closeness of their biologic relationship. Consanguineous matings produce a significant increase in recessive disorders and are seen most often in pedigrees for rare recessive disorders.

**X-Linked Inheritance**

Some genetic conditions are caused by mutations in genes located on the sex chromosomes, and this mode of inheritance is termed sex linked. Only a few diseases are known to be inherited as X-linked dominant or Y chromosome traits,
so only the more common X-linked recessive diseases are discussed here.

Because females receive two X chromosomes, one from the father and one from the mother, they can be homozygous for a disease allele at a given locus, homozygous for the normal allele at the locus, or heterozygous. Males, having only one X chromosome, are hemizygous for genes on this chromosome. If a male inherits a recessive disease gene on the X chromosome, he will be affected by the disease because the Y chromosome does not carry a normal allele to counteract the effects of the disease gene. Because a single copy of an X-linked recessive gene will cause disease in a male, whereas two copies are required for disease expression in females, more males are affected by X-linked recessive diseases than are females.

**X Inactivation**

In the late 1950s Mary Lyon proposed that one X chromosome in the somatic cells of females is permanently inactivated, a process termed X inactivation. This proposal, the Lyon hypothesis, explains why most gene products coded by the X chromosome are present in equal amounts in males and females, even though males have only one X chromosome and females have two X chromosomes. This phenomenon is called dosage compensation. The inactivated X chromosomes are observable in many interphase cells as highly condensed intranuclear chromatin bodies, termed Barr bodies (after Barr and Bertram, who discovered them in the late 1940s). Normal females have one Barr body in each somatic cell, whereas normal males have no Barr bodies.

X inactivation occurs very early in embryonic development—approximately 7 to 14 days after fertilization. In each somatic cell, one of the two X chromosomes is inactivated. In some cells, the inactivated X chromosome is the one contributed by the father; in other cells it is the one contributed by the mother. Once the X chromosome has been inactivated in a cell, all the descendants of that cell have the same chromosome inactivated (Figure 2-27). Thus inactivation is said to be random but fixed.
Some individuals do not have the normal number of X chromosomes in their somatic cells. For example, males with Klinefelter syndrome typically have two X chromosomes and one Y chromosome. These males do have one Barr body in each cell. Females whose cell nuclei have three X chromosomes have two Barr bodies in each cell, and females whose cell nuclei have four X chromosomes have three Barr bodies in each cell. Females with Turner syndrome have only one X chromosome and no Barr bodies. Thus the number of Barr bodies is always one less than the number of X chromosomes in the cell. All but one X chromosome are always inactivated.

Persons with abnormal numbers of X chromosomes, such as those with Turner syndrome or Klinefelter syndrome, are not physically normal. This situation presents a puzzle because they presumably have only one active X chromosome, the same as individuals with normal numbers of chromosomes. This is probably because the distal tips of the short and long arms of the X chromosome, as well as several other regions on the chromosome arm, are not inactivated. Thus X inactivation is also known to be *incomplete*.

The inactivated X chromosome DNA is heavily methylated. Inactive X
chromosomes can be at least partially reactivated in vitro by administering 5-azacytidine, a demethylating agent.

**Sex Determination**

The process of sexual differentiation, in which the embryonic gonads become either testes or ovaries, begins during the sixth week of gestation. A key principle of mammalian sex determination is that one copy of the Y chromosome is sufficient to initiate the process of gonadal differentiation that produces a male fetus. The number of X chromosomes does not alter this process. For example, an individual with two X chromosomes and one Y chromosome in each cell is still phenotypically a male. Thus the Y chromosome contains a gene that begins the process of male gonadal development.

This gene, termed SRY (for “sex-determining region on the Y”), has been located on the short arm of the Y chromosome. The SRY gene lies just outside the pseudoautosomal region (Figure 2-28), which pairs with the distal tip of the short arm of the X chromosome during meiosis and exchanges genetic material with it (crossover), just as autosomes do. The DNA sequences of these regions on the X and Y chromosomes are highly similar. The rest of the X and Y chromosomes, however, do not exchange material and are not similar in DNA sequence.
Other genes that contribute to male differentiation are located on other chromosomes. Thus SRY triggers the action of genes on other chromosomes. This concept is supported by the fact that the SRY protein product is similar to other proteins known to regulate gene expression.

Occasionally, the crossover between X and Y occurs closer to the centromere than it should, placing the SRY gene on the X chromosome after crossover. This variation can result in offspring with an apparently normal XX karyotype but a male phenotype. Such XX males are seen in about 1 in 20,000 live births and resemble males with Klinefelter syndrome. Conversely, it is possible to inherit a Y
chromosome that has lost the SRY gene (the result of either a crossover error or a deletion of the gene). This situation produces an XY female. Such females have gonadal streaks rather than ovaries and have poorly developed secondary sex characteristics.

Quick Check 2-2

1. Why is the influence of environment significant to phenotype?

2. Discuss the differences between a dominant and a recessive allele.

3. Why are the concepts of variable expressivity, incomplete penetrance, and delayed age of onset so important in relation to genetic diseases?

4. What is the recurrence risk for autosomal dominant inheritance and recessive inheritance?

Characteristics of Pedigrees

X-linked pedigrees show distinctive modes of inheritance. The most striking characteristic is that females seldom are affected. To express an X-linked recessive trait fully, a female must be homozygous: either both her parents are affected, or her father is affected and her mother is a carrier. Such matings are rare.

The following are important principles of X-linked recessive inheritance:

1. The trait is seen much more often in males than in females.

2. Because a father can give a son only a Y chromosome, the trait is never transmitted from father to son.

3. The gene can be transmitted through a series of carrier females, causing the appearance of one or more “skipped generations.”

4. The gene is passed from an affected father to all his daughters, who, as phenotypically normal carriers, transmit it to approximately half their sons, who are affected.

A relatively common X-linked recessive disorder is Duchenne muscular dystrophy (DMD), which affects approximately 1 in 3500 males. As its name suggests, this disorder is characterized by progressive muscle degeneration.
Affected individuals usually are unable to walk by age 10 or 12 years. The disease affects the heart and respiratory muscles, and death caused by respiratory or cardiac failure usually occurs before 20 years of age. Identification of the disease-causing gene (on the short arm of the X chromosome) has greatly increased our understanding of the disorder.\textsuperscript{15} The \textit{DMD} gene is the largest gene ever found in humans, spanning more than 2 million DNA bases. It encodes a previously undiscovered muscle protein, termed \textit{dystrophin}. Extensive study of dystrophin indicates that it plays an essential role in maintaining the structural integrity of muscle cells: it may also help to regulate the activity of membrane proteins. When dystrophin is absent, as in DMD, the cell cannot survive, and muscle deterioration ensues. Most cases of DMD are caused by frameshift deletions of portions of the \textit{DMD} gene and thus involve alterations of the amino acids encoded by the DNA following the deletion.

**Recurrence Risks**

The most common mating type involving X-linked recessive genes is the combination of a carrier female and a normal male (Figure 2-29, \textit{A}). On average, the carrier mother will transmit the disease-causing allele to half her sons (who are affected) and half her daughters (who are carriers).
The other common mating type is an affected father and a normal mother (see Figure 2-29, B). In this situation, all the sons will be normal because the father can transmit only his Y chromosome to them. Because all the daughters must receive the father's X chromosome, they will all be heterozygous carriers. Because the sons must receive the Y chromosome and the daughters must receive the X chromosome with the disease gene, these are precise outcomes and not probabilities. None of the children will be affected.

The final mating pattern, less common than the other two, involves an affected father and a carrier mother (see Figure 2-29, C). With this pattern, on average, half the daughters will be heterozygous carriers, and half will be homozygous for the disease allele and thus affected. Half the sons will be normal, and half will be

![Punnett Square and X-Linked Recessive Traits](image)

B, Punnett square for the mating of a normal female ($X^H X^H$) with a male affected by an X-linked recessive disease ($X^h Y$). C, Punnett square for the mating of a female who carries an X-linked recessive gene ($X^H X^h$) with a male who is affected with the disease caused by the gene ($X^h Y$).
affected. Some X-linked recessive diseases, such as DMD, are fatal or incapacitating before the affected individual reaches reproductive age, and therefore affected fathers are rare.

**Sex-Limited and Sex-Influenced Traits**

A **sex-limited trait** can occur in only one sex, often because of anatomic differences. Inherited uterine and testicular defects are two obvious examples. A **sex-influenced trait** occurs much more often in one sex than the other. For example, male-pattern baldness occurs in both males and females but is much more common in males. Autosomal dominant breast cancer, which is much more commonly expressed in females than males, is another example of a sex-influenced trait.
Linkage Analysis and Gene Mapping

Locating genes on specific regions of chromosomes has been one of the most important goals of human genetics. The location and identification of a gene can tell much about the function of the gene, the interaction of the gene with other genes, and the likelihood that certain individuals will develop a genetic disease.

Classic Pedigree Analysis

Mendel's second law, the principle of independent assortment, states that an individual's genes will be transmitted to the next generation independently of one another. This law is only partly true, however, because genes located close together on the same chromosome do tend to be transmitted together to the offspring. Thus Mendel's principle of independent assortment holds true for most pairs of genes but not those that occupy the same region of a chromosome. Such loci demonstrate linkage and are said to be linked.

During the first meiotic stage, the arms of homologous chromosome pairs intertwine and sometimes exchange portions of their DNA (Figure 2-30) in a process known as crossover. During crossover, new combinations of alleles can be formed. For example, two loci on a chromosome have alleles $A$ and $a$ and alleles $B$ and $b$. Alleles $A$ and $B$ are located together on one member of a chromosome pair, and alleles $a$ and $b$ are located on the other member. The genotype of this individual is denoted as $AB/ab$. 
As Figure 2-30, A, shows, the allele pairs $AB$ and $ab$ would be transmitted together when no crossover occurs. However, when crossover occurs (see Figure 2-30, B), all four possible pairs of alleles can be transmitted to the offspring: $AB$, $aB$, $Ab$, and $ab$. The process of forming such new arrangements of alleles is called recombinant. Crossover does not necessarily lead to recombination, however, because double crossover between two loci can result in no actual recombination of the alleles at the loci (see Figure 2-30, C).

Once a close linkage has been established between a disease locus and a “marker” locus (a DNA sequence that varies among individuals) and once the alleles of the two loci that are inherited together within a family have been determined, reliable predictions can be made as to whether a member of a family will develop the disease. Linkage has been established between several DNA polymorphisms and each of the two major genes that can cause autosomal dominant breast cancer (about 5% of breast cancer cases are caused by these autosomal dominant genes). Determining this kind of linkage means that it is possible for offspring of an individual with autosomal dominant breast cancer to know whether they also carry the gene and thus could pass it on to their own children. In most cases, specific disease-causing mutations can be identified, allowing direct detection and diagnosis.
For some genetic diseases, prophylactic treatment is available if the condition can be diagnosed in time. An example of this is hemochromatosis, a recessive genetic disease in which excess iron is absorbed, causing degeneration of the heart, liver, brain, and other vital organs. Individuals at risk for developing the disease can be determined by testing for a mutation in the hemochromatosis gene and through clinical tests, and preventive therapy (periodic phlebotomy) can be initiated to deplete iron stores and ensure a normal life span.

**Complete Human Gene Map: Prospects and Benefits**

The major goals of the Human Genome Project were to find the locations of all human genes (the “gene map”) and to determine the entire human DNA sequence. These goals have now been accomplished and the genes responsible for more than 4000 mendelian conditions have been identified (Figure 2-31). This has greatly increased our understanding of the mechanisms that underlie many diseases, such as retinoblastoma, cystic fibrosis, neurofibromatosis, and Huntington disease. The project also has led to more accurate diagnosis of these conditions, and in some cases more effective treatment.
DNA sequencing has become much less expensive and more efficient in recent years. Consequently, many thousands of individuals have now been completely sequenced, leading in some cases to the identification of disease-causing genes (see Health Alert: Gene Therapy).

**Health Alert**

**Gene Therapy**

Thousands of subjects are currently enrolled in more than 1000 gene therapy protocols. Most of these protocols involve the genetic alteration of cells to combat various types of cancer. Others involve the treatment of inherited diseases, such as β-thalassemia, hemophilia B, severe combined immunodeficiency, and retinitis pigmentosa.
Multifactorial Inheritance

Not all traits are produced by single genes; some traits result from several genes acting together. These are called polygenic traits. When environmental factors influence the expression of the trait (as is usually the case), the term multifactorial inheritance is used. Many multifactorial and polygenic traits tend to follow a normal distribution in populations (the familiar bell-shaped curve). Figure 2-32 shows how three loci acting together can cause grain color in wheat to vary in a gradual way from white to red, exemplifying multifactorial inheritance. If both alleles at each of the three loci are white alleles, the color is pure white. If most alleles are white but a few are red, the color is somewhat darker; if all are red, the color is dark red.
Other examples of multifactorial traits include height and IQ. Although both height and IQ are determined in part by genes, they are influenced also by environment. For example, the average height of many human populations has increased by 5 to 10 cm in the past 100 years because of improvements in nutrition and health care. Also, IQ scores can be improved by exposing individuals (especially children) to enriched learning environments. Thus both genes and
environment contribute to variation in these traits.

A number of diseases do not follow the bell-shaped distribution. Instead they appear to be either present in or absent from an individual. Yet they do not follow the patterns expected of single-gene diseases. Many of these are probably polygenic or multifactorial, but a certain **threshold of liability** must be crossed before the disease is expressed. Below the threshold the individual appears normal; above it, the individual is affected by the disease (Figure 2-33).

A good example of such a threshold trait is pyloric stenosis, a disorder characterized by a narrowing or obstruction of the pylorus, the area between the stomach and small intestine. Chronic vomiting, constipation, weight loss, and electrolyte imbalance can result from the condition, but it is easily corrected by surgery. The prevalence of pyloric stenosis is about 3 in 1000 live births in whites. This disorder is much more common in males than females, affecting 1 in 200
males and 1 in 1000 females. The apparent reason for this difference is the threshold of liability is much lower in males than females, as shown in Figure 2-33. Thus fewer defective alleles are required to generate the disorder in males. This situation also means the offspring of affected females are more likely to have pyloric stenosis because affected females necessarily carry more disease-causing alleles than do most affected males.

A number of other common diseases are thought to correspond to a threshold model. They include cleft lip and cleft palate, neural tube defects (anencephaly, spina bifida), clubfoot (talipes), and some forms of congenital heart disease.

Although recurrence risks can be given with confidence for single-gene diseases (e.g., 50% for autosomal dominants, 25% for autosomal recessives), it is considerably more difficult to do so for multifactorial diseases. The number of genes contributing to the disease is not known, the precise allelic constitution of the biologic parents is not known, and the extent of environmental effects can vary from one population to another. For most multifactorial diseases, empirical risks (i.e., those based on direct observation) have been derived. To determine empirical risks, a large sample of biologic families in which one child has developed the disease is examined. The siblings of each child are then surveyed to calculate the percentage who also develop the disease.

Another difficulty is distinguishing polygenic or multifactorial diseases from single-gene diseases having incomplete penetrance or variable expressivity. Large data sets and good epidemiologic data often are necessary to make the distinction. Box 2-1 lists criteria commonly used to define multifactorial diseases.

### Box 2-1

**Criteria Used to Define Multifactorial Diseases**

1. The recurrence risk becomes higher if more than one family member is affected. For example, the recurrence risk for neural tube defects in a British family increases to 10% if two siblings have been born with the disease. By contrast, the recurrence risk for single-gene diseases remains the same regardless of the number of siblings affected.

2. If the expression of the disease is more severe, the recurrence risk is higher. This is consistent with the liability model; a more severe expression indicates that the individual is at the extreme end of the liability distribution. Relatives of the affected individual are thus at a higher risk for inheriting disease genes. Cleft lip or cleft palate is a condition in which this has been shown to be true.
3. Relatives of probands of the less commonly affected are more likely to develop the disease. As with pyloric stenosis, this occurs because an affected individual of the less susceptible sex is usually at a more extreme position on the liability distribution.

4. Generally, if the population frequency of the disease is \( f \), the risk for offspring and siblings of probands is approximately \( \sqrt{f} \). This does not usually hold true for single-gene traits.

5. The recurrence risk for the disease decreases rapidly in more remotely related relatives. Although the recurrence risk for single-gene diseases decreases by 50% with each degree of relationship (e.g., an autosomal dominant disease has a 50% recurrence risk for siblings, 25% for uncle-nephew relationship, 12.5% for first cousins), the risk for multifactorial inheritance decreases much more quickly.

The genetics of common disorders such as hypertension, heart disease, and diabetes is complex and often confusing. Nevertheless, the public health impact of these diseases, together with the evidence for hereditary factors in their etiology, demands that genetic studies be pursued. Hundreds of genes contributing to susceptibility for these diseases have been discovered, and the next decade will undoubtedly witness substantial advancements in our understanding of these disorders.

**Quick Check 2-3**

1. Define linkage analysis; cite an example.

2. Why is “threshold of liability” an important consideration in multifactorial inheritance?

3. Discuss the concept of multifactorial inheritance, and include two examples.
Did You Understand?

DNA, RNA, and Proteins: Heredity at the Molecular Level

1. Genes, the basic units of inheritance, are composed of deoxyribonucleic acid (DNA) and are located on chromosomes.

2. DNA is composed of deoxyribose, a phosphate molecule, and four types of nitrogenous bases. The physical structure of DNA is a double helix.

3. The DNA bases code for amino acids, which in turn make up proteins. The amino acids are specified by triplet codons of nitrogenous bases.

4. DNA replication is based on complementary base pairing, in which a single strand of DNA serves as the template for attracting bases that form a new strand of DNA.

5. DNA polymerase is the primary enzyme involved in replication. It adds bases to the new DNA strand and performs “proofreading” functions.

6. A mutation is an inherited alteration of genetic material (i.e., DNA).

7. Substances that cause mutations are called mutagens.

8. The mutation rate in humans varies from locus to locus and ranges from $10^{-4}$ to $10^{-7}$ per gene per generation.

9. Transcription and translation, the two basic processes in which proteins are specified by DNA, both involve ribonucleic acid (RNA). RNA is chemically similar to DNA, but it is single stranded, has a ribose sugar molecule, and has uracil rather than thymine as one of its four nitrogenous bases.

10. Transcription is the process by which DNA specifies a sequence of messenger RNA (mRNA).

11. Much of the RNA sequence is spliced from the mRNA before the mRNA leaves the nucleus. The excised sequences are called introns, and those that remain to code for proteins are called exons.
12. Translation is the process by which RNA directs the synthesis of polypeptides. This process takes place in the ribosomes, which consist of proteins and ribosomal RNA (rRNA).

13. During translation, mRNA interacts with transfer RNA (tRNA), a molecule that has an attachment site for a specific amino acid.

**Chromosomes**

1. Human cells consist of diploid somatic cells (body cells) and haploid gametes (sperm and egg cells).

2. Humans have 23 pairs of chromosomes. Twenty-two of these pairs are autosomes. The remaining pair consists of the sex chromosomes. Females have two homologous X chromosomes as their sex chromosomes; males have an X and a Y chromosome.

3. A karyotype is an ordered display of chromosomes arranged according to length and the location of the centromere.

4. Various types of stains can be used to make chromosome bands more visible.

5. About 1 in 150 live births has a major diagnosable chromosome abnormality. Chromosome abnormalities are the leading known cause of mental retardation and miscarriage.

6. Polyploidy is a condition in which a euploid cell has some multiple of the normal number of chromosomes. Humans have been observed to have triploidy (three copies of each chromosome) and tetraploidy (four copies of each chromosome); both conditions are lethal.

7. Somatic cells that do not have a multiple of 23 chromosomes are aneuploid. Aneuploidy is usually the result of nondisjunction.

8. Trisomy is a type of aneuploidy in which one chromosome is present in three copies in somatic cells. A partial trisomy is one in which only part of a chromosome is present in three copies.

9. Monosomy is a type of aneuploidy in which one chromosome is present in only one copy in somatic cells.
10. In general, monosomies cause more severe physical defects than do trisomies, illustrating the principle that the loss of chromosome material has more severe consequences than the duplication of chromosome material.

11. Down syndrome, a trisomy of chromosome 21, is the best-known disease caused by a chromosome aberration. It affects 1 in 800 live births and is much more likely to occur in the offspring of women older than 35 years.

12. Most aneuploidies of the sex chromosomes have less severe consequences than those of the autosomes.

13. The most commonly observed sex chromosome aneuploidies are the 47,XXX karyotype, 45,X karyotype (Turner syndrome), 47,XXY karyotype (Klinefelter syndrome), and 47,XYY karyotype.

14. Abnormalities of chromosome structure include deletions, duplications, inversions, and translocations.

**Elements of Formal Genetics**

1. Mendelian traits are caused by single genes, each of which occupies a position, or locus, on a chromosome.

2. Alleles are different forms of genes located at the same locus on a chromosome.

3. At any given locus in a somatic cell, an individual has two genes, one from each parent. An individual may be homozygous or heterozygous for a locus.

4. An individual's genotype is his or her genetic makeup, and the phenotype reflects the interaction of genotype and environment.

5. In a heterozygote, a dominant gene's effects mask those of a recessive gene. The recessive gene is expressed only when it is present in two copies.

**Transmission of Genetic Diseases**

1. Genetic diseases caused by single genes usually follow autosomal dominant, autosomal recessive, or X-linked recessive modes of inheritance.
2. Pedigree charts are important tools in the analysis of modes of inheritance.

3. Recurrence risks specify the probability that future offspring will inherit a genetic disease. For single-gene diseases, recurrence risks remain the same for each offspring, regardless of the number of affected or unaffected offspring.

4. The recurrence risk for autosomal dominant diseases is usually 50%.

5. Germline mosaicism can alter recurrence risks for genetic diseases because unaffected parents can produce multiple affected offspring. This situation occurs because the germline of one parent is affected by a mutation but the parent's somatic cells are unaffected.

6. Skipped generations are not seen in classic autosomal dominant pedigrees.

7. Males and females are equally likely to exhibit autosomal dominant diseases and to pass them on to their offspring.

8. Many genetic diseases have a delayed age of onset.

9. A gene that is not always expressed phenotypically is said to have incomplete penetrance.

10. Variable expressivity is a characteristic of many genetic diseases.

11. Genomic imprinting, which is associated with methylation, results in differing expression of a disease gene, depending on which parent transmitted the gene.

12. Epigenetics involves changes, such as the methylation of DNA bases, that do not alter the DNA sequence but can alter the expression of genes.

13. Most commonly, biologic parents of children with autosomal recessive diseases are both heterozygous carriers of the disease gene.

14. The recurrence risk for autosomal recessive diseases is 25%.

15. Males and females are equally likely to be affected by autosomal recessive diseases.

16. Consanguinity is sometimes present in families with autosomal recessive diseases, and it becomes more prevalent with rarer recessive diseases.
17. Carrier detection tests for an increasing number of autosomal recessive diseases are available.

18. The frequency of genetic diseases approximately doubles in the offspring of first-cousin matings.

19. In each normal female somatic cell, one of the two X chromosomes is inactivated early in embryogenesis.

20. X inactivation is random, fixed, and incomplete (i.e., only part of the chromosome is actually inactivated). It may involve methylation.

21. Gender is determined embryonically by the presence of the SRY gene on the Y chromosome. Embryos that have a Y chromosome (and thus the SRY gene) become males, whereas those lacking the Y chromosome become females. When the Y chromosome lacks the SRY gene, an XY female can be produced. Similarly, an X chromosome that contains the SRY gene can produce an XX male.

22. X-linked genes are those that are located on the X chromosome. Nearly all known X-linked diseases are caused by X-linked recessive genes.

23. Males are hemizygous for genes on the X chromosome.

24. X-linked recessive diseases are seen much more often in males than in females because males need only one copy of the gene to express the disease.

25. Biologic fathers cannot pass X-linked genes to their sons.

26. Skipped generations often are seen in X-linked recessive disease pedigrees because the gene can be transmitted through carrier females.

27. Recurrence risks for X-linked recessive diseases depend on the carrier and affected status of the mother and father.

28. A sex-limited trait is one that occurs only in one sex (gender).

29. A sex-influenced trait is one that occurs more often in one sex than in the other.

**Linkage Analysis and Gene Mapping**
1. During meiosis I, crossover occurs and can cause recombinations of alleles located on the same chromosome.

2. The frequency of recombinations can be used to infer the map distance between loci on the same chromosome.

3. A marker locus, when closely linked to a disease-gene locus, can be used to predict whether an individual will develop a genetic disease.

4. The major goals of the Human Genome Project were to find the locations of all human genes (the “gene map”) and to determine the entire human DNA sequence. These goals have now been accomplished and the genes responsible for more than 4000 mendelian conditions have been identified.

**Multifactorial Inheritance**

1. Traits that result from the combined effects of several loci are polygenic. When environmental factors also influence the trait, it is multifactorial.

2. Many multifactorial traits have a threshold of liability. Once the threshold of liability has been crossed, the disease may be expressed.

3. Empirical risks, based on direct observation of large numbers of families, are used to estimate recurrence risks for multifactorial diseases.

4. Recurrence risks for multifactorial diseases become higher if more than one biologic family member is affected or if the expression of the disease in the proband is more severe.

5. Recurrence risks for multifactorial diseases decrease rapidly for more remote relatives.

Human beings exhibit an impressive diversity of physical and behavioral features. Some of this diversity is attributable to genetic variation. Another contributor to human diversity is epigenetic (“upon genetic”) modification (a change in phenotype or gene expression that does not involve DNA mutation or changes in nucleotide sequence). Basically, epigenetics is the study of mechanisms that will switch genes “on,” such that they are expressed, and “off,” such that they are silenced. Epigenetic mechanisms include chemical modifications to DNA and associated histones, and the production of small RNA molecules. Gene regulation by epigenetic processes can occur at the level of either transcription or translation. Epigenetic modification is critical for fundamental processes of human development, including the differentiation of embryonic stem cells into specific cell types, and the inactivation of one of the two X chromosomes in each cell of a genetic female. Some genes are noted to be imprinted, a form of epigenetic regulation where the expression of a gene depends on whether it is inherited from the mother or the father.
Epigenetic Mechanisms

A variety of diseases can result from abnormal epigenetic states. Metabolic disease can occur when there is aberrant expression of both copies of a locus that is typically imprinted. Environmental stressors can markedly increase the risk of aberrant epigenetic modification and are strongly associated with some cancers. It is because of their increasing clear role in a wide range of pathologies that abnormal epigenetic states are currently a focus of both preventative efforts and pharmaceutical intervention. Currently known epigenetic mechanisms include DNA methylation, histone modifications, and RNA-based mechanisms (Figure 3-1).
DNA Methylation

**DNA methylation** (see Figure 3-1) occurs through the attachment of a methyl group (CH$_3$) to a cytosine. Dense DNA methylation can be thought of as “insulation” that renders genes silent by blocking access by transcription factors. Dense methylation is typically coincident with hypoacetylation (decrease of the functional group acetyl) of the histone proteins around which the DNA is wound (see Histone Modifications). Together, DNA methylation and histone hypoacetylation can render a gene transcriptionally silent, preventing production of the encoded protein. Methylated cytosines have been found to occur principally at cytosines that are followed by a guanine base (sometimes known as cytosines in “CpG dinucleotides”). In human embryonic stem cells, methylation also can occur at cytosines outside of the CpG context (see Figure 2-24).

DNA methylation plays a prominent role in both human health and disease. For example, in each cell of a normal human female, one of the two X chromosomes is silenced by dense methylation and associated molecular marks, whereas the other X chromosome is transcriptionally active and largely devoid of methylation. During early embryonic development, there is epigenetic inactivation of one of the two X chromosomes in each cell of a human female—either the X chromosome inherited from her mother or the X chromosome inherited from her father. The determination of which chromosome is to be silenced occurs at random and independently in each of the cells present at this stage of development; the silent state of that chromosome is inherited by all subsequent copies. If a woman's two X chromosomes carry different alleles at a given locus, random X inactivation can lead to somatic mosaicism, wherein the alleles active in two different cells can confer two very different traits. Striking examples include the patchy coloration of calico cats and anhidrotic ectodermal dysplasia, a condition characterized by patchy presence and absence of sweat glands in the skin of human females who have one X chromosome bearing a normal allele and one X chromosome bearing a mutant allele at the X-encoded locus. Because of the somatic mosaicism that arises through random inactivation of the X chromosome, females tend to have less severe phenotypes than do males for a variety of X-linked disorders, including color blindness and fragile X syndrome.

Aberrant DNA methylation, either the presence of dense methylation where it is typically absent or the absence of methylation where it is typically present, can lead to misregulation of tumor-suppressor genes and oncogenes. Abnormal DNA methylation states are a common feature of several human cancers, including those of the colon$^{1-3}$ (see Figures 3-1 and 3-6 [p. 69]; also see Chapter 10).
Histone Modifications

Histone modifications (see Figure 3-1) include histone acetylation (adding an acetyl group) and deacetylation (deletion of an acetyl group) to the end of a histone protein. Like DNA methylation, these changes can alter the expression state of chromatin. Histones are proteins that facilitate compaction of genomic DNA into the nucleus of a cell, much as a spool helps to organize a long piece of thread for storage in a small space. When the DNA of the human genome is wound around histones, it is only ≈1/40,000 as long as it would be in its uncondensed state. Chemical modification of histones in a region of DNA can either up-regulate or down-regulate nearby gene expression by increasing or decreasing the tightness of the interaction between DNA and histones, thus modulating the extent to which DNA is accessible to transcription factors. DNA in association with histones is referred to as “chromatin.” At any given time, various regions of chromatin are typically in one of two forms: euchromatin, an open state in which most or all nearby genes are transcriptionally active; or heterochromatin, a closed state in which most or all nearby genes are transcriptionally inactive.

Chromatin structure plays a critical role in determining the developmental potential of a given cell lineage, and can undergo dramatic changes during organismal development. For example, chromatin states differ substantially between embryonic stem cells, which are poised to give rise to all of the different cell types that make up an individual, and terminally differentiated cells, which are committed to a specific developmental path. The fraction of DNA that is in the heterochromatic state increases as cells differentiate, consistent with the reduction in the number of genes that are active as a cell lineage transitions from pluripotency to terminal differentiation. Mutations in genes that encode histone-modifying proteins have been implicated in congenital heart disease, for example, highlighting histone modification states as critical for normal development.

In contrast to the vast majority of other cell types, including oocytes, sperm cells express not histones but protamines, which are evolutionarily derived from histones. Protamines enable sperm DNA to wind into an even more compact state than does the histone-bound DNA in somatic cells. This tight compaction improves the hydrodynamic features of the sperm head, facilitating its movement toward the egg.

RNA-Based Mechanisms

Noncoding RNAs (ncRNAs) and other RNA-based mechanisms (see Figure 3-1) play an important role in regulating a wide variety of cellular processes, including
RNA splicing and DNA replication. These ncRNAs have been likened to “sponges” in so far as they can “sop up” complementary RNAs, thus inhibiting their function (see, for example, www.ncbi.nlm.nih.gov/pmc/articles/PMC2957044/). Of particular relevance to gene regulation are the hairpin-shaped microRNAs (miRNAs), which are encoded by DNA sequences of approximately 22 nucleotides, typically within the introns (a segment of a DNA molecule that does not code for proteins) of genes or in noncoding DNA located between genes (see Chapter 2). In contrast to DNA methylation and histone modification, both of which principally affect gene expression at the level of transcription, miRNAs typically modulate the stability and translational efficiency of existing messenger RNAs (mRNAs) encoded at other loci. Interaction between miRNAs and mRNAs target for degradation is typically mediated by regions of partial sequence complementarity. As a result, miRNAs can at once be specific enough so that they do not bind to all of the mRNAs in a cell and general enough to regulate a large number of different mRNA sequences. miRNAs also directly modulate translation by impairing ribosomal function. miRNAs regulate diverse signaling pathways; those that stimulate cancer development and progression are called oncomirs. For example, miRNAs have been linked to carcinogenesis because they alter the activity of oncogenes and tumor-suppressor genes (see Chapter 10).
Epigenetics and Human Development

Each of the cells in the very early embryo has the potential to give rise to a somatic cell of any type. These embryonic stem cells are therefore said to be totipotent (“possessing all powers”). A key process in early development then is the differential epigenetic modification of specific DNA nucleotide sequences in these embryonic stem cells, ultimately leading to the differential gene-expression profiles that characterize the various differentiated somatic cell types. These early modifications ensure that specific genes are expressed only in the cells and tissue types in which their gene products typically function (e.g., factor VIII expression primarily in hepatocytes, or dopamine receptor expression in neurons).

Epigenetic modifications early in development also highlight a fundamental feature of genetics as compared to epigenetic information: all of the cells in a given individual contain almost exactly the same genetic information. It is the epigenetic information eventually placed on top of these sequences that enables them to achieve the diverse functions of differentiated somatic cells. A small percentage of genes, termed housekeeping genes, are necessary for the function and maintenance of all cells. These genes escape epigenetic silencing and remain transcriptionally active in all or nearly all cells. Housekeeping genes include encoding histones, DNA and RNA polymerases, and ribosomal RNA genes.

How do embryonic stem cells achieve epigenetic states typical of totipotency, whereby they can give rise to all of the diverse cell types that make up a fully developed organism? One explanation is that early embryogenesis (approximately the 10 days just after fertilization) is characterized by rapid fluctuation in genome-wide DNA methylation densities. Fertilization triggers a global loss of DNA methylation at most loci in both the oocyte-contributed and the sperm-contributed genomes. This loss of methylation is accomplished in part by suppression of the DNA methyltransferases, the enzymes that add methyl groups to DNA. Methylation is not directly copied by the DNA replication process. Instead, immediately following replication, the methyltransferases read the pattern of methylation on the parent DNA strand and use that information to determine which daughter-strand cytosines should be methylated. As embryonic cell division proceeds in the absence of DNA methyltransferases, cell division continues, eventually yielding cells that have nearly all of their loci in unmethylated, transcriptionally active states. Around the time of implantation in the uterus, the DNA methyltransferases become active again, permitting establishment of the cell-lineage–specific marks required for the establishment of organ systems.
Genomic Imprinting

A baby inherits two copies of each autosomal gene: one from its mother and one from its father. For a large subset of these genes, expression is biallelic, meaning that both the maternally and the paternally inherited copies contribute to offspring phenotype. For another, smaller subset of these genes, expression is stochastically monoallelic, meaning that the maternal copy is randomly chosen for inactivation in some somatic cells and the paternal copy is randomly chosen for inactivation in other somatic cells. For a third and smaller subset of autosomes (about 1%) either the maternal copy or the paternal copy is imprinted, meaning that either the copy inherited through the sperm or the copy inherited through the egg is inactivated and remains in this inactive state in all of the somatic cells of the individual.

The subset of genes that are subject to imprinting is highly enriched for loci relevant to organismal growth. The genetic conflict hypothesis was developed as a potential explanation for this pattern. Although both the mother and the father benefit genetically from the birth and survival of offspring, their interests are not entirely aligned. Because a mother makes a large physiologic investment in each child, it is in her evolutionary best interest to limit the flow of energetic resources to any given offspring so as to maintain her physiologic capacity to bear subsequent children. By contrast, except in cases of certain permanent, certain monogamy, it is in the best interest of the father for his child to extract maximal resources from its mother, as his own future fecundity, or fertility, is not contingent on the sustained fecundity of the mother. In general, imprinting of maternally inherited genes tends to reduce offspring size; imprinting of paternally inherited genes tends to increase offspring size. One hallmark of imprinting-associated disease is that the phenotype of affected individuals is critically dependent on whether the mutation is inherited from the mother or from the father. Some examples are included in the following syndromes.

Prader-Willi and Angelman Syndromes

A well-known disease example of imprinting is associated with a deletion of about 4 million base (Mb) pairs of the long arm of chromosome 15. When this deletion is inherited from the father, the child manifests Prader-Willi syndrome, with features including short stature, hypotonia, small hands and feet, obesity, mild to moderate intellectual disability, and hypogonadism (Figure 3-2, A). The same 4-Mb deletion, when inherited from the mother, causes Angelman syndrome, which is characterized by severe intellectual disability, seizures, and an ataxic gait (Figure 3-2, B). These diseases are each observed in about 1 of every 15,000 live births;
chromosome deletions are responsible for about 70% of cases of both diseases. The deletions that cause Prader-Willi and Angelman syndromes are indistinguishable at the DNA sequence level and affect the same group of genes.

For several decades, it was unclear how the same deletion could produce such disparate results in different individuals. Further analysis showed that the 4-Mb deletion (the critical region) contains several genes that are normally transcribed only on the copy of chromosome 15 that is inherited from the father. These genes are transcriptionally inactive (imprinted) on the copy of chromosome 15 inherited from the mother. Similarly, other genes in the critical region are transcriptionally
active only on the chromosome copy inherited from the mother and are inactive on the chromosome inherited from the father. Thus, several genes in this region are normally active on only one chromosome copy (Figure 3-3). If the single active copy of one of these genes is lost because of a chromosome deletion, then no gene product is produced, resulting in disease.

Molecular analysis has revealed much about genes in this critical region of chromosome 15. The gene responsible for Angelman syndrome encodes a ligase involved in protein degradation during brain development (consistent with the mental retardation and ataxia observed in this disorder). In brain tissue, this gene is active only on the chromosome copy inherited from the mother. Consequently, a maternally transmitted deletion removes the single active copy of this gene. Several genes in the critical region are associated with Prader-Willi syndrome and they are transcribed only on the chromosome transmitted by the father. A paternally transmitted deletion removes the only active copies of these genes producing the features of Prader-Willi syndrome.

Beckwith-Wiedemann Syndrome

Another well-known example of imprinting is Beckwith-Wiedemann syndrome, an overgrowth condition accompanied by an increased predisposition to cancer.
**Beckwith-Wiedemann syndrome** is usually identifiable at birth because of the presence of large size for gestational age, neonatal hypoglycemia, a large tongue, creases on the earlobe, and omphalocele (birth defect of infant intestines). Children with Beckwith-Wiedemann syndrome have an increased risk of developing Wilms tumor or hepatoblastoma. Both of these tumors can be treated effectively if they are detected early; thus screening at regular intervals is an important part of management. Some children with Beckwith-Wiedemann syndrome also develop asymmetric overgrowth of a limb or one side of the face or trunk (hemihyperplasia).

As with Angelman syndrome, a minority of Beckwith-Wiedemann syndrome cases (about 20% to 30%) are caused by the inheritance of two copies of a chromosome from the father and no copy of the chromosome from the mother (uniparental disomy, in this case affecting chromosome 11). Several genes on the short arm of chromosome 11 are imprinted on either the paternally or the maternally transmitted chromosome. These genes are found in two separate, differentially methylated regions (DMRs). In DMR1, the gene that encodes insulin-like growth factor 2 (IGF2) is inactive on the maternally transmitted chromosome but active on the paternally transmitted chromosome. Thus, a normal individual has only one active copy of IGF2. When two copies of the paternal chromosome are inherited (i.e., paternal uniparental disomy) or there is loss of imprinting on the maternal copy of IGF2, an active IGF2 gene is present in double dose. These changes produce increased levels of insulin-like growth factor 2 during fetal development, contributing to the overgrowth features of Beckwith-Wiedemann syndrome. Note that, in contrast to Prader-Willi and Angelman syndromes, which are produced by a missing gene product, Beckwith-Wiedemann syndrome is caused, in part, by overexpression of a gene product.

**Russell-Silver Syndrome**

**Russell-Silver syndrome** is characterized by growth retardation, proportionate short stature, leg length discrepancy, and a small, triangular face. About one third of Russell-Silver syndrome cases are caused by imprinting abnormalities of chromosome 11p15.5 that lead to down-regulation of IGF2 and therefore diminished growth. Another 10% of cases of Russell-Silver syndrome are caused by maternal uniparental disomy. Thus, whereas up-regulation, or extra copies, of active IGF2 causes overgrowth in Beckwith-Wiedemann syndrome, down-regulation of IGF2 causes the diminished growth seen in Russell-Silver syndrome.
Quick Check 3-1

1. Define epigenetics.

2. What are the three kinds of epigenetic mechanisms?

3. What is meant by the genetic conflict hypothesis?

4. Compare and contrast the molecular and phenotypic features of Prader-Willi and Angelman syndromes.
Long-Term and Multigenerational Persistence of Epigenetic States Induced by Stochastic and Environmental Factors

It is increasingly clear that imprinted genes are not the only loci for which epigenetic modifications persist over time. Conditions encountered in utero, during childhood, and even during adolescence or later can have long-term impacts on epigenetic states, sometimes with impacts that can be transmitted across generations. A few such examples are listed below.

Epigenetics and Nutrition

During the winter of 1943, millions of people in urban areas of the Netherlands suffered starvation conditions as a result of a Nazi blockage that prevented shipments of food from agricultural areas. When researchers sought to investigate how exposure to famine in utero had affected individuals born in a historically prosperous country, they found individuals who suffered nutritional deprivation in utero were more likely to suffer from obesity and diabetes as adults than individuals in the Netherlands who had not experienced nutritional deprivation during gestation. There also seemed to be a transgenerational impact, in that the children of individuals who were in utero during the Dutch Hunger Winter were found to be significantly smaller than the children of those not affected by the blockade. Other data sets reveal elevated risk of cardiovascular and metabolic disease for offspring of individuals exposed during early development to fluctuations in agricultural yields.\(^\text{12}\)

The specific molecular mechanisms that may mediate these apparent relationships between nutritional deprivation and disease risk on one or more generations are largely unknown. From some animal models, it seems that the insulin-like growth factor 2 gene (IGF2) is a possible target of epigenetic modifications arising through nutritional deprivation. Exposure in utero and through lactation to some chemicals (including bisphenol A, a constituent of plastics sometimes used in food preparation and storage) seems to lead to epigenetic modifications similar to those that arise through nutritional deprivation in early life.\(^\text{13}\)

Epigenetics and Maternal Care

It is increasingly clear that parenting style can affect epigenetic states, and that this information can be transmitted from one generation to the next. Mice and other
rodents can exhibit two alternate styles of nursing behavior: frequent arched-back nursing with a high level of licking and grooming behavior, and an alternate style with infrequent arched-back nursing and much reduced licking and grooming behavior. In one especially compelling study,\(^{14}\) pups of mothers that engaged in frequent arched-backed nursing were found to have significantly lower methylation levels and higher transcription activity of a glucocorticoid receptor–encoding locus. Because the glucocorticoid receptor is involved in a pathway that intensifies fearfulness and response to stress, these findings suggest that alteration to methylation states could help explain the finding that exposure to stress early in life can modulate behavior in adulthood. These findings also highlight the concept that epigenetic processes can help store information about the environment, and that the relevant epigenetic modifications can modulate behavior later in life.

**Epigenetics and Mental Illness**

**Epigenetics and Ethanol Exposure During Gestation**

The impact of ethanol exposure in utero on skeletal and neural development was first reported in 1973\(^{15}\) and led to broad awareness of fetal alcohol syndrome. It was not until recently, however, that population-based and molecular-level studies began to clarify the epigenetic signals that mediate these impacts. At first, researchers found alcohol exposure in utero can affect the DNA methylation states of various genomic elements but without specific emphasis on loci directly relevant to skeletal and neural development.\(^{11}\) More recently, it has been found that treating cultured neural stem cells with ethanol impairs their ability to differentiate to functional neurons; this impairment seems to be correlated with aberrant, dense methylation at loci that are active in normal neuronal tissue.\(^{16}\) One possible explanation for these effects is that ethanol exposure in utero modulates fetal expression of the DNA methyltransferases.\(^{17}\)

**Epigenetic Disease in the Context of Genetic Abnormalities**

In some diseases, both genetic and epigenetic factors contribute to the origin of abnormal phenotypes. For example, several abnormal phenotypes can arise in individuals with mutations at the **fragile X** locus *FMR1* (Figure 3-4, A). Some of these phenotypes arise in individuals for whom epigenetic changes are coincident with genetic changes. The most common genetic abnormality at *FMR1* involves expansion in the number of cytosine-guanine (CG) dinucleotide repeats in the gene promoter. Females who have CG repeats in excess of the approximately 35 that are typical at this locus are at risk for fragile X–associated primary ovarian
insufficiency, characterized by an elevated risk of early menopause. Males with moderate expansions are at risk of fragile X tremor ataxia syndrome (FXTAS), characterized by a late-onset intention tremor. Both of these conditions seem to arise through accumulation of excess levels of \( FMR1 \) mRNAs in nuclear inclusion bodies. Individuals with 200 repeats are at risk of fragile X syndrome, characterized by reduced IQ and a set of behavioral abnormalities. Remarkably, although possession of a large CG repeat in the \( FMR1 \) promoter dramatically increases the probability that an individual will have fragile X syndrome, the disease can be present in males who have the large repeat but be absent in their brothers who have inherited an allele of very similar size. This can be explained, at least in part, by the observation that acquisition of methylation-based silencing at \( FMR1 \) is stochastic, meaning that the presence of a large repeat increases the probability of the dense promoter methylation that could lead to gene silencing, but does not guarantee it. It remains to be seen whether dietary or environmental features can modulate the probability that dense methylation at \( FMR1 \) will accrue in individuals with the full-mutation allele.
In another genetic-epigenetic disease, **fascioscapulohumeral muscular dystrophy (FSHMD)** (see Figure 3-4, B), the disease phenotype arises through loss of normal methylation rather than gain of abnormal methylation. Symptoms of the disease include adverse impacts on skeletal musculature. Though lifespan is not typically reduced by the disease, wheelchair use becomes necessary late in life for a subset of individuals. The primary genetic event in FSHMD is deletion of a nucleotide repeat in the **DUX4** gene (see Figure 3-4, A). In normal individuals, the **D4Z4** gene promoter has between 11 and 150 copies. This number is typically found to have been reduced by mutation in individuals with FSHMD, who usually have only 1 to 10 such repeats. In healthy individuals with a normal-sized allele, the **D4Z4** promoter typically has dense methylation. In individuals with reduced copy-counts, the normally dense methylation is lost (see Figure 3-4, A). The disease allele typically also has fewer repressive histone marks than does the normal allele.
Together, fragile X syndrome and FSHMD highlight that both abnormal gain and abnormal loss of epigenetic modifications can result in disease.

**Twin Studies Provide Insights on Epigenetic Modification**

Identical (monozygotic) twin pairs, whose DNA sequences are essentially the same, offer a unique opportunity to isolate and examine the impacts of epigenetic modifications. A recent study found that as twins age, they exhibit increasingly substantial differences in methylation patterns of the DNA sequences of their somatic cells; these changes are often reflected in increasing numbers of phenotypic differences. Twins with significant lifestyle differences (e.g., smoking versus nonsmoking) tend to accumulate larger numbers of differences in their methylation patterns. These results, along with findings generated in animal studies, suggest that changes in epigenetic patterns may be an important part of the aging process\(^2\text{4}\) (Figure 3-5).
Molecular Approaches to Understand Epigenetic Disease

Because epigenetic information is not encoded by DNA molecules but instead by chemical modifications to those molecules, conventional sequencing approaches
are not sufficient to reveal epigenetic differences between normal individuals and those who have epigenetic modifications associated with disease. To collect information on DNA methylation states of individual nucleotides, DNA is typically subjected to bisulfite conversion before sequencing. Bisulfite treatment does not alter most nucleotides, including methylated cytosines, but deaminates unmethylated cytosines to uracil. Because uracil complements adenine, not guanine, methylated and unmethylated cytosines can be distinguished in resulting sequence data, so long as the genetic sequence is known. Histone modification states can be assayed through the use of antibodies specific for histones with various modifications.

Quick Check 3-2

1. Evaluate the statement: “Epigenetic information is highly dynamic in early development.”

2. How does the epigenetic regulation of imprinted genes compare with that of the rest of the genome?

3. Compare and contrast the molecular mechanisms leading to FX syndrome and to FSHMD.
Epigenetics and Cancer
DNA Methylation and Cancer

Some of the most extensive evidence for the role of epigenetic modification in human disease comes from studies of cancer (Figure 3-6). Tumor cells typically exhibit genome-wide hypomethylation (decreased methylation), which can increase the activity of oncogenes (see Chapter 10). Hypomethylation increases as tumors progress from benign neoplasms to malignancy. In addition, the promoter regions of tumor-suppressor genes are often hypermethylated, which decreases their rate of transcription and their ability to inhibit tumor formation. Hypermethylation of the promoter region of the \( RB1 \) gene is often seen in retinoblastoma\(^2^9\); hypermethylation of the \( BRCA1 \) gene is seen in some cases of inherited breast cancer (Chapter 33).\(^3^0\)

![Figure 3-6: Global Epigenomic Alterations and Cancer](image-url)

Oncogenesis often occurs through a combination of genetic mutations and epigenetic change. In cancer cells, the promoters of tumor-suppressor genes typically become hypermethylated, leading, in combination with histone modifications, to abnormal gene silencing. Because tumor-suppressor genes typically help to control cell division, their silencing can result in tumor progression. Global hypomethylation leads to chromosomal instability and fragility, and increases the risk of additional genetic mutations. Additionally, these modifications create abnormal mRNA and miRNA expression, which leads to activation of oncogenes and silencing of tumor-suppressor genes. (Adapted from Sandoval J, Esteller M: Cancer epigenomics: beyond genomics, Curr Opin Genet Dev 22:50-55, 2012.)
A major cause of one form of inherited colon cancer (hereditary nonpolyposis colorectal cancer [HNPCC]) is the methylation of the promoter region of a gene, \textit{MLH1}, whose protein product repairs damaged DNA. When \textit{MLH1} becomes inactive, DNA damage accumulates, eventually resulting in colon tumors\textsuperscript{31,32}. Abnormal methylation of tumor-suppressor genes also is common in the progression of Barrett esophagus, a condition in which the lining of the esophagus is replaced by cells that have features associated with the lower intestinal tract, and to adenocarcinoma possibly through up-regulation of one of the enzymes that adds methyl groups to DNA.\textsuperscript{33}

**miRNAs and Cancer**

Hypermethylation also is seen in microRNA genes, which encode small (22 base pair) RNA molecules that bind to the ends of mRNAs, degrading them and preventing their translation. More than 1000 microRNA sequences have been identified in humans, and hypermethylation of specific subgroups of microRNAs is associated with tumorigenesis. When microRNA genes are methylated, their mRNA targets are overexpressed, and this overexpression has been associated with metastasis.\textsuperscript{27}

**Epigenetic Screening for Cancer**

The common finding of epigenetic alteration in cancerous tissue raises the possibility that epigenetic screening approaches could complement or even replace existing early-detection methods. In some cases, epigenetic screening could be done using bodily fluids, such as urine or sputum, eliminating the need for the more invasive, costly, and risky strategies currently in place. Monitoring for misregulation of miRNAs has shown promise as a tool for early diagnosis of cancers of the colon,\textsuperscript{34} breast,\textsuperscript{35} and prostate.\textsuperscript{36} Other epigenetics-based screening approaches have shown promise for detection of cancers of the bladder,\textsuperscript{37} lung,\textsuperscript{38} and prostate.\textsuperscript{39}

**Emerging Strategies for the Treatment of Epigenetic Disease**

Epigenetic modifications are potentially reversible: DNA can be demethylated, histones can be modified to change the transcriptional state of nearby DNA, and miRNA-encoding loci can be up-regulated or down-regulated. This raises the prospect for treating epigenetic disease with pharmaceutical agents that directly
reverse the changes associated with the disease phenotype. In recent years, interventions involving all three types of epigenetic modulators (DNA methylation, histone modification, and miRNAs) have shown considerable promise for the treatment of disease.

**DNA Demethylating Agents**

5-Azacytidine (Figure 3-7) has been used as a therapeutic drug in the treatment of leukemia and myelodysplastic syndrome.\(^{40}\) A cytosine analog, 5-azacytidine, is incorporated into DNA opposite its complementary nucleotide, guanine. 5-Azacytidine differs from cytosine in that it has a nitrogen, rather than a carbon, in the 5th position of its cytidine ring. As result, the DNMTs cannot add methyl groups to 5-azacytidine, and DNAs that contain 5-azacytidine decline in their methylation density over successive rounds of DNA replication.\(^{41}\) Administration of 5-azacytidine is associated with various side effects, including digestive disturbance, but has shown promise in the treatment of diseases, including pancreatic cancer\(^{42}\) and myelodysplastic syndromes.\(^{43,44}\)
**Histone Deacetylase Inhibitors**

The activity of the histone deacetylases (HDACs) increases chromatin compaction, decreasing transcriptional activity (see Figure 3-7). In many cases, excessive activity of HDACs results in transcriptional inactivation of tumor-suppressor genes, leading ultimately to the development of tumors. Treatment with HDAC inhibitors, either alone or in combination with other drugs, has shown promise in the treatment of cancers of the breast\textsuperscript{45} and prostate,\textsuperscript{46} but only very limited success in the treatment of pancreatic cancer.\textsuperscript{47}

**miRNA Coding**

A major challenge in developing drugs that modify epigenetic alterations is to target only the genes responsible for a specific cancer. Therapeutic approaches that use microRNA offer a potential solution to this problem as treatment can be targeted to individual loci using sequence characteristics of relevant RNA molecules.
Quick Check 3-3

1. Assess the statement that cancer is, in many cases, an epigenetic disease.

2. Discuss the role of miRNAs in cancer.

3. Describe a potential strategy for the treatment of epigenetic disease.
Future Directions

Robust experimental observations are clarifying the roles of epigenetic states in determining cell fates and disease phenotypes. The well-documented involvement of epigenetic abnormalities in carcinogenesis and the mounting evidence for these epigenetic changes in other common diseases (discussed in other chapters) will likely elucidate possibilities for reversing the epigenetic abnormalities and possibly preventing their establishment in utero.
Did You Understand?

Overview

1. Why are pairs of identical twins especially useful in the study of epigenetic phenomena?

2. Describe some of the challenges of developing pharmaceutical approaches to remedy abnormal epigenetic states.

Epigenetics and Human Development

1. Epigenetics modification alters gene expression without changes to DNA sequence.

2. Investigators are studying three major types of epigenetic processes: (1) DNA methylation, which results from attachment of a methyl group to a cytosine; in the somatic cells, all or nearly all methylation occurs at cytosines that are followed by guanines (“CpG dinucleotides”); (2) histone modification, through the addition of various chemical groups, including methyl and acetyl; and (3) noncoding RNAs (ncRNAs or miRNAs), short nucleotides derived from introns of protein coding genes or transcribed as independent genes from regions of the genome whose functions, if any, remain poorly understood. MicroRNAs regulate diverse signaling pathways.

3. DNA methylation is, at present, the best-studied epigenetic process. When a gene becomes heavily methylated the DNA is less likely to be transcribed into mRNA.

4. Methylation, along with histone hypoacetylation and condensation of chromatin, inhibits the binding of proteins that promote transcription, such that the gene becomes transcriptionally inactive.

5. Environmental factors, such as diet and exposure to certain chemicals, may cause epigenetic modifications.

6. The heritable transmission to future generations of epigenetic modifications is called transgenerational inheritance.

7. As twins age, they demonstrate increasing differences in methylation patterns of
their DNA sequences, causing increasing numbers of phenotypic differences.

8. In studies of twins with significant lifestyle differences (e.g., smoking versus nonsmoking) large numbers of differences in their methylation patterns are observed to accrue over time.

**Genomic Imprinting**

1. Gregor Mendel’s experiments with garden peas demonstrated that the phenotype is the same whether a given allele is inherited from the mother or the father. This principle, which has long been part of the central dogma of genetics, does not always hold. For some human genes, a given gene is transcriptionally active on only one copy of a chromosome (e.g., the copy inherited from the father). On the other copy of the chromosome (the one inherited from the mother) the gene is transcriptionally inactive. This process of gene silencing, in which genes are silenced depending on which parent transmits them, is known as *imprinting*; the transcriptionally silenced genes are said to be “imprinted.”

2. When an allele is imprinted, it typically has heavy methylation. By contrast, the nonimprinted allele is typically not methylated.

3. A well-known disease example of imprinting is associated with a deletion of about 4 million base pairs (Mb) of the long arm of chromosome 15. When this deletion is inherited from the father, the child manifests Prader-Willi syndrome.

4. The same 4 Mb deletion, when inherited from the mother, causes Angelman syndrome.

5. Another well-known example of imprinting is Beckwith-Wiedemann syndrome, an overgrowth condition accompanied by an increased predisposition to cancer.

6. Whereas up-regulation, or extra copies, of active *IGF2* causes overgrowth in Beckwith-Wiedemann syndrome, down-regulation of *IGF2* causes the diminished growth seen in Russell-Silver syndrome.

**Long-Term and Multigenerational Persistence of Epigenetic States Induced by Stochastic and Environmental Factors**
1. Events encountered in utero, in childhood, and in adolescence can result in specific epigenetic changes that yield a wide range of phenotypic abnormalities, including metabolic syndromes.

2. Fetal alcohol syndrome, which results from ethanol exposure in utero, may be mediated by the repressive impact of ethanol on the DNA methyltransferases.

3. Both abnormal gain of methylation, as in the case of fragile X syndrome, and abnormal loss of methylation, as in the case of FSHMD, can produce disease phenotypes.

**Epigenetics and Cancer**

1. The best evidence for epigenetic effects on disease risk comes from studies of human cancer.

2. Methylation densities decline as tumors progress, which can increase the activity of oncogenes, causing tumors to progress from benign neoplasms to malignancy. Additionally, the promoter regions of tumor-suppressor genes are often hypermethylated. These elevated methylation levels decreases their rate of transcription at these critical genes, thus reducing the ability to inhibit tumor formation.

3. Hypermethylation also is seen in microRNA genes and is associated with tumorigenesis.

4. Unlike DNA sequence mutations, epigenetic modifications can be reversed through pharmaceutical intervention. For example, 5-azacytidine, a demethylating agent, has been used as a therapeutic drug in the treatment of leukemia and myelodysplastic syndrome.

**Future Directions**

1. Robust experimental observations are defining the roles of epigenetic states in shaping cell fates.

2. The well-documented involvement of epigenetic abnormalities in carcinogenesis and the mounting evidence for these epigenetic changes in other common diseases (discussed throughout the text) will likely elucidate new therapies with the
possibilities of reversing the epigenetic abnormalities.

The majority of diseases are caused by many factors acting together (i.e., *multifactorial*) or interacting with a genetically susceptible person. Injury to cells and their surrounding environment, called the extracellular matrix, leads to tissue and organ injury. Although the normal cell is restricted by a narrow range of structure and functions, including metabolism and specialization, it can adapt to physiologic demands or stress to maintain a steady state called *homeostasis*.  

**Adaptation** is a reversible, structural, or functional response both to normal or physiologic conditions and to adverse or pathologic conditions. For example, the uterus adapts to pregnancy—a normal physiologic state—by enlarging. Enlargement occurs because of an increase in the size and number of uterine cells. In an adverse condition, such as high blood pressure, myocardial cells are stimulated to enlarge by the increased work of pumping. Like most of the body's adaptive mechanisms, however, cellular adaptations to adverse conditions are usually only temporarily successful. Severe or long-term stressors overwhelm adaptive processes and cellular injury or death ensues. Altered cellular and tissue biology can result from adaptation, injury, neoplasia, accumulations, aging, or death. (Neoplasia is discussed in Chapters 10 and 11.)

Knowledge of the structural and functional reactions of cells and tissues to injurious agents, including genetic defects, is vital to understanding disease processes. Cellular injury can be caused by any factor that disrupts cellular structures or deprives the cell of oxygen and nutrients required for survival. Injury may be reversible (*sublethal*) or irreversible (*lethal*) and is classified broadly as chemical, hypoxic (lack of sufficient oxygen), free radical, intentional, unintentional, immunologic, infection, and inflammatory. Cellular injuries from various causes have different clinical and pathophysiologic manifestations. Stresses from metabolic derangements may be associated with intracellular *accumulations* and include carbohydrates, proteins, and lipids. Sites of cellular death can cause accumulations of calcium resulting in *pathologic calcification*. Cellular death is
confirmed by structural changes seen when cells are stained and examined under a microscope. The two main types of cell death include necrosis and apoptosis and nutrient deprivation can initiate autophagy that results in cell death. All of these pathways of cellular death are discussed later in this chapter.

Cellular aging causes structural and functional changes that eventually may lead to cellular death or a decreased capacity to recover from injury. Mechanisms explaining how and why cells age are not known, and distinguishing between pathologic changes and physiologic changes that occur with aging is often difficult. Aging clearly causes alterations in cellular structure and function, yet senescence, growing old, is both inevitable and normal.
Cellular Adaptation

Cells adapt to their environment to escape and protect themselves from injury. An adapted cell is neither normal nor injured—it lies somewhere between these two states. Adaptations are reversible changes in cell size, number, phenotype, metabolic activity, or functions of cells. Adaptive responses have limits, however, and additional cell stresses can affect essential cell function leading to cell injury. Cellular adaptations also can be a common and central part of many disease states. In the early stages of a successful adaptive response, cells may have enhanced function; thus, it is hard to distinguish a pathologic response from an extreme adaptation to an excessive functional demand. The most significant adaptive changes in cells include atrophy (decrease in cell size), hypertrophy (increase in cell size), hyperplasia (increase in cell number), and metaplasia (reversible replacement of one mature cell type by another less mature cell type or a change in the phenotype). Dysplasia (deranged cellular growth) is not considered a true cellular adaptation but rather an atypical hyperplasia. These changes are shown in Figure 4-1.
Atrophy

Atrophy is a decrease or shrinkage in cellular size. If atrophy occurs in a sufficient number of an organ's cells, the entire organ shrinks or becomes atrophic. Atrophy can affect any organ, but it is most common in skeletal muscle, the heart, secondary sex organs, and the brain. Atrophy can be classified as physiologic or pathologic. Physiologic atrophy occurs with early development. For example, the thymus gland undergoes physiologic atrophy during childhood. Pathologic atrophy...
occurs as a result of decreases in workload, pressure, use, blood supply, nutrition, hormonal stimulation, and nervous system stimulation (Figure 4-2). Individuals immobilized in bed for a prolonged time exhibit a type of skeletal muscle atrophy called **disuse atrophy**. Aging causes brain cells to become atrophic and endocrine-dependent organs, such as the gonads, to shrink as hormonal stimulation decreases. Whether atrophy is caused by normal physiologic conditions or by pathologic conditions, atrophic cells exhibit the same basic changes.

The atrophic muscle cell contains less endoplasmic reticulum (ER) and fewer mitochondria and myofilaments (part of the muscle fiber that controls contraction) than found in the normal cell. In muscular atrophy caused by nerve loss, oxygen consumption and amino acid uptake are immediately reduced. The mechanisms of atrophy include decreased protein synthesis, increased protein catabolism, or both. A new hypothesis includes ribosome function and its role as translation machinery or the conversion of mRNA into protein called ribosome biogenesis. Ribosome biogenesis has an important role in the regulation of skeletal muscle mass. The primary pathway of protein catabolism is the **ubiquitin-proteasome pathway** and catabolism involves **proteasomes** (protein-degrading complexes. Proteins degraded in this pathway are first conjugated to **ubiquitin** (another small protein) and then
degraded by proteasomes. An increase in proteasome activity is characteristic of atrophic muscle changes. Deregulation of this pathway often leads to abnormal cell growth and is associated with cancer and other diseases.

Atrophy as a result of chronic malnutrition is often accompanied by a “self-eating” process called autophagy that creates autophagic vacuoles (see p. 105). These vacuoles are membrane-bound vesicles within the cell that contain cellular debris and hydrolytic enzymes, which function to break down substances to the simplest units of fat, carbohydrate, or protein. The levels of hydrolytic enzymes rise rapidly in atrophy. The enzymes are isolated in autophagic vacuoles to prevent uncontrolled cellular destruction. Thus the vacuoles form as needed to protect uninjured organelles from the injured organelles and are eventually engulfed and destroyed by lysosomes. Certain contents of the autophagic vacuole may resist destruction by lysosomal enzymes and persist in membrane-bound residual bodies. An example of this is granules that contain lipofuscin, the yellow-brown age pigment. Lipofuscin accumulates primarily in liver cells, myocardial cells, and atrophic cells.

**Hypertrophy**

Hypertrophy is a compensatory increase in the size of cells in response to mechanical stimuli (also called mechanical load or stress, such as from repetitive stretching, chronic pressure, or volume overload) and consequently increases the size of the affected organ (Figures 4-3 and 4-4). The cells of the heart and kidneys are particularly prone to enlargement. Hypertrophy, as an adaptive response (muscular enlargement), occurs in the striated muscle cells of both the heart and skeletal muscles. Initial cardiac enlargement is caused by dilation of the cardiac chambers, is short lived, and is followed by increased synthesis of cardiac muscle proteins, allowing muscle fibers to do more work. The increase in cellular size is associated with an increased accumulation of protein in the cellular components (plasma membrane, ER, myofilaments, mitochondria) and not with an increase in cellular fluid. Yet, individual protein pools may expand or shrink. Cardiac hypertrophy involves changes in signaling and transcription factor pathways resulting in increased protein synthesis leading to left ventricular hypertrophy (LVH). Emerging evidence suggests that the ubiquitin-proteasome system (UPS) not only attends to damaged, misfolded, or mutant proteins by protein breakdown but also may attend to cell growth eventually leading to LVH. With time, cardiac hypertrophy is characterized by extracellular matrix remodeling and increased growth of adult myocytes. The myocytes progressively increase in size and reach a limit beyond which no further hypertrophy can occur.
Figure 4-3  Hypertrophy of Cardiac Muscle in Response to Valve Disease. A, Transverse slices of a normal heart and a heart with hypertrophy of the left ventricle (L, normal thickness of left ventricular wall; T, thickened wall from heart in which severe narrowing of aortic valve caused resistance to systolic ventricular emptying). B, Histology of cardiac muscle from the normal heart. C, Histology of cardiac muscle from a hypertrophied heart. (From Stevens A, Lowe J: Pathology: illustrated review in color, ed 2, Edinburgh, 2000, Mosby.)
Although hypertrophy can be classified as physiologic or pathologic, time may be the critical factor or determinant of the transition from physiologic to pathologic cardiac hypertrophy. With physiologic hypertrophy, preservation of myocardial structure characterizes postnatal development, moderate endurance exercise training, pregnancy, and the early phases of increased pressure and volume loading on the adult human heart. This physiologic response is temporary; however, aging, strenuous exercise, and sustained workload or stress lead to pathologic hypertrophy with structural and functional manifestations. Pathologic hypertrophy in the heart is secondary to hypertension, coronary heart disease, or problem valves and is presumably a key risk factor for heart failure. Additionally, it is associated with increased interstitial fibrosis, cell death, and abnormal cardiac function (see Figure 4-3). Historically, the progression of pathologic cardiac hypertrophy has been considered irreversible. Emerging data, however, from experimental studies and clinical observations show in certain cases reversal of pathologic cardiac hypertrophy. Cardiac hypertrophy can be reversed when the increased wall stress is

FIGURE 4-4 Mechanisms of Myocardial Hypertrophy. Mechanical sensors appear to be the main stimulators for physiologic hypertrophy. Other stimuli possibly more important for pathologic hypertrophy include agonists (initiators) and growth factors. These factors then signal transcription pathways whereby transcription factors then bind to DNA sequences, activating muscle proteins that are responsible for hypertrophy. These pathways include induction of embryonic/fetal genes, increased synthesis of contractile proteins, and production of growth factors. (Adapted from Kumar V et al, editors: Robbins and Cotran pathologic basis of disease, ed 9, Philadelphia, 2015, Elsevier.)
normalized, a process termed regression.\textsuperscript{7} For example, unloading of hemodynamic stress by a left ventricular assist device (used in individuals with heart failure for bridging to heart transplantation) induces regression of cardiac hypertrophy and improvement of left ventricular (LV) function in those with end-stage heart failure.\textsuperscript{8} Regression of cardiac hypertrophy is accompanied by activation of unique sets of genes, including fetal-type genes and those involved in protein degradation.\textsuperscript{9,10} However, the signaling mechanisms mediating regression of cardiac hypertrophy have been poorly understood. Improvement in new blood vessel development (angiogenesis) in the hypertrophic heart can lead to regression of the hypertrophy and prevention of heart failure.\textsuperscript{11,12} In mice, dietary supplementation of physiologically relevant levels of copper can reverse pathologic cardiac hypertrophy.\textsuperscript{12,13}

When a diseased kidney is removed, the remaining kidney adapts to the increased workload with an increase in both the size and the number of cells. The major contributing factor to this renal enlargement is hypertrophy. Another example of normal or physiologic hypertrophy is the increased growth of the uterus and mammary glands in response to pregnancy.

**Hyperplasia**

**Hyperplasia** is an increase in the number of cells, resulting from an increased rate of cellular division. Hyperplasia, as a response to injury, occurs when the injury has been severe and prolonged enough to have caused cell death. Loss of epithelial cells and cells of the liver and kidney triggers deoxyribonucleic acid (DNA) synthesis and mitotic division. Increased cell growth is a multistep process involving the production of growth factors, which stimulate the remaining cells to synthesize new cell components and, ultimately, to divide. Hyperplasia and hypertrophy often occur together, and both take place if the cells can synthesize DNA.

Two types of normal, or physiologic, hyperplasia are compensatory hyperplasia and hormonal hyperplasia. **Compensatory hyperplasia** is an adaptive mechanism that enables certain organs to regenerate. For example, removal of part of the liver leads to hyperplasia of the remaining liver cells (hepatocytes) to compensate for the loss. Even with removal of 70% of the liver, regeneration is complete in about 2 weeks. Several growth factors and cytokines (chemical messengers) are induced and play critical roles in liver regeneration.

Not all types of mature cells have the same capacity for compensatory hyperplastic growth. Nondividing tissues contain cells that can no longer (i.e., postnatally) go through the cell cycle and undergo mitotic division. These highly specialized cells, for example, neurons and skeletal muscle cells, never divide again
once they have differentiated—that is, they are **terminally differentiated**.\textsuperscript{14} In human cells, cell growth and cell division depend on signals from other cells; but cell growth, unlike cell division, does not depend on the cell-cycle control system.\textsuperscript{14} Nerve cells and most muscle cells do most of their growing after they have terminally differentiated and permanently ceased dividing.\textsuperscript{14} Significant compensatory hyperplasia occurs in epidermal and intestinal epithelia, hepatocytes, bone marrow cells, and fibroblasts; and some hyperplasia is noted in bone, cartilage, and smooth muscle cells. Another example of compensatory hyperplasia is the callus, or thickening, of the skin as a result of hyperplasia of epidermal cells in response to a mechanical stimulus.

**Hormonal hyperplasia** occurs chiefly in estrogen-dependent organs, such as the uterus and breast. After ovulation, for example, estrogen stimulates the endometrium to grow and thicken in preparation for receiving the fertilized ovum. If pregnancy occurs, hormonal hyperplasia, as well as hypertrophy, enables the uterus to enlarge. (Hormone function is described in Chapters 19 and 33.)

**Pathologic hyperplasia** is the abnormal proliferation of normal cells, usually in response to excessive hormonal stimulation or growth factors on target cells (Figure 4-5). The most common example is pathologic hyperplasia of the endometrium (caused by an imbalance between estrogen and progesterone secretion, with oversecretion of estrogen) (see Chapter 33). Pathologic endometrial hyperplasia, which causes excessive menstrual bleeding, is under the influence of regular growth-inhibition controls. If these controls fail, hyperplastic endometrial cells can undergo malignant transformation. Benign prostatic hyperplasia is another example of pathologic hyperplasia and results from changes in hormone balance. In both of these examples, if the hormonal imbalance is corrected, hyperplasia regresses.\textsuperscript{1}
Dysplasia: Not a True Adaptive Change

Dysplasia refers to abnormal changes in the size, shape, and organization of mature cells (Figure 4-6). Dysplasia is not considered a true adaptive process but is related to hyperplasia and is often called atypical hyperplasia. Dysplastic changes often are encountered in epithelial tissue of the cervix and respiratory tract, where they are strongly associated with common neoplastic growths and often are found adjacent to cancerous cells. Importantly, however, the term dysplasia does not indicate cancer and may not progress to cancer. Dysplasia is often classified as mild, moderate, or severe; yet, because this classification scheme is somewhat subjective, it has prompted some to recommend the use of either “low grade” or “high grade” instead. If the inciting stimulus is removed, dysplastic changes often are reversible. (Dysplasia is discussed further in Chapter 10.)
Metaplasia

Metaplasia is the reversible replacement of one mature cell type (epithelial or mesenchymal) by another, sometimes less differentiated, cell type. It is thought to develop, as an adaptive response better suited to withstand the adverse environment, from a reprogramming of stem cells that exist on most epithelia or of undifferentiated mesenchymal (tissue from embryonic mesoderm) cells present in connective tissue. These precursor cells mature along a new pathway because of
signals generated by growth factors in the cell's environment. The best example of metaplasia is replacement of normal columnar ciliated epithelial cells of the bronchial (airway) lining by stratified squamous epithelial cells (Figure 4-7). The newly formed cells do not secrete mucus or have cilia, causing loss of a vital protective mechanism. Bronchial metaplasia can be reversed if the inducing stimulus, usually cigarette smoking, is removed. With prolonged exposure to the inducing stimulus, however, dysplasia and cancerous transformation can occur.

FIGURE 4-7 Reversible Changes in Cells Lining the Bronchi.
Cellular Injury

Injury to cells and to the extracellular matrix (ECM) leads to injury of tissues and organs, ultimately determining the structural patterns of disease. Loss of function is derived from cell and ECM injury and cell death. Cellular injury occurs if the cell is unable to maintain homeostasis—a normal or adaptive steady state—in the face of injurious stimuli or stress. Injured cells may recover (reversible injury) or die (irreversible injury). Injurious stimuli include chemical agents, lack of sufficient oxygen (hypoxia), free radicals, infectious agents, physical and mechanical factors, immunologic reactions, genetic factors, and nutritional imbalances. Types of injuries and their responses are summarized in Table 4-1 and Figure 4-8.

ATP, Adenosine triphosphate; Ca++, calcium.
The extent of cellular injury depends on the type, state (including level of cell differentiation and increased susceptibility to fully differentiated cells), and adaptive processes of the cell, as well as the type, severity, and duration of the injurious stimulus. Two individuals exposed to an identical stimulus may incur varying degrees of cellular injury. Modifying factors, such as nutritional status, can profoundly influence the extent of injury. The precise “point of no return” that leads to cellular death is a biochemical puzzle, but once changes to the nucleus occur and cell membranes are disrupted, the cell moves to irreversible injury and death.

**General Mechanisms of Cell Injury**

Common biochemical themes are important to understanding cell injury and cell death regardless of the injuring agent. These include adenosine triphosphate (ATP) depletion, mitochondrial damage, oxygen and oxygen-derived free radical membrane damage (depletion of ATP), protein folding defects, DNA damage defects, and calcium level alterations (Table 4-2). Examples of common forms of
cell injury are (1) hypoxic injury, (2) free radicals and reactive oxygen species injury, and (3) chemical injury.

ATP, Adenosine triphosphate; Ca$^{++}$, calcium.

### Hypoxic Injury

**Hypoxia**, or lack of sufficient oxygen within cells, is the single most common cause of cellular injury (Figure 4-9). Hypoxia can result from a reduced amount of oxygen in the air, loss of hemoglobin or decreased efficacy of hemoglobin, decreased production of red blood cells, diseases of the respiratory and cardiovascular systems, and poisoning of the oxidative enzymes (cytochromes) within the cells. Hypoxia plays a role in physiologic processes including cell differentiation, angiogenesis, proliferation, erythropoiesis, and overall cell viability.\(^{15}\) The main consumers of oxygen are mitochondria and the cellular responses to hypoxia are reported to be mediated by the production of reactive oxygen species (ROS) at the mitochondrial complex III.\(^{15}\) Investigators are studying the role of ROS as hypoxia signaling molecules. More commonly, hypoxia is associated with the pathophysiologic conditions such as inflammation, ischemia, and cancer. Hypoxia can induce inflammation and inflamed lesions can become hypoxic (Figure 4-10).\(^{16}\) The cellular mechanisms involved in hypoxia and inflammation are emerging and include activation of immune responses and oxygen-sensing compounds called prolyl hydroxylases (PHDs) and hypoxia-inducible transcription factor (HIF). The hypoxia-inducible factor (HIF) is a family of transcription regulators that coordinate the expression of many genes in response to oxygen deprivation. Mammalian development occurs in a hypoxic
environment. Hypoxia-induced signaling involves complicated crosstalk between hypoxia and inflammation, linking hypoxia and inflammation to inflammatory bowel disease, certain cancers, and infections. Research is ongoing to understand the mechanisms of how tumors adapt to low oxygen levels by inducing angiogenesis, increasing glucose consumption, and promoting the metabolic state of glycolysis.
FIGURE 4-9 Hypoxic Injury Induced by Ischemia. A, Consequences of decreased oxygen delivery or ischemia with decreased ATP. The structural and physiologic changes are reversible if oxygen is delivered quickly. Significant decreases in ATP result in cell death, mostly by necrosis. B, Mitochondrial damage can result in changes in membrane permeability, loss of membrane potential, and decrease in ATP concentration. Between the outer and inner membranes of the mitochondria are proteins that can activate the cell's suicide pathways, called apoptosis. C, Calcium ions are critical mediators of cell injury. Calcium ions are usually maintained at low concentrations in the cell's cytoplasm; thus ischemia and certain toxins can initially cause an increase in the release of Ca^{++} from intracellular stores and later an increased movement (influx) across the plasma membrane. (Adapted from Kumar V et al, editors: Pathology, St Louis, 2014, Elsevier.)
The most common cause of hypoxia is **ischemia** (reduced blood supply). Ischemic injury often is caused by the gradual narrowing of arteries (arteriosclerosis) or complete blockage by blood clots (thrombosis), or both. Progressive hypoxia caused by gradual arterial obstruction is better tolerated than the acute **anoxia** (total lack of oxygen) caused by a sudden obstruction, as with an embolus (a blood clot or other blockage in the circulation). An acute obstruction in
a coronary artery can cause myocardial cell death (infarction) within minutes if the blood supply is not restored, whereas the gradual onset of ischemia usually results in myocardial adaptation. Myocardial infarction and stroke, which are common causes of death in the United States, generally result from atherosclerosis (a type of arteriosclerosis) and consequent ischemic injury. (Vascular obstruction is discussed in Chapter 24.)

Cellular responses to hypoxic injury caused by ischemia have been demonstrated in studies of the heart muscle. Within 1 minute after blood supply to the myocardium is interrupted, the heart becomes pale and has difficulty contracting normally. Within 3 to 5 minutes, the ischemic portion of the myocardium ceases to contract because of a rapid decrease in mitochondrial phosphorylation, causing insufficient ATP production. Lack of ATP leads to increased anaerobic metabolism, which generates ATP from glycogen when there is insufficient oxygen. When glycogen stores are depleted, even anaerobic metabolism ceases.

A reduction in ATP levels causes the plasma membrane's sodium-potassium (Na\(^+\)-K\(^-\)) pump and sodium-calcium exchange mechanism to fail, which leads to an intracellular accumulation of sodium and calcium and diffusion of potassium out of the cell. Sodium and water then can enter the cell freely, and cellular swelling, as well as early dilation of the endoplasmic reticulum (ER), results. Dilation causes the ribosomes to detach from the rough ER, reducing protein synthesis. With continued hypoxia, the entire cell becomes markedly swollen, with increased concentrations of sodium, water, and chloride and decreased concentrations of potassium. These disruptions are reversible if oxygen is restored. If oxygen is not restored, however, vacuolation (formation of vacuoles) occurs within the cytoplasm and swelling of lysosomes and marked mitochondrial swelling result from damage to the outer membrane. Continued hypoxic injury with accumulation of calcium subsequently activates multiple enzyme systems resulting in membrane damage, cytoskeleton disruption, DNA and chromatin degradation, ATP depletion, and eventual cell death (see Figures 4-9, C, and 4-27). Structurally, with plasma membrane damage, extracellular calcium readily moves into the cell and intracellular calcium stores are released. Increased intracellular calcium levels activate cell enzymes (caspases) that promote cell death by apoptosis (see Figures 4-29 and 4-33). Persistent ischemia is associated with irreversible injury and necrosis. Irreversible injury is associated structurally with severe swelling of the mitochondria, severe damage to plasma membranes, and swelling of lysosomes. Overall, death is mainly by necrosis but apoptosis also contributes.\(^1\)

Restoration of blood flow and oxygen, however, can cause additional injury called ischemia-reperfusion injury (Figure 4-11). Ischemia-reperfusion injury is very important clinically because it is associated with tissue damage during
myocardial and cerebral infarction. Several mechanisms are now proposed for ischemia-reperfusion injury and include:

- **Oxidative stress**—Reoxygenation causes the increased generation of reactive oxygen species (ROS) and nitrogen species. Highly reactive oxygen intermediates (oxidative stress) generated include hydroxyl radical (OH·), superoxide radical (O₂⁻), and hydrogen peroxide (H₂O₂) (see pp. 82-83). The nitrogen species include nitric oxide (NO) generated by endothelial cells, macrophages, neurons, and other cells. These radicals can all cause further membrane damage and mitochondrial calcium overload. The white blood cells (neutrophils) are especially affected with **reperfusion injury**, including neutrophil adhesion to the endothelium. Antioxidant treatment not only reverses neutrophil adhesion but also can reverse neutrophil-mediated heart injury. In one study of individuals undergoing elective percutaneous coronary intervention (PCI), pretreatment with vitamin C was associated with less myocardial injury. The PREVEC Trial (Prevention of reperfusion damage associated with percutaneous coronary angioplasty following acute myocardial infarction) seeks to evaluate whether vitamins C and E reduce infarct size in patients subjected to percutaneous coronary angioplasty after acute myocardial infarction.

- **Increased intracellular calcium concentration**—Intracellular and mitochondrial calcium overload the cell; this process begins during acute ischemia. Reperfusion causes even more calcium influx because of cell membrane damage and ROS-induced injury to the sarcoplasmic reticulum. The increased calcium increases mitochondrial permeability, eventually leading to depletion of ATP and further cell injury.

- **Inflammation**—Ischemic injury increases inflammation because danger signals (from cytokines) are released by resident immune cells when cells die and this signaling initiates inflammation.

- **Complement activation**—The activation of complement may increase the tissue damage from reperfusion-ischemia injury.

---

**Quick Check 4-1**

1. When does a cell become irreversibly injured?
2. Discuss the pathogenesis of hypoxic injury?
3. What are the mechanisms of ischemia-reperfusion injury?
Free Radicals and Reactive Oxygen Species—Oxidative Stress

An important mechanism of cellular injury is injury induced by free radicals, especially by reactive oxygen species (ROS); this form of injury is called oxidative stress. Oxidative stress occurs when excess ROS overwhelm endogenous antioxidant systems. A free radical is an electrically uncharged atom or group of atoms that has an unpaired electron. Having one unpaired electron makes the molecule unstable; the molecule becomes stabilized either by donating or by accepting an electron from another molecule. When the attacked molecule loses its electron, it becomes a free radical. Therefore it is capable of injurious chemical bond formation with proteins, lipids, and carbohydrates—key molecules in membranes and nucleic acids. Free radicals are difficult to control and initiate chain reactions. They are highly reactive because they have low chemical specificity, meaning they can react with most molecules in their proximity. Oxidative stress can activate several intracellular signaling pathways because ROS can modulate enzymes and transcription factors. This is an important mechanism of cell damage in many conditions including chemical and radiation injury, ischemia-reperfusion.
injury, cellular aging, and microbial killing by phagocytes, particularly neutrophils and macrophages.\textsuperscript{1} Free radicals may be generated within cells, first by the reduction-oxidation reactions (redox reactions) in normal metabolic processes such as respiration. Under normal physiologic conditions ROS serve as “redox messengers” in the regulation of intracellular signaling; however, excess ROS may produce irreversible damage to cellular components. All biologic membranes contain redox systems, which also are important for cell defense (e.g., inflammation, iron uptake, growth and proliferation, and signal transduction) (Figure 4-12). Second, absorption of extreme energy sources (e.g., ultraviolet light, radiation) produces free radicals. Third, enzymatic metabolism of exogenous chemicals or drugs (e.g., CCl\textsubscript{3}, a product of carbon tetrachloride [CCl\textsubscript{4}]) results in the formation of free radicals. Fourth, transition metals (i.e., iron and copper) donate or accept free electrons during intracellular reactions and activate the formation of free radicals such as in the Fenton reaction (see Figure 4-12). Finally, nitric oxide (NO) is an important colorless gas that is an intermediate in many reactions generated by endothelial cells, neurons, macrophages, and other cell types. NO can act as a free radical and can be converted to highly reactive peroxynitrite anion (ONOO\textsuperscript{−}), NO\textsubscript{2}, and NO\textsubscript{3}\textsuperscript{−}. Table 4-3 describes the most significant free radicals.
Free radicals are generated within cells in several ways, including from normal respiration; absorption of radiant energy; activation of leukocytes during inflammation; metabolism of chemicals or drugs; transition metals, such as iron (Fe\(^{+++}\)) or copper (Cu\(^{+}\)), where the metals donate or accept electrons as in the Fenton reaction; nitric oxide (NO) generated by endothelial cells (not shown); and reperfusion injury. Ubiquinone (coenzyme Q), a lipophilic molecule, transfers electrons in the inner membrane of mitochondria, ultimately enabling their interaction with oxygen (O\(_2\)) and hydrogen (H\(_2\)) to yield water (H\(_2\)O). In so doing, the transport allows free energy change and the synthesis of 1 mole of adenosine triphosphate (ATP). With the transport of electrons, free radicals are generated within the mitochondria. Reactive oxygen species (O\(_2\), H\(_2\)O\(_2\), OH\(^{•}\)) act as physiologic modulators of some mitochondrial functions but may also cause cell damage. O\(_2\) is converted to superoxide (O\(_2^{•−}\)) by oxidative enzymes in the mitochondria, endoplasmic reticulum (ER), plasma membrane, peroxisomes, and cytosol. O\(_2\) is converted to H\(_2\)O\(_2\) by superoxide dismutase (SOD) and further to OH\(^{•}\) by the Cu/Fe Fenton reaction. Superoxide catalyzes the reduction of Fe\(^{+++}\) to Fe\(^{+++}\), thus increasing OH\(^{•}\) formation by the Fenton reaction. H\(_2\)O\(_2\) is also derived from oxidases in peroxisomes. The three reactive oxygen species (H\(_2\)O\(_2\), OH\(^{•}\), and O\(_2\)) cause free radical damage to lipids (peroxidation of the membrane), proteins (ion pump damage), and DNA (impaired protein synthesis). The major antioxidant enzymes include SOD, catalase, and glutathione peroxidase.

</tr>
</tbody>
</table>

Free radicals cause several damaging effects by (1) **lipid peroxidation**, which is the destruction of polyunsaturated lipids (the same process by which fats become rancid), leading to membrane damage and increased permeability; (2) protein alterations, causing fragmentation of polypeptide chains that can lead to loss and protein misfolding; and (3) DNA damage, causing mutations (Figure 4-13; also see p. 39). Because of the increased understanding of free radicals, a growing number of diseases and disorders have been linked either directly or indirectly to these reactive species (Box 4-1).
The production of ROS can be initiated by many cell stressors, such as radiation, toxins, and reperfusion of oxygen. Free radicals are removed by normal decay and enzymatic systems. ROS accumulates in cells because of insufficient removal or excess production leading to cell injury, including lipid peroxidation, protein modifications, and DNA damage or mutations. (Adapted from Kumar V et al, editors: Robbins and Cotran pathologic basis of disease, ed 9, Philadelphia, 2015, Elsevier.)

Metal irons (Ni, Cu, Fe, etc.)

The body can eliminate free radicals. The oxygen free radical superoxide may spontaneously decay into oxygen and hydrogen peroxide. Table 4-4 summarizes other methods that contribute to inactivation or termination of free radicals. The toxicity of certain drugs and chemicals can be attributed either to conversion of these chemicals to free radicals or to the formation of oxygen-derived metabolites (see the following discussion).

*These enzymes are important in modulating the cellular destructive effects of free radicals, also released in inflammation.

### Mitochondrial Effects

Mitochondria are key players in cell injury and cell death because they produce ATP or life-sustaining energy. Mitochondria can be damaged by ROS and by increases of cytosolic Ca$^{++}$ concentration (see Figure 4-9). Box 4-2 summarizes the three major types and consequences of mitochondrial damage. Currently, investigators are trying to identify the polypeptides (i.e., proteomes) directly involved in diseases associated with mitochondrial dysfunction. ROS not only damage proteins and mitochondria but also can promote damage in neighboring cells. An important area of research emphasis is that protein aggregates can increase mitochondrial damage and damaged mitochondria can further induce protein damage, thus resulting in neurodegeneration. An emerging area of research concerns mitochondrial DNA that escapes from autophagy, which may be a mechanism of tissue inflammation.$^{21}$

### Box 4-2
Three Major Types and Consequences of Mitochondrial Damage

1. Damage to the mitochondria results in the formation of the mitochondrial
permeability transition pore, a high-conductance channel or pore. The opening of this channel results in the loss of mitochondrial membrane potential, causing failure of oxidative phosphorylation, depletion of ATP, and damage to mitochondrial DNA (mtDNA), leading to necrosis of the cell.

2. Altered oxidative phosphorylation leads to the formation of ROS that can damage cellular components.

3. Because mitochondria store several proteins between their membranes, increased permeability of the outer membrane may result in leakage of pro-apoptotic proteins and cause cell death by apoptosis.

Chemical or Toxic Injury

Mechanisms

Humans are exposed to thousands of chemicals that have inadequate toxicologic data. The given societal considerations of time, cost, and reduced animal use have increased the need to develop new methods for toxicity testing. To meet this public health need, many agencies have partnered to investigate how chemicals interact with biologic systems. Advances in molecular and systems biology, computational toxicology, and bioinformatics have increased the development of powerful new tools.

The systems biology approach includes delineation of toxicity pathways that may be defined as cellular response pathways, which when disturbed are expected to result in adverse health effects. Using this model of testing, investigators proposed screening and classifying compounds using a “cellular stress response pathway.” Components or mechanisms of these pathways include oxidative stress, heat shock response, DNA damage response, hypoxia, ER stress (see Chapter 1), mental stress, inflammation, and osmotic stress. Many chemicals have already been classified under these mechanisms.

Humans are constantly exposed to a variety of compounds termed xenobiotics (Greek xenos, “foreign”; bios, “life”) that include toxic, mutagenic, and carcinogenic chemicals (Figure 4-14). Some of these chemicals are found in the human diet, for example, fungal mycotoxins such as aflatoxin B₁. Many xenobiotics are toxic to the liver (hepatotoxic). The liver is the initial site of contact for many ingested xenobiotics, drugs, and alcohol, making this organ most susceptible to
chemically induced injury. The toxicity of many chemicals results from absorption through the gastrointestinal tract after oral ingestion. A main cause for withdrawing medications from the market is hepatotoxicity. Dietary supplements, for example, chaparral and ma huang, are potent hepatotoxins. Other common routes of exposure for xenobiotics are absorption through the skin and inhalation. The severity of chemically induced liver injury varies from minor liver injury to acute liver failure, cirrhosis, and liver cancer.
Pollutants contained in air, water, and soil are absorbed through the lungs, gastrointestinal tract, and skin. In the body, the pollutants may act at the site of absorption but are generally transported through the bloodstream to various organs where they can be stored or metabolized. Metabolism of xenobiotics may result in the formation of water-soluble compounds that are excreted, or a toxic metabolite may be created by activation of the agent. (From Kumar V et al, editors: Robbins and Cotran pathologic basis of disease, ed 9, Philadelphia, 2015, Elsevier.)
The liver as the principal site for xenobiotic metabolism, called *biotransformation*, converts the lipophilic xenobiotics to more hydrophilic forms for efficient excretion. Biotransformation, however, also can produce short-lived unstable highly reactive chemical intermediates that can lead to adverse effects.\textsuperscript{25} These harmful intermediates, classified and cataloged, are called *toxicophores*. The intermediates include electrophiles, nucleophiles, free radicals, and redox-active reactants. **Electrophiles** (electron lovers) are an atom or molecule attracted to electrons and accepts a pair of electrons to make a covalent bond. This process creates a partially or fully charged center in electrophilic molecules.\textsuperscript{25} A **nucleophile** is an atom or molecule that donates an electron pair to an electrophile to make a chemical bond. All chemical species with a free pair of electrons can act as nucleophiles. Nucleophiles are strongly attracted to positively charged regions in other chemicals and can be oxidized to free radicals and electrophiles.\textsuperscript{25} In general, the majority of all reactive chemical species are electrophilic because the formation of nucleophiles is rare\textsuperscript{25} (for a discussion on free radicals, see p. 81). The generation of these excess reactive chemical species leads to molecular damage in liver cells (**Figure 4-15**). These reactive intermediates can interact with cellular macromolecules (such as proteins and DNA), can covalently bind to proteins and form **protein adducts** (chemical bound to protein) and DNA adducts, or can react directly with cell structures to cause cell damage.\textsuperscript{26} Adduct formation can lead to adverse conditions including disruption in protein function, excess formation of fibrous connective tissue (fibrogenesis), and activation of immune responses.\textsuperscript{25} The identity of proteins modified by xenobiotics can be found in the resource known as the reactive metabolite target protein database.\textsuperscript{27} The body has two major defense systems for counteracting these effects: (1) detoxification enzymes and their cofactors and (2) antioxidant systems (see p. 82). Phases of detoxification include phase I enzymes, such as cytochrome P-450 (CYP) oxidases, which are the most important oxidative reactions. Other phase I detoxification enzymes include those for reduction and hydrolysis. In phase II detoxification, conjugation enzymes, such as glutathione (GSH), detoxify reactive electrophiles and produce polar metabolites that cannot diffuse across membranes. Most conjugation enzymes are located in the cytosol. Phase III detoxification is often called the efflux transporter system because enzymes remove the parent drugs, metabolites, and xenobiotics from cells. The liver has the highest supply of biotransformation enzymes of all organs and, therefore, has the key role in protection from chemical toxicity.\textsuperscript{25} **Figure 4-16** is a summary of chemically induced liver injury.
FIGURE 4-15  Liver Toxicants: Chemical Injury.
Liver injury is a result of genetic, environmental, biologic, and dietary factors. Certain chemicals can form toxic or chemically reactive metabolites. The risk of liver injury also can increase with increasing doses of a toxicant. Xenobiotic enzyme induction can lead to altered metabolism of chemicals, and drugs can either inhibit or induce drug-metabolizing enzymes. These changes can lead to greater toxicity. The dose at the site of action is controlled by the Phase I to III xenobiotic metabolites and metabolizing enzymes are encoded by numerous different genes. Therefore, the metabolism and toxicity outcomes can vary greatly among individuals. Additionally, all aspects of xenobiotic metabolism are regulated by certain transcription factors (cellular mediators of gene regulation). Overall, the extent of cell damage depends on the balance between reactive chemical species and protective responses aimed at decreasing oxidative stress, repairing macromolecular damage, or preserving cell health by inducing apoptosis or cell death. Significant clinical outcomes of chemical-induced liver injury occur with necrosis and the immune response. Covalent binding of reactive metabolites to cellular proteins can produce new antigens (haptons) that initiate autoantibody production and cytotoxic T-cell responses. Necrosis, a form of cell death (see p. 102), can result from extensive damage to the plasma membrane with altered ion transport, changes of membrane potential, cell swelling, and eventual dissolution. Altogether the pathogenesis of chemically induced liver injury is determined by genetics, environmental factors, and other underlying pathologic conditions. Green arrows are pathways leading to cell recovery; red arrows indicate pathways to cell damage or death; black arrows are pathways leading to chemically induced liver injury. (Adapted from Gu X, Manautou JE: Molecular mechanisms underlying chemical liver injury. Exp Rev Mol Med 14:e4, 2013.)

The consequence of self-propagating chain reactions of free radicals is lipid peroxidation (also see p. 82). Free radicals react mainly with polyunsaturated fatty
acids in membranes and can initiate lipid peroxidation. The breakdown of membrane lipids results in altered function of the mitochondria, ER, plasma membranes, and Golgi apparatus, and therefore has a role in acute liver cell death (necrosis) and progression of liver injury (Figure 4-17).
FIGURE 4-17 Chemical Injury of Liver Cells Induced by Carbon Tetrachloride (CCl₄) Poisoning. Light blue boxes are mechanisms unique to chemical injury, purple boxes involve hypoxic injury, and green boxes are clinical manifestations.

Chemical Agents Including Drugs
Numerous chemical agents cause cellular injury. Because chemical injury remains a constant problem in clinical settings, it is a major limitation to drug therapy. Over-the-counter and prescribed drugs can cause cellular injury, sometimes leading to death. The leading cause of child poisoning is medications (see Health Alert: The Percentage of Child Medication–Related Poisoning Deaths Is Increasing). The site of injury is frequently the liver, where many chemicals and drugs are metabolized (see Figure 4-17). Long-term exposure to air pollutants, insecticides, and herbicides can cause cellular injury (see Health Alert: Air Pollution Reported as Largest Single Environmental Health Risk).

**Health alert**

**The Percentage of Child Medication–Related Poisoning Deaths Is Increasing**

Today, the leading cause of child poisoning is medications. Each year, more than 500,000 children, ages 5 and younger, experience a potential poisoning related to medications. More than 60,000 children are treated in emergency departments because of accidental medication exposure or overdose. Of every 150 2-year-old children, one is being sent to the emergency department for an unintentional medication overdose. Among children younger than age 5, 95% of emergency department visits are caused by unsupervised accidental ingestions and about 5% from dosing errors made by clinicians.

Importantly, investigators analyzed records from the American Association of Poison Control Centers’ National Poison Data System (NPDS), an electronic database of all calls to the 61 poison control centers across the United States. Their analysis included all calls for children age 5 years or younger who were seen in a hospital emergency department between 2001 and 2008 for either unintentional self-exposure to a single drug (prescription or over-the-counter [OTC]) or unintentional therapeutic error for a single drug (prescription or OTC). The number of such calls during this 8-year period totaled 453,559. Medication-related poisoning deaths among children 5 years and younger now most frequently involve exposures to opioid analgesics and cardiovascular medications. About half of all poisoning–related deaths involve analgesics, antihistamines, and sedatives.

Development of new medications also has led to more of them being available in American homes. With aging, more adults are taking OTC and prescription medications as well as multiple medications. Oxycodone, morphine, and methadone prescriptions have increased between 159% and 559% between 2000 and 2009,
depending on the drug; the number of prescribed cardiovascular drugs (e.g., metoprolol) has increased about fivefold. Additionally, more medications, such as those utilized for attention-deficit disorder and diabetes, are being prescribed to younger adults and children. Prescription pain killer overdose is a growing epidemic, especially among women.

How can we increase the safety of children exposed to so many medications? Safe storage is the most important solution and safe dosing from clinicians will reduce dosing errors. Additionally, improvements are continuing through improved packaging and labeling of medications as well as education of parents and consumers on dosing information.

---

**Health Alert**

**Air Pollution Reported as Largest Single Environmental Health Risk**

The World Health Organization (WHO) reports that about 7 million people died in 2012 as a result of air pollution exposure. Improved measurements and better technology have enabled scientists to make more detailed analyses of health risks. These findings confirm that air pollution is now the world’s largest single environmental health risk and reducing air pollution could save millions of lives. New data show a stronger link between indoor and outdoor air pollution exposure and cardiovascular diseases, for example, strokes and ischemic heart disease, as well as the link between air pollution and cancer. These data are in addition to the role of air pollution and the development of respiratory diseases including infections and chronic obstructive pulmonary diseases. Using these 2012 data for low- and middle-income countries, Southeast Asia and Western Pacific regions had the largest air pollution burden. Included in the analysis is a breakdown of deaths for adults and children attributed to specific diseases:

**Outdoor Air Pollution–Caused Deaths—Breakdown by Disease:**

- 40% ischemic heart disease
- 40% stroke
• 11% chronic obstructive pulmonary disease (COPD)
• 6% lung cancer
• 3% acute lower respiratory tract infections in children

**Indoor Air Pollution—Caused Deaths—Breakdown by Disease:**

• 34% stroke
• 26% ischemic heart disease
• 22% COPD
• 12% acute lower respiratory tract infections in children
• 6% lung cancer

The WHO estimates that indoor air pollution was linked to 4.3 million deaths in 2012 from cooking over coal, wood, dung, and biomass stoves. Outdoor air pollution estimates were 3.7 million deaths in 2012 from urban and rural sources.

Another way to classify mechanisms by which drug actions, chemicals, and toxins produce injury includes (1) direct damage, also called on-target toxicity; (2) exaggerated response at the target, including overdose; (3) biologic activation to toxic metabolites, including free radicals; (4) hypersensitivity and related immunologic reactions; and (5) rare toxicities.28 These mechanisms are not mutually exclusive; thus several may be operating concurrently.

Direct damage is when chemicals and drugs injure cells by combining directly with critical molecular substances. For example, cyanide is highly toxic (e.g., poisonous) because it inhibits mitochondrial cytochrome oxidase and hence blocks electron transport. Many chemotherapeutic drugs, known as antineoplastic agents, induce cell damage by direct cytotoxic effects. Exaggerated pharmacologic responses at the target include tumors caused by industrial chemicals and the birth defects attributed to thalidomide.28 Importantly, another example includes common drugs of abuse (Table 4-5). Drug abuse can involve mind-altering substances beyond therapeutic or social norms (Table 4-6). Drug addiction and overdose are serious public health issues.

Social or Street Drugs and Their Effects

<table>
<thead>
<tr>
<th>Type of Drug</th>
<th>Description and Effects</th>
</tr>
</thead>
</table>
| Marijuana (pot)    | Active substance: Δ9-Tetrahydrocannabinol (THC), found in resin of Cannabis sativa plant
With smoking (e.g., “joints”), about 5% to 10% is absorbed through lungs; with heavy use the following adverse effects have been reported: alterations of sensory perception; cognitive and psychomotor impairment (e.g., inability to judge time, speed, distance); it increases heart rate and blood pressure; increases susceptibility to laryngitis, pharyngitis, bronchitis; causes cough and hoarseness; may contribute to lung cancer (different dosages need study; contains large number of carcinogens); data from animal studies only indicate reproductive changes include reduced fertility, decreased sperm motility, and decreased levels of circulatory testosterone; fetal abnormalities include low birth weight; increased frequency of infectious illness is thought to be result of depressed self-mediated and humoral immunity; beneficial effects include decreased nausea secondary to cancer chemotherapy and decreased pain in certain chronic conditions. |
| Methamphetamine (meth) | An amine derivation of amphetamine (C8H10N) used as crystalline hydrochloride
CNS stimulant; in large doses causes irritability, aggressive (violent) behavior, anxiety, excitement, auditory hallucinations, and paranoia (delusions and psychosis); mood changes are common and abuser can swiftly change from friendly to hostile; paranoid swings can result in suspiciousness, hyperactive behavior, and dramatic mood swings
Appeals to abusers because body’s metabolism is increased and produces euphoria, alertness, and perception of increased energy
Stages:
Low intensity: User is not psychologically addicted and uses methamphetamine by swallowing or snorting
Binge and high intensity: User has psychologic addiction and smokes or injects to achieve a faster, stronger high
Tweaking: Most dangerous stage; user is continually under the influence, not sleeping for 3-15 days, extremely irritated, and paranoid |
| Cocaine and crack | Extracted from leaves of cocoa plant and sold as a water-soluble powder (cocaine hydrochloride) liberally diluted with talcum powder or other white powders; extraction of pure alkaloid from cocaine hydrochloride is “free-base” called crack because it “cracks” when heated
Crack is more potent than cocaine; cocaine is widely used as an anesthetic; usually in procedures involving oral cavity; it is a potent CNS stimulant, blocking reuptake of neurotransmitters norepinephrine, dopamine, and serotonin; also increases synthesis of norepinephrine and dopamine; dopamine induces sense of euphoria, and norepinephrine causes adrenergic potentiation, including hypertension, tachycardia, and vasoconstriction; cocaine can therefore cause severe coronary artery narrowing and ischemia; reason cocaine increases thrombus formation is unclear; other cardiovascular effects include dysrhythmias, sudden death, dilated cardiomyopathy, rupture of descending aorta (i.e., secondary to hypertension); effects on fetus include prematurity labor, retarded fetal development, stillbirth, hyperirritability |
| Heroin             | Opiate closely related to morphine, methadone, and codeine
Highly addictive, and withdrawal causes intense fear (“I’ll die without it”); sold “cut” with similar-looking white powder; dissolved in water it is often highly contaminated; feeling of tranquility and sedation lasts only a few hours and thus encourages repeated intravenous or subcutaneous injections; acts on the receptors enkephalins, endorphins, and dynorphins, which are widely distributed throughout body with high affinity to CNS; effects can include infectious complications, especially Staphylococcus aureus, granulomas of lung, septic embolism, and pulmonary edema—in addition, viral infections from casual exchange of needles and HIV; sudden death is related to overdose secondary to respiratory depression, decreased cardiac output, and severe pulmonary edema |

CNS, Central nervous system; HIV, human immunodeficiency virus.

Most toxic chemicals are not biologically active in their parent (native) form but must be converted to reactive metabolites, which then act on target molecules. This conversion is usually performed by the cytochrome P-450 oxidase enzymes in the smooth ER of the liver and other organs. These toxic metabolites cause membrane damage and cell injury mostly from formation of free radicals and subsequent membrane damage from lipid peroxidation (see Figure 4-17). For example, acetaminophen (paracetamol) is converted to a toxic metabolite in the liver, causing cell injury (Figure 4-18). Acetaminophen is one of the most common causes of poisoning worldwide.29 Many investigators are studying hepatoprotective strategies.30
Hypersensitivity reactions are a common drug toxicity and range from mild skin rashes to immune-mediated organ failure. One type of hypersensitivity reaction is the delayed-onset reaction, which occurs after multiple doses of a drug are administered. Some protein drugs and large polypeptide drugs (e.g., insulin) can directly stimulate antibody production (see Chapter 8). Most drugs, however, act as haptens and bind covalently to serum or cell-bound proteins. The binding makes the protein immunogenic, stimulating antidrug antibody production, T-cell responses against the drug, or both. For example, penicillin itself is not antigenic but its metabolic degradation products can become antigenic and cause an allergic reaction. Rare toxicities simply mean infrequent occurrences as described previously by the other four mechanisms. These toxicities reflect individual genetic predispositions that affect drug or chemical metabolism, disposition, and immune responses.

Carbon monoxide, carbon tetrachloride, and social drugs, such as alcohol, can significantly alter cellular function and injure cellular structures. Accidental or
suicidal poisonings by chemical agents cause numerous deaths. The injurious effects of some agents—lead, carbon monoxide, ethyl alcohol, mercury—are common cellular injuries.

**Lead.**

Lead (Pb) is a heavy toxic metal that persists in older homes, the environment, and the workplace. Lead may be found in hazardous concentrations in food, water, and air and it is one of the most common overexposures found in industry. Despite efforts to reduce exposure through government regulation, exposure still persists for many people and toxicity is still a primary hazard for children (see Health Alert: Low-Level Lead Exposure Harms Children: A Renewed Call for Primary Prevention). Although Pb was removed from paint in Europe in 1922 and removed in the United States in 1978, many homes in the United States still contain leaded paint and chipped and peeling leaded paint constitutes a major source of current childhood exposure. The chipped paint can disintegrate at friction surfaces to form Pb dust. Another source of contamination is Pb dust dispersed along roadways from previous leaded gasoline emissions. When Pb was removed from gasoline, blood lead levels (BLLs) dropped significantly. Previous emissions of leaded fuel created large dispersions of lead dust in the environment. Particulate lead (2 to 10 µm) does not degrade and persists in the environment, making it a notable source of human exposure. Other airborne sources include smelters and piston-engine airplanes. Drinking water exposed to Pb occurs from outdated fixtures, plumbing without corrosion control, and solders. Because well water is not subject to EPA regulation it may not be tested for Pb. Although the average blood levels of Pb in children in the United States have dropped since the 1970s, there are at-risk populations with higher than average BLLs. Children of lower social economic status or racial minority status are still at higher risk of Pb poisoning and some regions in the United States have an increased prevalence of higher BLLs in children. Importantly, the CDC reports “no safe blood lead level in children has been identified.” Common sources of Pb are included in Table 4-7.

---

**Health Alert**

**Low-Level Lead Exposure Harms Children: A Renewed Call for Primary Prevention**

An advisory committee of the CDC recently suggested that the current threshold for harmful lead exposure in children should be cut in half because even lower levels
cause irreversible harm. The report noted that studies have found reduced intelligence quotients (IQs) and behavioral problems in children with exposure levels less than 10 mcg/dl and that such low levels have effects on cardiovascular, endocrine, and immunologic systems. Based on these data, the panel recommended reducing the threshold for harmful levels of lead in the blood to 5 mcg/dl. Despite progress in reducing blood lead levels (BLLs), racial and income disparities persist. An internal review process from both the Centers for Disease Control and Prevention and the U.S. Department of Health and Human Services will determine how to implement any accepted recommendations. This is a very important process because BLLs appear to be irreversible, underscoring the need for primary prevention.

### TABLE 4-7
Common Sources of Lead Exposure

<table>
<thead>
<tr>
<th>Exposure</th>

</table>

Children are more susceptible to the effects of Pb than adults for several reasons, including (1) children have increased hand-to-mouth behavior and exposure from the ingestion of Pb dust; (2) the blood-brain barrier in children is immature during fetal development, contributing to greater accumulation in the developing brain; and (3) infant absorption of Pb is greater than that in adults and bone turnover (in adults the body burden of lead is found in bone) in children from skeletal growth results in continuous leaching of Pb into blood, causing constant body exposure. If nutrition is compromised, especially if dietary intake of iron and calcium is insufficient, children are more likely to have elevated BLLs. Particularly worrisome is lead exposure during pregnancy because the developing fetal nervous system is especially vulnerable; lead exposure can result in lower IQs, learning disorders, hyperactivity, and attention problems. The organ systems primarily affected by lead ingestion include the nervous system, the hematopoietic system (tissues that produce blood cells), and the kidneys
of the urologic system. The neurologic effect of Pb in exposed children is the driving factor for reducing Pb levels in the environment. Elevated BLLs not only are linked to cognitive deficits but also are associated with behavioral changes including antisocial behavior, acting out in school, and difficulty paying attention. The cognitive and behavioral changes of Pb-exposed children persist after complete cessation of Pb exposure. In 1991 the CDC lowered the definition of Pb intoxication to 10 µm/dl BLL because several studies reported that children with BLLs of at least 10 µm/dl had impaired intellectual functioning (Figure 4-19). Studies in animals have led to the hypothesis that Pb targets the learning and memory processes by inhibiting the N-methyl-D-aspartate receptor (NMDAR), which is necessary for hippocampus-mediated learning and memory. Similar changes also have been found in cultured neuron systems. Inhibition of either voltage-gated calcium channels or NMDARs by Pb results in reduction of Ca²⁺ entry into the cell, thereby disrupting the necessary Ca²⁺ signaling for neurotransmission. Lead induces cellular damage by increasing oxidative stress. Lead toxicity involves the direct formation of ROS (singlet oxygen, hydrogen peroxides, hydroperoxides) and depletion of antioxidants. Pb exposure leads to lowered levels of glutathione; and because glutathione is important for the metabolism of specific drugs and other toxins, low Pb levels can increase their toxicity, as well as the levels of other metals. From animal studies and human population studies, low-level lead exposure may cause hypertension. Lead interferes with the normal remodeling of cartilage and bone in children. From radiologic studies of bone, “lead lines” are detectable and lead also can be found in the gums as a result of hyperpigmentation. Lead inhibits several enzymes involved in hemoglobin synthesis and causes anemia (most obvious is a microcytic hypochromic anemia). Renal lesions can cause tubular dysfunction resulting in glycosuria (glucose in the urine), aminoaciduria (amino acids in the urine), and hyperphosphaturia (excess phosphate in the urine). Gastrointestinal symptoms are less severe and include nausea, loss of appetite, weight loss, and abdominal cramping.
Carbon monoxide.

Gaseous substances can be classified according to their ability to asphyxiate (interrupt respiration) or irritate. Toxic asphyxiants, such as carbon monoxide, hydrogen cyanide, and hydrogen sulfide, directly interfere with cellular respiration. **Carbon monoxide (CO)** is an odorless, colorless, nonirritating, and undetectable gas unless it is mixed with a visible or odorous pollutant. CO is produced by the incomplete combustion of fuels such as gasoline. Although CO is a chemical agent, the ultimate injury it produces is a hypoxic injury—namely, oxygen deprivation. As a systemic asphyxiant, CO causes death by inducing central nervous system (CNS)
depression. Normally, oxygen molecules are carried to tissues bound to hemoglobin in red blood cells (see Chapter 27). Because CO's affinity for hemoglobin is 300 times greater than that of oxygen, CO quickly binds with the hemoglobin, preventing the oxygen molecules' ability to bind to the hemoglobin. Minute amounts of CO can produce a significant percentage of carboxyhemoglobin (carbon monoxide bound with hemoglobin). With increasing levels of carboxyhemoglobin, hypoxia occurs insidiously, evoking widespread ischemic changes in the CNS, and individuals are often unaware of their plight. The diagnosis is made from measurement of carboxyhemoglobin levels in the blood.

Symptoms related to CO poisoning include headache, giddiness, tinnitus (ringing in the ears), chest pain, confusion, nausea, weakness, and vomiting. CO is an air pollutant found in combustion fumes produced by cars and trucks, small gasoline engines, stoves, gas ranges, gas refrigerators, heating systems, lanterns, burning charcoal or wood, and cigarette smoke. Chronic exposure can occur in people working in confined spaces, such as underground garages and tunnels. Fumes can accumulate in enclosed or semi-enclosed spaces, and poisoning from breathing CO can occur in humans and animals. High levels of CO can cause loss of consciousness and death. Death can occur in individuals sleeping or intoxicated before experiencing any symptoms. Although all people and animals are at risk, those most susceptible to poisoning include unborn babies, infants, and people with chronic heart disease, respiratory problems, and anemia. For information on preventing CO poisoning from home appliances and proper venting, see the Centers for Disease Control and Prevention (CDC) website at www.cdc.gov/co/faqs.htm.

**Ethanol.**

Alcohol (ethanol) is the primary choice among mood-altering drugs available in the United States. It is estimated there are more than 10 million chronic alcoholics in the United States. Alcohol contributes to more than 100,000 deaths annually with 50% of these deaths from drunk driving accidents, alcohol-related homicides, and suicides. A blood concentration of 80 mg/dl is the legal definition for drunk driving in the United States. This level of alcohol in an average person may be reached after consumption of three drinks (three 12-ounce bottles of beer, 15 ounces of wine, and 4 to 5 ounces of distilled liquor). The effects of alcohol vary by age, gender, and percent body fat; the rate of metabolism affects the blood alcohol level. Because alcohol is not only a psychoactive drug but also a food, it is considered part of the basic food supply in many societies.

A large intake of alcohol has enormous effects on nutritional status. Liver and nutritional disorders are the most serious consequences of alcohol abuse. Major
nutritional deficiencies include magnesium, vitamin B₆, thiamine, and phosphorus. Folic acid deficiency is a common problem in chronic alcoholic populations. Ethanol alters folic acid (folate) homeostasis by decreasing intestinal absorption of folate, increasing liver retention of folate, and increasing the loss of folate through urinary and fecal excretion. Folic acid deficiency becomes especially serious in pregnant women who consume alcohol and may contribute to fetal alcohol syndrome (see p. 92).

Most of the alcohol in blood is metabolized to acetaldehyde in the liver by three enzyme systems: alcohol dehydrogenase (ADH), the microsomal ethanol-oxidizing system (MEOS; CYP2E1), and catalase (Figure 4-20). The major pathway involves ADH, an enzyme located in the cytosol of hepatocytes. The microsomal ethanol oxidizing system (MEOS) depends on cytochrome P-450 (CYP2E1), an enzyme needed for cellular oxidation. Activation of CYP2E1 requires a high ethanol concentration and thus is thought to be important in the accelerated ethanol metabolism (i.e., tolerance) noted in persons with chronic alcoholism. Acetaldehyde has many toxic tissue effects and is responsible for some of the acute effects of alcohol and for development of head and neck cancer (HNC). A recent and first study showed that head and neck cancer risk may be influenced by alcohol-metabolizing genes (ADH1B and ALDH2) and oral hygiene.
The major effects of acute alcoholism involve the central nervous system (CNS). After alcohol is ingested, it is absorbed, unaltered, in the stomach and small intestine. Fatty foods and milk slow absorption. Alcohol then is distributed to all tissues and fluids of the body in direct proportion to the blood concentration. Individuals differ in their capability to metabolize alcohol. Genetic differences in the metabolism of liver alcohol, including levels of aldehyde dehydrogenases, have been identified.\(^{51}\) These genetic polymorphisms may account for ethnic and gender differences in ethanol metabolism. Persons with chronic alcoholism develop tolerance because of production of enzymes, leading to an increased rate of metabolism (e.g., P-450).

Numerous studies have validated the so-called \(J\)- or \(U\)-shaped inverse association between alcohol and overall or cardiovascular mortality, such as from myocardial infarction and ischemic stroke. These studies have found that light to moderate (nonbinge) drinkers tend to have lower mortality than nondrinkers and heavy drinkers have higher mortality.\(^{52}\) For both men and women, former drinkers and regular heavy drinkers had higher mortality.\(^{52}\) Light to moderate drinkers in the United States may have reduced mortality but this may be confounded by medical

---

**FIGURE 4-20** Ethanol Metabolism Pathway. Ethanol is metabolized into acetaldehyde through the cytosolic enzyme alcohol dehydrogenase (ADH), the microsomal enzyme cytochrome P-450 2E1 (CYP2E1), and the peroxisomal enzyme catalase. The ADH enzyme reaction is the main ethanol metabolic pathway involving an intermediate carrier of electrons, namely, nicotinamide adenine dinucleotide (NAD\(^+\)), which is reduced by two electrons to form NADH. Acetaldehyde is metabolized mainly by aldehyde dehydrogenase 2 (ALDH2) in the mitochondria to acetate and NADH before being cleared into the systemic circulation. (Adapted from Zhang Y, Ren J: Pharmacol Ther 132[1]:86-92, 2011.)
care and social relationships, especially among women\textsuperscript{52,53} These relationships need further study. The suggested mechanisms for cardioprotection for light to moderate drinkers include increase in levels of high-density lipoprotein–cholesterol (HDL-C), decrease in levels of low-density lipoprotein (LDL), prevention of clot formation, reduction in platelet aggregation, decrease in blood pressure, increase in coronary vessel vasodilation, increase in coronary blood flow, decrease in coronary inflammation, decrease in atherosclerosis, limited ischemia-reperfusion injury (I/R injury), and a decrease in diabetic vessel pathology.\textsuperscript{54} The American Heart Association recommends no more than two drinks per day for men and one drink per day for women (one 12-oz beer, 4 oz of wine, 1.5 oz of 80-proof spirits, or 1 oz of 100-proof spirits). Drinking more alcohol can increase the risks of alcoholism, high blood pressure, obesity, stroke, breast cancer, suicide, and accidents.\textsuperscript{55} Individuals who do not consume alcohol should not be encouraged to start drinking.\textsuperscript{56}

*Acute alcoholism* (drunkenness) affects the CNS (see **Health Alert: Alcohol: Global Burden, Adolescent Onset, Chronic or Binge Drinking**). Alcohol intoxication causes CNS depression. Depending on the amount consumed, CNS depression is associated with sedation, drowsiness, loss of motor coordination, delirium, altered behavior, and loss of consciousness. Toxic amounts (300 to 400 mg/dl) result in a lethal coma or respiratory arrest because of medullary center depression. Investigators studied the effects of snoring and multiple variables including alcohol. They found that a low level of self-reported physical activity is a risk factor for future habitual snoring complaints in women independent of alcohol dependence, smoking, current weight, and weight gain. Furthermore, increased physical activity can modify the risk.\textsuperscript{57} Acute alcoholism may induce reversible hepatic and gastric changes.\textsuperscript{48} Acute alcoholism contributes significantly to motor vehicle fatalities.

**Health Alert**

**Alcohol: Global Burden, Adolescent Onset, Chronic or Binge Drinking**

Alcohol is widely consumed worldwide, and in the United States 50\% of the adult population (18 years and older) consumes alcohol regularly. Alcohol continues to be the drug of choice among teens and young adults with one third of twelfth graders and 40\% of college students reporting “binge drinking” (four standard alcohol drinks on one occasion in females and five in males). Alcohol abuse is the
leading cause of liver-related morbidity and mortality. Chronic and binge drinking causes alcoholic liver disease (ALD) with a spectrum from hepatic steatosis (fatty change) to steatohepatitis (fatty change and inflammation) and cirrhosis (see Chapter 36). These alterations can eventually lead to hepatocellular carcinoma. The pathogenesis of ALD is not fully characterized and recent studies reveal a major role of mitochondria. Animal studies have shown that alcohol causes mitochondrial DNA damage, lipid accumulation, and oxidative stress. Understanding the role of the mitochondria may help identify therapeutic targets.

Investigations of adolescent drinking behaviors, especially binge drinking, is providing evidence of neurocognitive changes, including changes in both gray and white matter. These studies are examining risk-taking behaviors that begin in adolescence and coincide with vulnerable and significant neurodevelopmental changes.

Chronic alcoholism causes structural alterations in practically all organs and tissues in the body because most tissues contain enzymes capable of ethanol oxidation or nonoxidative metabolism. The most significant activity, however, occurs in the liver. Alcohol is the leading cause of liver-related morbidity and mortality. In general, hepatic changes, initiated by acetaldehyde, include inflammation, deposition of fat, enlargement of the liver, interruption of microtubular transport of proteins and their secretion, increase in intracellular water, depression of fatty acid oxidation in the mitochondria, increase in membrane rigidity, and acute liver cell necrosis (see Chapter 36). Specifically, chronic or binge alcohol consumption causes alcoholic liver disease (ALD) with a spectrum ranging from simple fatty liver (steatosis), to steatohepatitis (fatty with inflammation), to cirrhosis (Figure 4-21) (see Chapter 36). Cirrhosis is associated with portal hypertension and an increased risk for hepatocellular carcinoma. Cellular damage is increased by reactive oxygen species (ROS) and oxidative stress (see p. 81). Activation of proinflammatory cytokines from neutrophils and lymphocytes mediates liver damage. Oxidative stress is associated with cell membrane phospholipid depletion, which alters the fluidity and function of cell membranes as well as intercellular transport. Chronic alcoholism is related to several disorders, including injury to the myocardium (alcoholic cardiomyopathy);
increased tendency to hypertension, acute gastritis, and acute and chronic pancreatitis; and regressive changes in skeletal muscle. Chronic alcohol consumption is associated with an increased incidence of cancer of the oral cavity, liver, esophagus, and breast (see *Health Alert: Alcohol: Global Burden, Adolescent Onset, Chronic or Binge Drinking*).

![FIGURE 4-21](image)

**FIGURE 4-21** Alcoholic Hepatitis. Chicken-wire fibrosis extending between hepatocytes (Mallory trichrome stain). (From Damjanov I, Linder J, editors: *Anderson's pathology*, ed 10, St Louis, 1996, Mosby)

Ethanol is implicated in the onset of a variety of immune defects, including effects on the production of cytokines involved in inflammatory responses. Alcohol can induce epigenetic variations in the developmental pathways of many types of immune cells (e.g., granulocytes, macrophages, and T-lymphocytes) that promote increased inflammation. Alcohol increases the development of serious medical conditions related to immune system dysfunction, including acute respiratory distress syndrome (ARDS) as well as liver cancer and alcoholic liver disease (ALD). Binge and chronic drinking increases susceptibility to many infectious microorganisms and can enhance the progression of human immunodeficiency virus (HIV) by affecting innate and adaptive immunity.

The deleterious effects of prenatal alcohol exposure can cause mental deficiency and neurobehavioral disorders, as well as fetal alcohol syndrome. **Fetal alcohol syndrome** includes growth retardation, facial anomalies, cognitive impairment, and ocular malformations (Figure 4-22). It is among the common causes of mental deficiency. Evidence of epigenetic alterations has led to the hypothesis that alcohol
effects on fetal development may be caused not only by maternal alcohol consumption but also by the father's exposure as well. Epigenetic alterations may be carried through the male germline for generations. Alcohol crosses the placenta, reaching the fetus, and blood levels of the fetus may reach equivalent levels to maternal levels in 1 to 2 hours. Research has demonstrated an unimpeded bidirectional movement of alcohol between the fetus and the mother. The fetus may completely depend on maternal hepatic detoxification because the activity of alcohol dehydrogenase (ADH) in fetal liver is less than 10% of that in the adult liver. Additionally, the amniotic fluid acts as a reservoir for alcohol, prolonging fetal exposure. The specific mechanisms of injury are unknown; however, acetaldehyde can alter fetal development by disrupting differentiation and growth; DNA and protein synthesis; modification of carbohydrates, proteins, and fats; flow of nutrients across the placenta; and neuro-circuitry dysfunction that may be long-lasting.

![FIGURE 4-22 Fetal Alcohol Syndrome.](image)

Mercury.

Mercury is a global threat to human and environmental health. A recent report
presents an overview of the *Global Mercury Assessment 2013*.\textsuperscript{64} This report provides the most recent information on worldwide atmospheric mercury emissions, releases to the aquatic environment, and the fate of mercury in the global environment. Causes from human activity, called *anthropogenic*, are responsible for about 30\% of annual emissions of mercury to air, another 10\% arise from natural geologic sources, and the remainder (60\%) occurs from re-emissions or earlier released mercury that has increased over decades and centuries in surface soil and water.\textsuperscript{64} The major sources of anthropogenic mercury emissions to air are artisanal and small-scale gold mining (ASGM) and coal burning. The next major sources are the production of ferrous and nonferrous metals, and cement production. Importantly, investigators report that emissions from industrial sectors have increased since 2005.\textsuperscript{64} Types of aquatic releases of mercury include industrial sites (power plants, factories), old mines, landfills, and waste disposal locations. Artisanal and small-scale gold mining are significant producers of aquatic mercury release. It is estimated that more than 90\% of mercury in marine animals is from anthropogenic emissions.\textsuperscript{64} Large amounts of inorganic mercury have accumulated in surface soils and in the oceans. Climate change, with thawing of enormous areas of frozen lands, may release even more long-stored mercury and organic matter into lakes, rivers, and oceans.\textsuperscript{64}

Dental amalgams, or “silver fillings,” are made of two almost equal parts of liquid mercury and a powder containing silver, tin, copper, zinc, and other metals.\textsuperscript{41} When amalgams are placed or removed they can release a small amount of mercury vapor. Chewing can release a small amount of vapor and people absorb the vapor by inhalation or ingestion.\textsuperscript{41} Researchers are studying the effects of exposure to magnetic fields, such as from mobile phone use, and the release of mercury from amalgams.\textsuperscript{65} Susceptibility to mercury toxicity varies in a dose-dependent fashion, and among individuals based on multiple genes, not all have been identified.\textsuperscript{66,67} Worldwide efforts are under way to phase down or eliminate the use of mercury dental amalgam.\textsuperscript{67} Thimerosal, a mercury-containing preservative, was removed from all vaccines in 2001, with the exception of inactivated influenza vaccines.\textsuperscript{68}

\textbf{Quick Check 4-2}

1. Why are children more susceptible to the toxic effects of lead exposure?

2. Discuss the sources of lead exposure?

3. Discuss the mechanisms of cell injury related to chronic alcoholism?
4. What are the sources of mercury exposure?

**Unintentional and Intentional Injuries**

Unintentional and intentional injuries are an important health problem in the United States. In 2012 there were 192,945 deaths, an injury death rate of 60.2/100,000. The number of deaths because of poisoning was 48,545 with 15.4 deaths per 100,000. Motor vehicle traffic deaths were 33,804 with a rate of 10.7 deaths per 100,000. Deaths from all firearms were 33,636 with a rate of 10.6 deaths per 100,000. From data reporting in 2010, drug poisoning deaths were 12.4 per 100,000.

Death from injury is significantly more common for men than for women; the overall rate for men is 83.46/100,000 versus 39.28/100,000 for women. Significant racial differences are noted in the death rate, with whites at 64.85/100,000, blacks at 56.20/100,000, and other racial groups at a combined rate of 28.96/100,000. There also is a bimodal age distribution for injury-related deaths, with peaks in the young adult and elderly groups. Unintentional injury is the leading cause of death for people between the ages of 1 and 34 years; intentional injury (suicide, homicide) ranks between the second and fourth leading cause of death in this age group. The 1999 report published by the Institute of Medicine (IOM) indicated that between 44,000 and 98,000 unnecessary deaths per year occurred in hospitals alone as a result of errors by healthcare professionals (see *Health Alert: Unintentional Injury Errors in Health Care and Patient Safety*). Statistics on nonfatal injuries are harder to document accurately, but they are known to be a significant cause of morbidity and disability and to cost society billions of dollars annually. The more common terms used to describe and classify unintentional and intentional injuries and brief descriptions of important features of these injuries are discussed in **Table 4-8**.

**Health Alert**

**Unintentional Injury Errors in Health Care and Patient Safety**

According to a US Senate subcommittee hearing (July 17, 2014), despite more than a decade of national efforts to improve patient safety, hospitals and ambulatory care centers remain problematic for patients. This assessment follows the 15-year anniversary of the release of the IOM report on patient safety. Testimony from the senate hearings challenged the IOM report that patient harms were likely underestimated. A more recent estimate suggests the number of U.S. deaths as a result of medical error may be greater than 400,000 per year with more than 1000 each day.
Progress has been made in certain areas including the reduction of bloodstream infections from central lines. Success with this program has been expanded nationwide. Checklists are a very useful tool for improving patient safety. They have become more widely implemented and their success depends on appropriately targeting the intervention and utilizing a careful implementation strategy. Besides checklists, other examples of patient safety primers include adverse events after hospital discharge, computerized provider order entry, detection of safety hazards, diagnostic errors, disruptive and unprofessional behavior, error disclosure, handoffs and signouts, health care–associated infections, nursing and patient safety, and medication errors. In a testimony at the hearings it was stated “that one of the biggest barriers to improved patient safety is the lack of a robust national system for tracking patient safety data.” Additionally, speakers testified that better systems of care are needed in understanding that a complex set of factors—complexity of hospital systems, time pressures, growing use of technology, financial incentives that reward hospitals by paying them to care for patients' complications, CEO compensation not tied to quality of care—all contribute to poor patient outcomes. The entrenched challenges of the U.S. health care system demand a transformed approach. Left unchanged, health care will continue to underperform; cause unnecessary harm; and strain national, state, and family budgets. The actions required to reverse this trend will be notable, substantial, sometimes disruptive—and absolutely necessary.” (IOM Best Care at Lower Cost; The Path to Continuously Learning Health Care in America Institute of Medicine Report Brief Washington DC, 2012)

### TABLE 4-8

**Unintentional and Intentional Injuries**

<table>
<thead>
<tr>
<th>Type of Injury</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>BLUNT-FORCE INJURIES</td>
<td>Mechanical injury to body resulting in tearing, shearing, or crushing; most common type of injury seen in healthcare settings; caused by blows or impacts; motor vehicle accidents and falls most common cause (see photo, A)</td>
</tr>
<tr>
<td>Contusion (bruise)</td>
<td>Bleeding into skin or underlying tissues; initial color will be red-purple, then</td>
</tr>
</tbody>
</table>
blue-black, then yellow-brown or green (see Figure 4-26); duration of bruise depends on extent, location, and degree of vascularization; bruising of soft tissue may be confined to deeper structures; hematoma is collection of blood in soft tissue; subdural hematoma is blood between inner surface of dura mater and surface of brain; can result from blows, falls, or sudden acceleration/deceleration of head as occurs in shaken baby syndrome; epidural hematoma is collection of blood between inner surface of skull and dura; is most often associated with a skull fracture

Laceration: Tear or rip resulting when tensile strength of skin or tissue is exceeded; is ragged and irregular with abraded edges; an extreme example is avulsion, where a wide area of tissue is pulled away; lacerations of internal organs are common in blunt-force injuries; lacerations of liver, spleen, kidneys, and bowel occur from blows to abdomen; thoracic aorta may be lacerated in sudden deceleration accidents; severe blows or impacts to chest may rupture heart with lacerations of atria or ventricles

Fracture: Blunt-force blows or impacts can cause bone to break or shatter (see Chapter 39)

SHARP-FORCE INJURIES

Cutting and piercing injuries accounted for 2734 deaths in 2007; men have a higher rate (1.37/100,000) than women (0.44/100,000); differences by race are whites 0.71/100,000, blacks 2.12/100,000, and other groups 0.80/100,000

Incised wound: A wound that is longer than it is deep; wound can be straight or jagged with sharp, distinct edges without abrasion; usually produces significant external bleeding with little internal hemorrhage; these wounds are noted in sharp-force injury suicides; in addition to a deep, lethal cut, there will be superficial
incisions in same area called hesitation marks (see photo, B)

Stab wound: A penetrating sharp-force injury that is deeper than it is long; if a sharp instrument is used, depths of wound are clean and distinct but can be abraded if object is inserted deeply and wider portion (e.g., hilt of a knife) impacts skin; depending on size and location of wound, external bleeding may be surprisingly small; after an initial spurt of blood, even if a major vessel or heart is struck, wound may be almost completely closed by tissue pressure, thus allowing only a trickle of visible blood despite copious internal bleeding

Puncture wound: Instruments or objects with sharp points but without sharp edges produce puncture wounds; classic example is wound of foot after stepping on a nail; wounds are prone to infection, have abrasion of edges, and can be very deep

Chopping wound: Heavy, edged instruments (axes, hatchets, propeller blades) produce wounds with a combination of sharp- and blunt-force characteristics

GUNSHOT WOUNDS

Accounted for more than 33,636 deaths in the United States in 2015; men more likely to die than women (18.16 vs. 2.73/100,000); black men between ages of 15 and 24 have greatest death rate (86.95/100,000); gunshot wounds are either penetrating (bullet remains in body) or perforating (bullet exits body); bullet also can fragment; most important factors or appearances are whether it is an entrance or exit wound and range of fire
Entrance wound: All wounds share some common features; overall appearance is most affected by range of fire.

Contact range entrance wound: Distinctive type of wound when gun is held so muzzle rests on or presses into skin surface; there is searing of edges of wound from flame and soot or smoke on edges of wound in addition to hole; hard contact wounds of head cause severe tearing and disruption of tissue (because of thin layer of skin and muscle overlying bone); wound is gaping and jagged, known as blow back; can produce a patterned abrasion that mirrors weapon used (see photo, C).

Intermediate (distance) range entrance wound: Surrounded by gunpowder tattooing or stippling; tattooing results from fragments of burning or unburned pieces of gunpowder exiting barrel and forcefully striking skin; stippling results when gunpowder abrades but does not penetrate skin (see photo, D).

Indeterminate range entrance wound: Occurs when flame, soot, or gunpowder does not reach skin surface but bullet does; indeterminate is used rather than distant because appearance may be same regardless of distance; for example, if an individual is shot at close range through multiple layers of clothing the wound may look the same as if the shooting occurred at a distance.

Exit wound: Has the same appearance regardless of range of fire; most important factors are speed of projectile and degree of
deformation; size cannot be used to determine if hole is an exit or entrance wound; usually has clean edges that can often be reapproximated to cover defect; skin is one of toughest structures for a bullet to penetrate; thus it is not uncommon for a bullet to pass entirely through body but stopped just beneath skin on “exit” side.

Wounding potential of bullets: Most damage done by a bullet is a result of amount of energy transferred to tissue impacted; speed of bullet has much greater effect than increased size; some bullets are designed to expand or fragment when striking an object, for example, hollow-point ammunition; lethality of a wound depends on what structures are damaged; wounds of brain may not be lethal; however, they are usually immediately incapacitating and lead to significant long-term disability; a person with a “lethal” injury (wound of heart or aorta) also may not be immediately incapacitated.

Asphyxial Injuries

Asphyxial injuries are caused by a failure of cells to receive or use oxygen. Deprivation of oxygen may be partial (hypoxia) or total (anoxia). Asphyxial injuries can be grouped into four general categories: suffocation, strangulation, chemical asphyxiants, and drowning.
**Suffocation.**

*Suffocation*, or oxygen failing to reach the blood, can result from a lack of oxygen in the environment (entrapment in an enclosed space or filling of the environment with a suffocating gas) or blockage of the external airways. Classic examples of these types of asphyxial injuries are a child who is trapped in an abandoned refrigerator or a person who commits suicide by putting a plastic bag over his or her head. A reduction in the ambient oxygen level to 16% (normal is 21%) is immediately dangerous. If the level is below 5%, death can ensue within a matter of minutes. The diagnosis of these types of asphyxial injuries depends on obtaining an accurate and thorough history because there will be no specific physical findings.

Diagnosis and treatment in *choking asphyxiation* (obstruction of the internal airways) depend on locating and removing the obstructing material. Injury or disease also may cause swelling of the soft tissues of the airway, leading to partial or complete obstruction and subsequent asphyxiation. Suffocation also may result from compression of the chest or abdomen (mechanical or compressional asphyxia), preventing normal respiratory movements. Usual signs and symptoms include florid facial congestion and petechiae (pinpoint hemorrhages) of the eyes and face.

**Strangulation.**

*Strangulation* is caused by compression and closure of the blood vessels and air passages resulting from external pressure on the neck. This causes cerebral hypoxia or anoxia secondary to the alteration or cessation of blood flow to and from the brain. It is important to remember that the amount of force needed to close the jugular veins (2 kg [4.5 lb]) or carotid arteries (5 kg [11 lb]) is significantly less than that required to crush the trachea (15 kg [33 lb]). It is the alteration of cerebral blood flow in most types of strangulation that causes injury or death—not the lack of airflow. With complete blockage of the carotid arteries, unconsciousness can occur within 10 to 15 seconds.

A noose is placed around the neck, and the weight of the body is used to cause constriction of the noose and compression of the neck in *hanging strangulations*. The body does not need to be completely suspended to produce severe injury or death. Depending on the type of ligature used, there usually is a distinct mark on the neck—an inverted V with the base of the V pointing toward the point of suspension. Internal injuries of the neck are actually quite rare in hangings, and only in judicial hangings, in which the body is weighted and dropped, is significant soft tissue or cervical spinal trauma seen. Petechiae of the eyes or face may be seen, but they are
rare.

In **ligature strangulation**, the mark on the neck is horizontal without the inverted V pattern seen in hangings. Petechiae may be more common because intermittent opening and closure of the blood vessels may occur as a result of the victim's struggles. Internal injuries of the neck are rare.

Variable amounts of external trauma on the neck are found with contusions and abrasions in **manual strangulation** caused either by the assailant or by the victim clawing at his or her own neck in an attempt to remove the assailant's hands. Internal damage can be quite severe, with bruising of deep structures and even fractures of the hyoid bone and tracheal and cricoid cartilages. Petechiae are common.

**Chemical asphyxiants.**

**Chemical asphyxiants** either prevent the delivery of oxygen to the tissues or block its utilization. Carbon monoxide is the most common chemical asphyxiant (see p. 90). **Cyanide** acts as an asphyxiant by combining with the ferric iron atom in cytochrome oxidase, thereby blocking the intracellular use of oxygen. A victim of cyanide poisoning will have the same cherry-red appearance as a carbon monoxide intoxication victim because cyanide blocks the use of circulating oxyhemoglobin. An odor of bitter almonds also may be detected. (The ability to smell cyanide is a genetic trait that is absent in a significant portion of the general population.) **Hydrogen sulfide** (sewer gas) is a chemical asphyxiant in which victims of hydrogen cyanide poisoning may have brown-tinged blood in addition to the nonspecific signs of asphyxiation.

**Drowning.**

**Drowning** is an alteration of oxygen delivery to tissues resulting from the inhalation of fluid, usually water. In 2012 there were 3391 drowning deaths in the United States. Although research in the 1940s and 1950s indicated that changes in blood electrolyte levels and volume as a result of absorption of fluid from the lungs may be an important factor in some drownings, the major mechanism of injury is hypoxemia (low blood oxygen levels). Even in freshwater drownings, where large amounts of water can pass through the alveolar-capillary interface, there is no evidence that increases in blood volume cause significant electrolyte disturbances or hemolysis, or that the amount of fluid loading is beyond the compensatory capabilities of the kidneys and heart. Airway obstruction is the more important pathologic abnormality, underscored by the fact that in as many as 15% of drownings little or no water enters the lungs because of vagal nerve–mediated laryngospasms. This phenomenon is called **dry-lung drowning**.
No matter what mechanism is involved, cerebral hypoxia leads to unconsciousness in a matter of minutes. Whether this progresses to death depends on a number of factors, including the age and the health of the individual. One of the most important factors is the temperature of the water. Irreversible injury develops much more rapidly in warm water than it does in cold water. Submersion times of up to 1 hour with subsequent survival have been reported in children who were submerged in very cold water. Complete submersion is not necessary for a person to drown. An incapacitated or helpless individual (epileptic, alcoholic, infant) may drown in water that is only a few inches deep.

It is important to remember that no specific or diagnostic findings prove that a person recovered from the water is actually a drowning victim. In cases where water has entered the lung, there may be large amounts of foam exiting the nose and mouth, although this also can be seen in certain types of drug overdoses. A body recovered from water with signs of prolonged immersion could just as easily be a victim of some other type of injury with the immersion acting to obscure the actual cause of death. When working with a living victim recovered from water, it is essential to keep in mind that an underlying condition may have led to the person's becoming incapacitated and submerged—a condition that also may need to be treated or corrected while correcting hypoxemia and dealing with its sequelae.

Quick Check 4-3

2. Discuss unintentional injury as a form of injury with health care delivery in the United States.
3. What is the major mechanism of injury with drowning?

Infectious Injury

The pathogenicity (virulence) of microorganisms lies in their ability to survive and proliferate in the human body, where they injure cells and tissues. The disease-producing potential of a microorganism depends on its ability to (1) invade and destroy cells, (2) produce toxins, and (3) produce damaging hypersensitivity reactions. (See Chapter 8 for a description of infection and infectious organisms.)

Immunologic and Inflammatory Injury
Cellular membranes are injured by direct contact with cellular and chemical components of the immune and inflammatory responses, such as phagocytic cells (lymphocytes, macrophages) and substances such as histamine, antibodies, lymphokines, complement, and proteases (see Chapter 6). Complement is responsible for many of the membrane alterations that occur during immunologic injury.

Membrane alterations are associated with a rapid leakage of potassium ($K^+$) out of the cell and a rapid influx of water. Antibodies can interfere with membrane function by binding with and occupying receptor molecules on the plasma membrane. Antibodies also can block or destroy cellular junctions, interfering with intercellular communication. Other mechanisms of cellular injury are genetic and epigenetic factors, nutritional imbalances, and physical agents. These are summarized in Table 4-9.

Manifestations of Cellular Injury: Accumulations

An important manifestation of cell injury is the intracellular accumulation of abnormal amounts of various substances and the resultant metabolic disturbances. **Cellular accumulations**, also known as **infiltrations**, not only result from sublethal, sustained injury by cells, but also result from normal (but inefficient) cell function. Two categories of substances can produce accumulations: (1) a **normal cellular substance** (such as excess water, proteins, lipids, and carbohydrates) or (2) an **abnormal substance**, either endogenous (such as a product of abnormal metabolism or synthesis) or exogenous (such as infectious agents or a mineral). These products can accumulate transiently or permanently and can be toxic or harmless. Most accumulations are attributed to four types of mechanisms, all abnormal (Figure 4-23). Abnormal accumulations of these substances can occur in the cytoplasm (often in the lysosomes) or in the nucleus if (1) there is insufficient removal of the normal substance because of altered packaging and transport, for example, fatty change in the liver called **steatosis**; (2) an abnormal substance, often the result of a mutated gene, accumulates because of defects in protein folding, transport, or abnormal degradation; (3) an endogenous substance (normal or abnormal) is not effectively catabolized, usually because of lack of a vital lysosomal enzyme, called **storage diseases**; or (4) harmful exogenous materials, such as heavy metals, mineral dusts, or microorganisms, accumulate because of inhalation, ingestion, or infection.
1. Abnormal metabolism

Normal cell → Fatty liver

2. Protein mutation
   Defect in protein folding, transport
   X

Protein mutation → Accumulation of abnormal proteins

3. Lack of enzyme
   Complex substrate → Soluble products
   Enzyme

Complex substrate → Lack of enzyme

Lysosomal storage disease: accumulation of endogenous materials

4. Ingestion of indigestible materials

Ingestion of indigestible materials → Accumulation of exogenous materials
In all storage diseases, the cells attempt to digest, or catabolize, the “stored” substances. As a result, excessive amounts of metabolites (products of catabolism) accumulate in the cells and are expelled into the extracellular matrix, where they are consumed by phagocytic cells called *macrophages* (see Chapter 6). Some of these scavenger cells circulate throughout the body, whereas others remain fixed in certain tissues, such as the liver or spleen. As more and more macrophages and other phagocytes migrate to tissues that are producing excessive metabolites, the affected tissues begin to swell. This is the mechanism that causes enlargement of the liver (hepatomegaly) or the spleen (splenomegaly) as a clinical manifestation of many storage diseases.

### Water

**Cellular swelling**, the most common degenerative change, is caused by the shift of extracellular water into the cells. In hypoxic injury, movement of fluid and ions into the cell is associated with acute failure of metabolism and loss of ATP production. Normally, the pump that transports sodium ions ($Na^+$) out of the cell is maintained by the presence of ATP and adenosinetriphosphatase (ATPase), the active transport enzyme. In metabolic failure caused by hypoxia, reduced levels of ATP and ATPase permit sodium to accumulate in the cell while potassium ($K^+$) diffuses outward. The increased intracellular sodium concentration increases osmotic pressure, drawing more water into the cell. The cisternae of the ER become distended, rupture, and then unite to form large vacuoles that isolate the water from the cytoplasm, a process called *vacuolation*. Progressive vacuolation results in cytoplasmic swelling called *oncosis* (which has replaced the old term *hydropic [water] degeneration*) or *vacuolar degeneration* (Figure 4-24). If cellular swelling affects all the cells in an organ, the organ increases in weight and becomes distended and pale.
Cellular swelling is reversible and is considered sublethal. It is, in fact, an early manifestation of almost all types of cellular injury, including severe or lethal cell injury. It is also associated with high fever, hypokalemia (abnormally low concentrations of potassium in the blood; see Chapter 5), and certain infections.

**Lipids and Carbohydrates**

Certain metabolic disorders result in the abnormal intracellular accumulation of carbohydrates and lipids. These substances may accumulate throughout the body but are found primarily in the spleen, liver, and CNS. Accumulations in cells of the CNS can cause neurologic dysfunction and severe intellectual disability. Lipids accumulate in Tay-Sachs disease, Niemann-Pick disease, and Gaucher disease; whereas in the diseases known as mucopolysaccharidoses, carbohydrates are in excess. The mucopolysaccharidoses are progressive disorders that usually involve multiple organs, including liver, spleen, heart, and blood vessels. The accumulated mucopolysaccharides are found in reticuloendothelial cells, endothelial cells, intimal smooth muscle cells, and fibroblasts throughout the body. These carbohydrate accumulations can cause clouding of the cornea, joint stiffness, and intellectual disability.

Although lipids sometimes accumulate in heart, muscle, and kidney cells, the most common site of intracellular lipid accumulation, or fatty change (steatosis),
is liver cells (Figure 4-25). Because hepatic metabolism and secretion of lipids are crucial to proper body function, imbalances and deficiencies in these processes lead to major pathologic changes. In developed countries the most common cause of fatty change in the liver is alcohol abuse. Other causes of fatty change include diabetes mellitus, protein malnutrition, toxins, anoxia, and obesity. As lipids fill the cells, vacuolation pushes the nucleus and other organelles aside. The liver’s outward appearance is yellow and greasy. Alcohol abuse is one of the most common causes of fatty liver (see Chapter 36).

Lipid accumulation in liver cells occurs after cellular injury instigates one or more of the following mechanisms:

1. Increased movement of free fatty acids into the liver (starvation, for example, increases the metabolism of triglycerides in adipose tissue, releasing fatty acids that subsequently enter liver cells)

2. Failure of the metabolic process that converts fatty acids to phospholipids, resulting in the preferential conversion of fatty acids to triglycerides

3. Increased synthesis of triglycerides from fatty acids (increased levels of the enzyme α-glycerophosphatase can accelerate triglyceride synthesis)

4. Decreased synthesis of apoproteins (lipid-acceptor proteins)
5. Failure of lipids to bind with apoproteins and form lipoproteins

6. Failure of mechanisms that transport lipoproteins out of the cell

7. Direct damage to the ER by free radicals released by alcohol's toxic effects

Many pathologic states show accumulation of cholesterol and cholesterol esters. These states include atherosclerosis, in which atherosclerotic plaques, smooth muscle cells, and macrophages within the intimal layer of the aorta and large arteries are filled with lipid-rich vacuoles of cholesterol and cholesterol esters. Other states include cholesterol-rich deposits in the gallbladder and Niemann-Pick disease (type C), which involve genetic mutations of an enzyme affecting cholesterol transport.

**Glycogen**

Glycogen storage is important as a readily available energy source in the cytoplasm of normal cells. Intracellular accumulations of glycogen are seen in genetic disorders called *glycogen storage diseases* and in disorders of glucose and glycogen metabolism. As with water and lipid accumulation, glycogen accumulation results in excessive vacuolation of the cytoplasm. The most common cause of glycogen accumulation is the disorder of glucose metabolism (i.e., diabetes mellitus) (see Chapter 19).

**Proteins**

Proteins provide cellular structure and constitute most of the cell's dry weight. The proteins are synthesized on ribosomes in the cytoplasm from the essential amino acids lysine, threonine, leucine, isoleucine, methionine, tryptophan, valine, phenylalanine, and histidine. The accumulation of protein probably damages cells in two ways. First, metabolites, produced when the cell attempts to digest some proteins, are enzymes that when released from lysosomes can damage cellular organelles. Second, excessive amounts of protein in the cytoplasm push against cellular organelles, disrupting organelle function and intracellular communication.

Protein excess accumulates primarily in the epithelial cells of the renal convoluted tubules of the nephron unit and in the antibody-forming plasma cells (B lymphocytes) of the immune system. Several types of renal disorders cause excessive excretion of protein molecules in the urine (proteinuria). Normally, little or no protein is present in the urine, and its presence in significant amounts indicates cellular injury and altered cellular function.
Accumulations of protein in B lymphocytes can occur during active synthesis of antibodies during the immune response. The excess aggregates of protein are called *Russell bodies* (see Chapter 6). Russell bodies have been identified in multiple myeloma (plasma cell tumor) (see Chapter 21).

Mutations in protein can slow protein folding, resulting in the accumulation of partially folded intermediates. An example is $\alpha_1$-antitrypsin deficiency, which can cause emphysema. Certain types of cell injury are associated with the accumulation of cytoskeleton proteins. For example, the *neurofibrillary tangle* found in the brain in Alzheimer disease contains these types of proteins.

**Pigments**

Pigment accumulations may be normal or abnormal, endogenous (produced within the body) or exogenous (produced outside the body). Endogenous pigments are derived, for example, from amino acids (e.g., tyrosine, tryptophan). They include melanin and the blood proteins porphyrins, hemoglobin, and hemosiderin. Lipid-rich pigments, such as lipofuscin (the aging pigment), give a yellow-brown color to cells undergoing slow, regressive, and often atrophic changes. The most common exogenous pigment is carbon (coal dust), a pervasive air pollutant in urban areas. Inhaled carbon interacts with lung macrophages and is transported by lymphatic vessels to regional lymph nodes. This accumulation blackens lung tissues and involved lymph nodes. Other exogenous pigments include mineral dusts containing silica and iron particles, lead, silver salts, and dyes for tattoos.

**Melanin**

*Melanin* accumulates in epithelial cells (keratinocytes) of the skin and retina. It is an extremely important pigment because it protects the skin against long exposure to sunlight and is considered an essential factor in the prevention of skin cancer (see Chapters 11 and 41). Ultraviolet light (e.g., sunlight) stimulates the synthesis of melanin, which probably absorbs ultraviolet rays during subsequent exposure. Melanin also may protect the skin by trapping the injurious free radicals produced by the action of ultraviolet light on skin.

Melanin is a brown-black pigment derived from the amino acid *tyrosine*. It is synthesized by epidermal cells called *melanocytes* and is stored in membrane-bound cytoplasmic vesicles called *melanosomes*.

Melanin also can accumulate in melanophores (melanin-containing pigment cells), macrophages, or other phagocytic cells in the dermis. Presumably these cells acquire the melanin from nearby melanocytes or from pigment that has been
extruded from dying epidermal cells. This is the mechanism that causes freckles. Melanin also occurs in the benign form of pigmented moles called nevi (see Chapter 41). Malignant melanoma is a cancerous skin tumor that contains melanin.

A decrease in melanin production occurs in the inherited disorder of melanin metabolism called albinism. Albinism is often diffuse, involving all the skin, the eyes, and the hair. Albinism is also related to phenylalanine metabolism. In classic types, the person with albinism is unable to convert tyrosine to DOPA (3,4-dihydroxyphenylalanine), an intermediate in melanin biosynthesis. Melanocytes are present in normal numbers, but they are unable to make melanin. Individuals with albinism are very sensitive to sunlight and quickly become sunburned. They are also at high risk for skin cancer.

Hemoproteins

**Hemoproteins** are among the most essential of the normal endogenous pigments. They include hemoglobin and the oxidative enzymes, the cytochromes. Central to an understanding of disorders involving these pigments is knowledge of iron uptake, metabolism, excretion, and storage (see Chapter 20). Hemoprotein accumulations in cells are caused by excessive storage of iron, which is transferred to the cells from the bloodstream. Iron enters the blood from three primary sources: (1) tissue stores, (2) the intestinal mucosa, and (3) macrophages that remove and destroy dead or defective red blood cells. The amount of iron in blood plasma depends also on the metabolism of the major iron transport protein, transferrin.

Iron is stored in tissue cells in two forms: as ferritin and, when increased levels of iron are present, as hemosiderin. **Hemosiderin** is a yellow-brown pigment derived from hemoglobin. With pathologic states, excesses of iron cause hemosiderin to accumulate within cells, often in areas of bruising and hemorrhage and in the lungs and spleen after congestion caused by heart failure. With local hemorrhage, the skin first appears red-blue and then lysis of the escaped red blood cells occurs, causing the hemoglobin to be transformed to hemosiderin. The color changes noted in bruising reflect this transformation (Figure 4-26).
**Hemosiderosis** is a condition in which excess iron is stored as hemosiderin in the cells of many organs and tissues. This condition is common in individuals who have received repeated blood transfusions or prolonged parenteral administration of iron. Hemosiderosis is associated also with increased absorption of dietary iron, conditions in which iron storage and transport are impaired, and hemolytic anemia. Excessive alcohol (wine) ingestion also can lead to hemosiderosis. Normally, absorption of excessive dietary iron is prevented by an iron absorption process in the intestines. Failure of this process can lead to total body iron accumulations in the range of 60 to 80 g, compared with normal iron stores of 4.5 to 5 g. Excessive accumulations of iron, such as occur in hemochromatosis (a genetic disorder of iron metabolism and the most severe example of iron overload), are associated with liver and pancreatic cell damage.

**Bilirubin** is a normal, yellow-to-green pigment of bile derived from the porphyrin structure of hemoglobin. Excess bilirubin within cells and tissues causes jaundice (icterus), or yellowing of the skin. Jaundice occurs when the bilirubin level exceeds 1.5 to 2 mg/dl of plasma, compared with the normal values of 0.4 to 1 mg/dl. Hyperbilirubinemia occurs with (1) destruction of red blood cells (erythrocytes), such as in hemolytic jaundice; (2) diseases affecting the metabolism and excretion of bilirubin in the liver; and (3) diseases that cause obstruction of the common bile duct, such as gallstones or pancreatic tumors. Certain drugs (specifically chlorpromazine and other phenothiazine derivatives), estrogenic hormones, and halothane (an anesthetic) can cause the obstruction of normal bile flow through the liver.
Because unconjugated bilirubin is lipid soluble, it can injure the lipid components of the plasma membrane. Albumin, a plasma protein, provides significant protection by binding unconjugated bilirubin in plasma. Unconjugated bilirubin causes two cellular outcomes: uncoupling of oxidative phosphorylation and a loss of cellular proteins. These two changes could cause structural injury to the various membranes of the cell.

**Calcium**

Calcium salts accumulate in both injured and dead tissues (Figure 4-27). An important mechanism of cellular calcification is the influx of extracellular calcium in injured mitochondria. Another mechanism that causes calcium accumulation in alveoli (gas-exchange airways of the lungs), gastric epithelium, and renal tubules is the excretion of acid at these sites, leading to the local production of hydroxyl ions. Hydroxyl ions result in precipitation of calcium hydroxide, Ca(OH)$_2$, and hydroxyapatite, (Ca$_3$[PO$_4$]$_2$)$_3$•Ca(OH)$_2$, a mixed salt. Damage occurs when calcium salts cluster and harden, interfering with normal cellular structure and function.
Normally, calcium is removed from the cytosol by adenosine triphosphate (ATP)-dependent calcium pumps. In normal cells, calcium is bound to buffering proteins, such as calbindin or parvalbumin, and is contained in the endoplasmic reticulum and the mitochondria. If there is abnormal permeability of calcium-ion channels, direct damage to membranes, or depletion of ATP (i.e., hypoxic injury), calcium increases in the cytosol. If the free calcium cannot be buffered or pumped out of cells, uncontrolled enzyme activation takes place, causing further damage. Uncontrolled entry of calcium into the cytosol is an important final common pathway in many causes of cell death.

Pathologic calcification can be dystrophic or metastatic. Dystrophic calcification occurs in dying and dead tissues in areas of necrosis (see also the types of necrosis: coagulative, liquefactive, caseous, and fatty). It is present in chronic tuberculosis of the lungs and lymph nodes, advanced atherosclerosis (narrowing of the arteries as a result of plaque accumulation), and heart valve injury (Figure 4-28). Calcification of the heart valves interferes with their opening and closing, causing heart murmurs (see Chapter 24). Calcification of the coronary arteries predisposes them to severe narrowing and thrombosis, which can lead to myocardial infarction. Another site of dystrophic calcification is the center of tumors. Over time, the center is deprived of its oxygen supply, dies, and becomes calcified. The calcium salts appear as gritty, clumped granules that can become hard as stone. When several layers clump together, they resemble grains of sand and are called psammoma bodies.
Metastatic calcification consists of mineral deposits that occur in undamaged normal tissues as the result of hypercalcemia (excess calcium in the blood; see
Conditions that cause hypercalcemia include hyperparathyroidism, toxic levels of vitamin D, hyperthyroidism, idiopathic hypercalcemia of infancy, Addison disease (adrenocortical insufficiency), systemic sarcoidosis, milk-alkali syndrome, and the increased bone demineralization that results from bone tumors, leukemia, and disseminated cancers. Hypercalcemia also may occur in advanced renal failure with phosphate retention. As phosphate levels increase, the activity of the parathyroid gland increases, causing higher levels of circulating calcium.

Urate

In humans, uric acid (urate) is the major end product of purine catabolism because of the absence of the enzyme urate oxidase. Serum urate concentration is, in general, stable: approximately 5 mg/dl in postpubertal males and 4.1 mg/dl in postpubertal females. Disturbances in maintaining serum urate levels result in hyperuricemia and the deposition of sodium urate crystals in the tissues, leading to painful disorders collectively called gout. These disorders include acute arthritis, chronic gouty arthritis, tophi (firm, nodular, subcutaneous deposits of urate crystals surrounded by fibrosis), and nephritis (inflammation of the nephron). Chronic hyperuricemia results in the deposition of urate in tissues, cell injury, and inflammation. Because urate crystals are not degraded by lysosomal enzymes, they persist in dead cells.

Systemic Manifestations

Systemic manifestations of cellular injury include a general sense of fatigue and malaise, a loss of well-being, and altered appetite. Fever is often present because of biochemicals produced during the inflammatory response. Table 4-10 summarizes the most significant systemic manifestations of cellular injury.
### TABLE 4-10

The rapidity of enzyme transfer is a function of the weight of the enzyme and the concentration gradient across the cellular membrane. The specific metabolic and excretory rates of the enzymes determine how long levels of enzymes remain elevated.
Cellular Death

In response to significant external stimuli, cell injury becomes irreversible and cells are forced to die. Cell death has historically been classified as necrosis and apoptosis. Necrosis is characterized by rapid loss of the plasma membrane structure, swelling of organelles, dysfunction of the mitochondria, and lack of typical features of apoptosis. Apoptosis is known as a regulated or programmed cell process characterized by the “dropping off” of cellular fragments called apoptotic bodies. Too little or too much apoptosis is linked to many disorders, including neurodegenerative diseases, ischemic damage, autoimmune disorders, and cancers. Yet, apoptosis can have normal functions, and unlike necrosis it is not always linked with a pathologic process. Until recently, necrosis was only considered passive or accidental cell death occurring after severe and sudden injury. It is the main outcome in several common injuries including ischemia, toxin exposure, certain infections, and trauma. It has now been proposed that under certain conditions, such as activation of death proteases, necrosis may be regulated or programmed in a well-orchestrated way as a back-up for apoptosis (apoptosis may progress to necrosis)—hence the new term programmed necrosis, or necroptosis. Necroptosis shares traits with both necrosis and apoptosis. Although the identification of the signaling mechanisms for necroptosis is incomplete, necroptosis is recognized in both normal physiologic conditions and pathologic conditions, including bone growth plate disorders, cell death in fatty liver disease, acute pancreatitis, reperfusion injury, and certain neurodegenerative disorders, such as Parkinson disease.

Historically, programmed cell death only referred to apoptosis. Figure 4-29 illustrates the structural changes in cell injury resulting in necrosis or apoptosis. Table 4-11 compares the unique features of necrosis and apoptosis. Other forms of cell loss include autophagy (self-eating) (see p. 105).
**FIGURE 4-29** Schematic Illustration of the Morphologic Changes in Cell Injury Culminating in Necrosis or Apoptosis. Myelin figures come from degenerating cellular membranes and are noted within the cytoplasm or extracellularly. (From Kumar V et al, editors: *Robbins and Cotran pathologic basis of disease*, ed 9, Philadelphia, 2015, Elsevier.)

**Necrosis**
Cellular death eventually leads to cellular dissolution, or necrosis. **Necrosis** is the sum of cellular changes after local cell death and the process of cellular self-digestion, known as autodigestion or **autolysis** (see Figure 4-29). Cells die long before any necrotic changes are noted by light microscopy.\(^7^1\) The structural signs that indicate irreversible injury and progression to necrosis are dense clumping and progressive disruption both of genetic material and of plasma and organelle membranes. Because membrane integrity is lost, necrotic cell contents leak out and may cause the signaling of inflammation in surrounding tissue. In later stages of necrosis, most organelles are disrupted, and **karyolysis** (nuclear dissolution and lysis of chromatin from the action of hydrolytic enzymes) is under way. In some cells the nucleus shrinks and becomes a small, dense mass of genetic material (**pyknosis**). The pyknotic nucleus eventually dissolves (by karyolysis) as a result of the action of hydrolytic lysosomal enzymes on DNA. **Karyorrhexis** means fragmentation of the nucleus into smaller particles or “nuclear dust.”

Although necrosis still refers to death induced by nonspecific trauma or injury (e.g., cell stress or the heat shock response), with the very recent identification of molecular mechanisms regulating the process of necrosis, the study of necrosis has experienced a new twist. Unlike apoptosis, necrosis has been viewed as passive with cell death occurring in a disorganized and unregulated manner. Some molecular regulators governing programmed necrosis have been identified and demonstrated to be interconnected by a large network of signaling pathways.\(^7^1,7^3\) Emerging evidence shows that programmed necrosis is associated with pathologic diseases and provides innate immune response to viral infection.\(^7^1,7^3\)

Different types of necrosis tend to occur in different organs or tissues and sometimes can indicate the mechanism or cause of cellular injury. The four major types of necrosis are coagulative, liquefactive, caseous, and fatty. Another type, gangrenous necrosis, is *not* a distinctive type of cell death but refers instead to larger areas of tissue death. These necroses are summarized as follows:

1. **Coagulative necrosis.** Occurs primarily in the kidneys, heart, and adrenal glands; commonly results from hypoxia caused by severe ischemia or hypoxia caused by chemical injury, especially ingestion of mercuric chloride. Coagulation is a result of protein denaturation, which causes the protein albumin to change from a gelatinous, transparent state to a firm, opaque state (Figure 4-30, A). The area of coagulative necrosis is called an **infarct**.
2. **Liquefactive necrosis.** Commonly results from ischemic injury to neurons and glial cells in the brain (Figure 4-30, B). Dead brain tissue is readily affected by liquefactive necrosis because brain cells are rich in digestive hydrolytic enzymes and lipids and the brain contains little connective tissue. Cells are digested by their own hydrolases, so the tissue becomes soft, liquefies, and segregates from healthy tissue, forming cysts. This can be caused by bacterial infection, especially *Staphylococci, Streptococci,* and *Escherichia coli.*

3. **Caseous necrosis.** Usually results from tuberculous pulmonary infection, especially by *Mycobacterium tuberculosis* (Figure 4-30, C). It is a combination of coagulative and liquefactive necroses. The dead cells disintegrate, but the debris is not completely digested by the hydrolases. Tissues resemble clumped cheese in that they are soft and granular. A granulomatous inflammatory wall encloses areas of
caseous necrosis.

4. **Fatty necrosis.** Fat necrosis is cellular dissolution caused by powerful enzymes, called lipases, that occur in the breast, pancreas, and other abdominal structures (Figure 4-30, D). Lipases break down triglycerides, releasing free fatty acids that then combine with calcium, magnesium, and sodium ions, creating soaps (saponification). The necrotic tissue appears opaque and chalk-white.

5. **Gangrenous necrosis.** Refers to death of tissue but is not a specific pattern of cell death and results from severe hypoxic injury, commonly occurring because of arteriosclerosis, or blockage, of major arteries, particularly those in the lower leg (Figure 4-31). With hypoxia and subsequent bacterial invasion, the tissues can undergo necrosis. *Dry gangrene* is usually the result of coagulative necrosis. The skin becomes very dry and shrinks, resulting in wrinkles, and its color changes to dark brown or black. *Wet gangrene* develops when neutrophils invade the site, causing liquefactive necrosis. This usually occurs in internal organs, causing the site to become cold, swollen, and black. A foul odor is present, and if systemic symptoms become severe, death can ensue.

![Figure 4-31: Gangrene, a Complication of Necrosis.](image)

6. **Gas gangrene.** Refers to a special type of gangrene caused by infection of injured tissue by one of many species of *Clostridium*. These anaerobic bacteria produce hydrolytic enzymes and toxins that destroy connective tissue and cellular membranes and cause bubbles of gas to form in muscle cells. This can be fatal if enzymes lyse the membranes of red blood cells, destroying their oxygen-carrying capacity. Death is caused by shock.
Apoptosis

Apoptosis ("dropping off") is an important distinct type of cell death that differs from necrosis in several ways (see Figure 4-29 and Table 4-11). Apoptosis is an active process of cellular self-destruction called programmed cell death and is implicated in both normal and pathologic tissue changes. Cells need to die; otherwise, endless proliferation would lead to gigantic bodies. The average adult may create 10 billion new cells every day—and destroy the same number.\(^{74}\) Death by apoptosis causes loss of cells in many pathologic states including the following:

- **Severe cell injury.** When cell injury exceeds repair mechanisms, the cell triggers apoptosis. DNA damage can result either directly or indirectly from production of free radicals.

- **Accumulation of misfolded proteins.** This may result from genetic mutations or free radicals. Excessive accumulation of misfolded proteins in the ER leads to a condition known as **endoplasmic reticulum stress (ER stress)** (see Chapter 1). ER stress results in apoptotic cell death. This mechanism has been linked to several degenerative diseases of the CNS and other organs (Figure 4-32).

![Figure 4-32](https://example.com/figure.png)

**FIGURE 4-32** The Unfolded Protein Response, Endoplasmic Stress, and Apoptosis. A. In normal or healthy cells the newly made proteins are folded with help from chaperones and then incorporated into the cell or secreted. B. Various stressors can cause ER stress whereby the cell is challenged to cope with the increased load of misfolded proteins. The accumulation of the protein load initiates the unfolded protein response in the ER; if restoration of the protein fails, the cell dies by apoptosis. An example of a disease caused by misfolding of proteins is Alzheimer disease. (From Kumar V et al, editors: Robbins and Cotran pathologic basis of disease, ed 9, Philadelphia, 2015, Elsevier.)
• **Infections (particularly viral).** Apoptosis may be the result of the virus directly or indirectly by the host immune response. Cytotoxic T lymphocytes respond to viral infections by inducing apoptosis and, therefore, eliminating the infectious cells. This process can cause tissue damage and it is the same for cell death in tumors and rejection of tissue transplants.

• **Obstruction in tissue ducts.** In organs with duct obstruction, including the pancreas, kidney, and parotid gland, apoptosis causes pathologic atrophy.

   Excessive or insufficient apoptosis is known as dysregulated apoptosis. A low rate of apoptosis can permit the survival of abnormal cells, for example, mutated cells that can increase cancer risk. Defective apoptosis may not eliminate lymphocytes that react against host tissue (self-antigens), leading to autoimmune disorders. Excessive apoptosis is known to occur in several neurodegenerative diseases, from ischemic injury (such as myocardial infarction and stroke), and from death of virus-infected cells (such as seen in many viral infections).

   Apoptosis depends on a tightly regulated cellular program for its initiation and execution.\(^4\) This death program involves enzymes that divide other proteins—proteases, which are activated by proteolytic activity in response to signals that induce apoptosis. These proteases are called **caspases**, a family of aspartic acid–specific proteases. The activated suicide caspases cleave and, thereby, activate other members of the family, resulting in an amplifying “suicide” cascade. The activated caspases then cleave other key proteins in the cell, killing the cell quickly and neatly. The two different pathways that converge on caspase activation are called the **mitochondrial (intrinsic) pathway** and the **death receptor (extrinsic) pathway** (Figure 4-33). Cells that die by apoptosis release chemical factors that recruit phagocytes that quickly engulf the remains of the dead cell, thus reducing chances of inflammation. With necrosis, cell death is not tidy because cells that die as a result of acute injury swell, burst, and spill their contents all over their neighbors, causing a likely damaging inflammatory response.
Autophagy

The Greek term **autophagy** means “eating of self.” Autophagy, as a “recycling factory,” is a self-destructive process and a survival mechanism. Basically, autophagy involves the delivery of cytoplasmic contents to the lysosome for degradation. **Box 4-3** contains the terms used to describe autophagy.

**Box 4-3**
The Major Forms of Autophagy

Macroautophagy, the most common term to refer to autophagy, involves the sequestration and transportation of parts (cargo) of the cytosol in an autophagic vacuole (autophagosome).

Microautophagy is the inward invagination of the lysosomal membrane for cargo delivery.

Chaperone-mediated autophagy is the chaperone-dependent proteins that direct cargo across the lysosomal membrane.

When cells are starved or nutrient deprived, the autophagic process institutes cannibalization and recycles the digested contents. Autophagy can maintain cellular metabolism under starvation conditions and remove damaged organelles under stress conditions, improving the survival of cells. With the central role of autophagy in cell homeostasis, autophagy has been implicated in cancer, heart disease, neurodegeneration diseases, inflammation, and infection. Autophagy begins with a membrane, also known as a phagophore (although controversial) (Figure 4-34). This cup-shaped, curved phagophore expands and engulfs intracellular cargo—organelles, ribosomes, proteins—forming a double membrane autophagosome. The cargo-laden autophagosome fuses with the lysosome, now called an autophagolysosome, which promotes the degradation of the autophagosome by lysosomal acid proteases. The phagophore membrane is highly curved along the rim of the open cup, suggesting that mechanisms responsible for its formation and growth may depend on membrane curvature-dependent events. Lysosomal transporters export amino acids and other byproducts of degradation out of the cytoplasm where they can be reused for the synthesis of macromolecules and for metabolism. ATP is generated and cellular damage is reduced during autophagy that removes nonfunctional proteins and organelles.
Investigators are excited about the utilization of autophagy for therapeutic strategies. Autophagy is a critical garbage collecting and recycling process in healthy cells, and this process becomes less efficient and less discriminating as the cell ages. Consequently, harmful agents accumulate in cells, damaging cells and leading to aging: for example, failure to clear protein products in neurons of the CNS can cause dementia; failure to clear ROS-producing mitochondria can lead to nuclear DNA mutations and cancer. Thus these processes may even partially define aging. Therefore normal autophagy may potentially rejuvenate an organism and prevent cancer development as well as other degenerative diseases. In addition, autophagy may be the last immune defense against infectious microorganisms that penetrate intracellularly.

Quick Check 4-4

1. Why is an increase in the concentration of intracellular calcium injurious?
2. Compare and contrast necrosis and apoptosis.
3. Why is apoptosis significant?

4. Define autophagy.
Aging and Altered Cellular and Tissue Biology

The terms *aging* and *life span* tend to be used synonymously; however, they are not equivalent. **Aging** is usually defined as a normal physiologic process that is universal and inevitable, whereas **life span** is the time from birth to death and has been used to study the aging process.\(^8^2\) Aging is associated with a gradual loss of homeostatic mechanisms whose underlying cause is perplexing,\(^8^3\) and is a complex process because of a multiplicity of factors. Investigators are focused on genetic, epigenetic, inflammatory, oxidative stress, and metabolic origins of aging, including the study of genetic signatures in humans with exceptional longevity; the identification and recent discovery of epigenetic mechanisms that modulate gene expression; the role of intrauterine environment and lifelong patterns of health; the effects of personality, behavior, and social support; the influence of insulin/insulin-like growth factor 1 (IGF-1) signaling; and the contributions of cellular dysfunction and senescence to an inflammatory microenvironment that leads to chronic disease, frailty, and decreased life span. To focus more simply, the factors that may be most important for aging include increased damage to the cell, reduced capacity to divide (replicative senescence), reduced ability to repair damaged DNA, and increased likelihood of defective protein balance or homeostasis.\(^1\) A major challenge of aging research has been to separate the causes of cell and tissue aging from the vast changes that accompany it.\(^8^3\) Public health issues related to healthy aging require understanding of the nature of aging and the factors that predict healthy aging and delayed transition to increasing vulnerability and frailty.

**Aging** traditionally has not been considered a disease because it is “normal”; disease is usually considered “abnormal.” Conceptually, this distinction seems clear until the concept of “injury” or “damage” is introduced; disease has been defined by some pathologists as the result of injury. **Chronologic aging** has been defined as the time-dependent loss of structure and function that proceeds very slowly and in such small increments that it appears to be the result of the accumulation of small, imperceptible injuries—a gradual result of wear and tear. One of the hallmarks of aging is the accumulation of damaged macromolecules. DNA damage can lead to cellular dysfunction both directly and indirectly as a consequence of cellular responses to damage that can lead to altered gene expression.\(^8^4,8^5\) Age-related changes to macromolecules for long-lived cells, such as neurons and myofibers, lead to gradual loss of structure and function.

**Replicative aging** or **senescence** is the accumulation of cellular damage in continuously dividing cells, for example, epithelia of the skin or gastrointestinal
tract. One mechanism of replicative senescence is the progressive shortening of telomeres—the repeated sequences of DNA at the ends of chromosomes. Replicative aging and chronologic aging are particularly important for adult stem cells because they divide throughout life. As mutations increase with age, cell fates include apoptosis, malignant transformation, cell cycle arrest, or senescence.

Despite the fact that aging and death are inevitable, life span, on the other hand, can be experimentally changed. Genetic and environmental interventions have extended the life span of model organisms, such as the nematode worm Caenorhabditis elegans (C. elegans), the fruit fly Drosophila melanogaster, and mice. Extending life span, however, is not equivalent to delaying aging. For example, treatment of an acute infection can prevent death but the fundamental rate of aging continues. Yet, investigators will study and try to isolate, manipulate, and reset so-called longevity genes to slow the rate of aging.

Recent advances in stem cell biology have begun to reveal the molecular mechanisms behind reprogramming events that occur during fertilization and when the nucleus of a mature somatic cell is transferred to an enucleated oocyte. Called somatic cell nuclear transfer (SCNT), this process gave rise to the first cloned mammal, Dolly the sheep, and lead to the explosion of research in cloning. SCNT is important in terms of demonstrating the ability of the oocyte cytoplasm to reprogram the donor nucleus. These reprogramming events have led to the process to create induced pluripotent stem cells (iPSCs). The major emphasis of reprogramming research is the reversal of the differentiated program and attainment of a pluripotent state (differentiated cells in all three germ layers of the embryo) and not the reversal of aging. Nevertheless, each of these processes is discussed in the context of resetting the aging clock.

Restoration of youthfulness to aged cells and tissues has created so-called rejuvenating interventions. Experiments to test whether cells and tissues from an old animal can be restored to a younger self include the approach called heterochronic (i.e., young-to-old or old-to-young) transplantations and heterochronic parabiosis, when the systemic circulations of two animals are joined. The systemic environment may become more youthful with restoration of protein components in the blood and tissues, especially chemokines and cytokines. For example, investigators found a protein, GDF-11, may reverse age-associated cardiac hypertrophy when injected into old animals.

Administration of the drug rapamycin, an mTOR inhibitor, can extend the life span of mice. These and future studies may not just change differentiation programs of cells and tissue, but also possibly alter the aging clock. Observations in C. elegans suggest strongly that the causes of aging may be largely epigenetic.
Normal Life Span, Life Expectancy, and Quality-Adjusted Life Year

The maximal life span of humans is between 80 and 100 years and does not vary significantly among populations. Life expectancy is the average number of years of life remaining at a given age, however, it does not include quality of life. The quality-adjusted life year (QALY) is a measure of disease burden including quality and not just quantity of live lived. The Centers for Disease Control and Prevention reported in 2009 that the overall life expectancy at birth was 78.5 years. Between 2008 and 2009, life expectancy at birth increased for all groups reviewed. It increased for males, from 75.6 to 76.0 years, and females, 80.6 to 80.9 years; for the white population, 78.5 to 78.8 years; the black population, 74.0 to 74.5 years; the Hispanic population, 81.0 to 81.2 years; the non-Hispanic white population, 78.4 to 78.7 years; and the non-Hispanic black population, 73.7 to 74.0 years.\(^97\)

Degenerative Extracellular Changes

Extracellular factors that affect the aging process include the binding of collagen; the increase in the effects of free radicals on cells; the structural alterations of fascia, tendons, ligaments, bones, and joints; and the development of peripheral vascular disease, particularly arteriosclerosis (see Chapter 24).

Aging affects the extracellular matrix with increased cross-linking (e.g., aging collagen becomes more insoluble, chemically stable but rigid, resulting in decreased cell permeability), decreased synthesis, and increased degradation of collagen. The extracellular matrix determines the tissue's physical properties.\(^98\) These changes, together with the disappearance of elastin and changes in proteoglycans and plasma proteins, cause disorders of the ground substance that result in dehydration and wrinkling of the skin (see Chapter 41). Other age-related defects in the extracellular matrix include skeletal muscle alterations (e.g., atrophy, decreased tone, loss of contractility), cataracts, diverticula, hernias, and rupture of intervertebral disks.

Free radicals of oxygen that result from oxidative cellular metabolism, oxidative stress (e.g., respiratory chain, phagocytosis, prostaglandin synthesis), damage tissues during the aging process. The oxygen radicals produced include superoxide radical, hydroxyl radical, and hydrogen peroxide (see p. 81). These oxygen products are extremely reactive and can damage nucleic acids, destroy polysaccharides, oxidize proteins, peroxidize unsaturated fatty acids, and kill and lyse cells. Oxidant effects on target cells can lead to malignant transformation, presumably through DNA damage. That progressive and cumulative damage from
oxygen radicals may lead to harmful alterations in cellular function is consistent with those alterations of aging. This hypothesis is founded on the wear-and-tear theory of aging, which states that damages accumulate with time, decreasing the organism's ability to maintain a steady state. Because these oxygen-reactive species not only can permanently damage cells but also may lead to cell death, there is new support for their role in the aging process.

Of much interest is the relationship between aging and the disappearance or alteration of extracellular substances important for vessel integrity. With aging, lipid, calcium, and plasma proteins are deposited in vessel walls. These depositions cause serious basement membrane thickening and alterations in smooth muscle functioning, resulting in arteriosclerosis (a progressive disease that causes such problems as stroke, myocardial infarction, renal disease, and peripheral vascular disease).

**Cellular Aging**

Cellular changes characteristic of aging include atrophy, decreased function, and loss of cells, possibly caused by apoptosis (Figure 4-35). Loss of cellular function from any of these causes initiates the compensatory mechanisms of hypertrophy and hyperplasia of the remaining cells, which can lead to metaplasia, dysplasia, and neoplasia. All of these changes can alter receptor placement and function, nutrient pathways, secretion of cellular products, and neuroendocrine control mechanisms. In the aged cell, DNA, RNA, cellular proteins, and membranes are most susceptible to injurious stimuli. DNA is particularly vulnerable to such injuries as breaks, deletions, and additions. Lack of DNA repair increases the cell's susceptibility to mutations that may be lethal or may promote the development of neoplasia (see Chapter 10).
Mitochondria are the organelles responsible for the generation of most of the energy used by eukaryotic cells. **Mitochondrial DNA (mtDNA)** encodes some of the proteins of the electron-transfer chain, the system necessary for the conversion of adenosine diphosphate (ADP) to ATP. Mutations in mtDNA can deprive the cell of ATP, and mutations are correlated with the aging process. The accumulation of mutations could be caused by errors in replication or by unrepaired damage.\(^99,100\)

The most common age-related mtDNA mutation in humans is a large rearrangement called the 4977 deletion, or common deletion, and is found in humans older than 40 years. It is a deletion that removes all or part of 7 of the 13 protein-encoding mtDNA genes and 5 of the 22 tRNA genes. Individual cells containing this deletion have a condition known as heteroplasmy. Heteroplasmy levels rise with aging. Cumulative damage of mtDNA is implicated in the progression of such common diseases as diabetes, cancer, heart failure, and neurodegenerative
Tissue and Systemic Aging

It is probably safe to say that every physiologic process functions less efficiently with increasing age. The most characteristic tissue change with age is a progressive stiffness or rigidity that affects many systems, including the arterial, pulmonary, and musculoskeletal systems. A consequence of blood vessel and organ stiffness is a progressive increase in peripheral resistance to blood flow. The movement of intracellular and extracellular substances also decreases with age, as does the diffusion capacity of the lung. Blood flow through organs also decreases.

Changes in the endocrine and immune systems include thymus atrophy. Although this occurs at puberty, causing a decreased immune response to T-dependent antigens (foreign proteins), increased formation of autoantibodies and immune complexes (antibodies that are bound to antigens) and an overall decrease in the immunologic tolerance for the host's own cells further diminish the effectiveness of the immune system later in life. In women the reproductive system loses ova, and in men spermatogenesis decreases. Responsiveness to hormones decreases in the breast and endometrium.

The stomach experiences decreases in the rate of emptying and secretion of hormones and hydrochloric acid. Muscular atrophy diminishes mobility by decreasing motor tone and contractility. Sarcopenia, loss of muscle mass and strength, can occur into old age. The skin of the aged individual is affected by atrophy and wrinkling of the epidermis and by alterations in the underlying dermis, fat, and muscle.

Total body changes include a decrease in height; a reduction in circumference of the neck, thighs, and arms; widening of the pelvis; and lengthening of the nose and ears. Several of these changes are the result of tissue atrophy and of decreased bone mass caused by osteoporosis and osteoarthritis. Some body composition changes include an increase in body weight, which begins in middle age (men gain until 50 years of age and women until 70 years), and an increase fat mass followed by a decrease in stature, weight, fat-free mass, and body cell mass at older ages. Fat-free mass (FFM) includes all minerals, proteins, and water plus all other constituents except lipids. As the amount of fat increases, the percentage of total body water decreases. Increased body fat and centralized fat distribution (abdominal area) are associated with non–insulin-dependent diabetes and heart disease. Total body potassium concentration also decreases because of decreased cellular mass. An increased sodium/potassium ratio suggests that the decreased cellular mass is accompanied by an increased extracellular compartment.
Although some of these alterations are probably inherent in aging, others represent consequences of the process. Advanced age increases susceptibility to disease, and death occurs after an injury or insult because of diminished cellular, tissue, and organ function.

**Frailty**

*Frailty* is a common clinical syndrome in older adults, leaving a person vulnerable to falls, functional decline, disability, disease, and death. With an increasing aged population worldwide efforts to promote independence and decrease frailty are challenging and needed. Sarcopenia and cachexia are common as a consequence of aging and many acute and chronic illnesses.\(^{101}\) Investigators are grappling with a common nomenclature to develop consensus for definitions of sarcopenia and cachexia. One proposal has been to define it simply as “muscle wasting disease,” which can be applied in both acute and chronic settings.\(^{101}\) An acceptable vocabulary and classification system is yet to be developed.

The determinants of sarcopenia include environmental and genetic factors, which presently are poorly understood.\(^{102}\) Common themes of mechanisms for sarcopenia include the following: (1) decrease in the number of skeletal muscle fibers, mainly type II fibers; (2) decline in muscle protein synthesis with age; (3) decline in muscle fractions, such as myofibrillar and mitochondrial, with age; (4) reduction in protein turnover adversely affecting muscle function by inducing protein loss and protein accumulation; (5) loss of alpha motor neurons in the spinal column; (6) dysregulation of anabolic hormones; (7) cytokine productions and inflammation; (8) inadequate nutrition; and (9) sedentary history.\(^{102,103}\) For research and clinical purposes, the criteria indicating compromised energetics include low grip strength, slowed walking speed, low physical activity, and unintentional weight loss.\(^{104}\) The syndrome is complex and involves other alterations such as osteopenia, cognitive impairment, anemia, and gender differences.
Somatic Death

**Somatic death** is death of the entire person. Unlike the changes that follow cellular death in a live body, **postmortem change** is diffuse and does not involve components of the inflammatory response. Within minutes after death, postmortem changes appear, eliminating any difficulty in determining that death has occurred. The most notable manifestations are complete cessation of respiration and circulation. The surface of the skin usually becomes pale and yellowish; however, the lifelike color of the cheeks and lips may persist after death that is caused by carbon monoxide poisoning, drowning, or chloroform poisoning.\(^\text{105}\)

Body temperature falls gradually immediately after death and then more rapidly (approximately 1.0° to 1.5° F/hour) until, after 24 hours, body temperature equals that of the environment.\(^\text{106}\) After death caused by certain infective diseases, body temperature may continue to rise for a short time. Postmortem reduction of body temperature is called **alg"or mortis**.

Blood pressure within the retinal vessels decreases, causing muscle tension to decrease and the pupils to dilate. The face, nose, and chin become sharp or peaked-looking as blood and fluids drain from these areas.\(^\text{105}\) Gravity causes blood to settle in the most dependent, or lowest, tissues, which develop a purple discoloration called **livor mortis**. Incisions made at this time usually fail to cause bleeding. The skin loses its elasticity and transparency.

Within 6 hours after death, acidic compounds accumulate within the muscles because of the breakdown of carbohydrates and the depletion of ATP. This interferes with ATP-dependent detachment of myosin from actin (contractile proteins), and muscle stiffening, or **rigor mortis**, develops. The smaller muscles are usually affected first, particularly the muscles of the jaw. Within 12 to 14 hours, rigor mortis usually affects the entire body.

Signs of putrefaction are generally obvious about 24 to 48 hours after death. Rigor mortis gradually diminishes, and the body becomes flaccid at 36 to 62 hours. Putrefactive changes vary depending on the temperature of the environment. The most visible is greenish discoloration of the skin, particularly on the abdomen. The discoloration is thought to be related to the diffusion of hemolyzed blood into the tissues and the production of sulfhemoglobin, choleglobin, and other denatured hemoglobin derivatives.\(^\text{106,107}\) Slippage or loosening of the skin from underlying tissues occurs at the same time. After this, swelling or bloating of the body and liquefactive changes occur, sometimes causing opening of the body cavities. At a microscopic level, putrefactive changes are associated with the release of enzymes and lytic dissolution called **postmortem autolysis**.
1. Aging is a complex process, discuss the multitude of mechanisms of aging.

2. What are the body composition changes that occur with aging?

3. Define frailty and possible endocrine-immune system involvement.
Did You Understand?

Cellular Adaptation

1. Cellular adaptation is a reversible, structural, or functional response both to normal or physiologic conditions and to adverse or pathologic conditions. Cells can adapt to physiologic demands or stress to maintain a steady state called homeostasis.

2. The most significant adaptive changes include atrophy, hypertrophy, hyperplasia, and metaplasia.

3. Atrophy is a decrease in cellular size caused by aging, disuse, or reduced/absent blood supply, hormonal stimulation, or neural stimulation. The amounts of ER, mitochondria, and microfilaments decrease. The mechanisms of atrophy probably include decreased protein synthesis, increased protein catabolism, or both. A new hypothesis called ribosome biogenesis involves the role of mRNA and protein translation.

4. Hypertrophy is an increase in the size of cells in response to mechanical stimuli and consequently increases the size of the affected organ. The amounts of protein in the plasma membrane, ER, microfilaments, and mitochondria increase. Hypertrophy can be classified as physiologic or pathologic.

5. Hyperplasia is an increase in the number of cells caused by an increased rate of cellular division. Hyperplasia is classified as physiologic (compensatory and hormonal) and pathologic.

6. Metaplasia is the reversible replacement of one mature cell type by another less mature cell type.

7. Dysplasia, or atypical hyperplasia, is an abnormal change in the size, shape, and organization of mature tissue cells. It is considered atypical rather than a true adaptational change.

Cellular Injury

1. Injury to cells and to the extracellular matrix (ECM) leads to injury of tissues and organs and ultimately determining the structural patterns of disease. Cellular injury
occurs if the cell is unable to maintain homeostasis—a normal or adaptive steady state—in the face of injurious stimuli or stress. Injured cells may recover (reversible injury) or die (irreversible injury).

2. Injury is caused by lack of oxygen (hypoxia), free radicals, caustic or toxic chemicals, infectious agents, inflammatory and immune responses, genetic factors, insufficient nutrients, or physical and mechanical trauma from many causes.

3. Four biochemical themes are important to cell injury: (1) ATP depletion, resulting in mitochondrial damage; (2) accumulation of oxygen and oxygen-derived free radicals, causing membrane damage; (3) protein folding defects; and (4) increased intracellular calcium concentration and loss of calcium steady state.

4. The sequence of events leading to cell death is commonly decreased ATP production, failure of active transport mechanisms (the sodium-potassium pump), cellular swelling, detachment of ribosomes from the ER, cessation of protein synthesis, mitochondrial swelling as a result of calcium accumulation, vacuolation, leakage of digestive enzymes from lysosomes, autodigestion of intracellular structures, lysis of the plasma membrane, and death.

5. The initial insult in hypoxic injury is usually ischemia (the cessation of blood flow into vessels that supply the cell with oxygen and nutrients).

6. Free radicals cause cellular injury because they have an unpaired electron that makes the molecule unstable. To stabilize itself, the molecule either donates or accepts an electron from another molecule. Therefore it forms injurious chemical bonds with proteins, lipids, and carbohydrates—key molecules in membranes and nucleic acids.

7. The damaging effects of free radicals, especially activated oxygen species such as $\mathrm{O}_2^\cdot$, $\mathrm{OH}^\cdot$, and $\mathrm{H}_2\mathrm{O}_2$, called oxidative stress, include (1) peroxidation of lipids, (2) alteration of ion pumps and transport mechanisms, (3) fragmentation of DNA, and (4) damage to mitochondria, releasing calcium into the cytosol.

8. Restoration of oxygen, however, can cause additional injury, called reperfusion injury. The mechanisms discussed for reperfusion-injury include oxidative stress, increased intracellular calcium concentration, inflammation, and complement activation.

9. Humans are exposed to thousands of chemicals that have inadequate toxicologic
data. A systems biology approach is now being used to investigate toxicity pathways that include oxidative stress, heat shock proteins, DNA damage response, hypoxia, ER stress, mental stress, inflammation, and osmotic stress.

10. Unintentional and intentional injuries are an important health problem in the United States. Death as a result of these injuries is more common for men than women and higher among blacks than whites and other racial groups.

11. Injuries by blunt force are the result of the application of mechanical energy to the body, resulting in tearing, shearing, or crushing of tissues. The most common types of blunt-force injuries include motor vehicle accidents and falls.

12. A contusion is bleeding into the skin or underlying tissues as a consequence of a blow. A collection of blood in soft tissues or an enclosed space may be referred to as a hematoma.

13. An abrasion (scrape) results from removal of the superficial layers of the skin caused by friction between the skin and injuring object. Abrasions and contusions may have a patterned appearance that mirrors the shape and features of the injuring object.

14. A laceration is a tear or rip resulting when the tensile strength of the skin or tissue is exceeded.

15. An incised wound is a cut that is longer than it is deep. A stab wound is a penetrating sharp-force injury that is deeper than it is long.

16. Gunshot wounds may be either penetrating (bullet retained in the body) or perforating (bullet exits the body). The most important factors determining the appearance of a gunshot injury are whether it is an entrance or an exit wound and the range of fire.

17. Asphyxial injuries are caused by a failure of cells to receive or utilize oxygen. These injuries can be grouped into four general categories: suffocation, strangulation, chemical, and drowning.

18. Activation of inflammation and immunity, which occurs after cellular injury or infection, involves powerful biochemicals and proteins capable of damaging normal (uninjured and uninfected) cells.
19. Genetic disorders injure cells by altering the nucleus and the plasma membrane's structure, shape, receptors, or transport mechanisms.

20. Deprivation of essential nutrients (proteins, carbohydrates, lipids, vitamins) can cause cellular injury by altering cellular structure and function, particularly of transport mechanisms, chromosomes, the nucleus, and DNA.

21. Injurious physical agents include temperature extremes, changes in atmospheric pressure, ionizing radiation, illumination, mechanical stresses, and noise.

22. Errors in health care are a leading cause of injury or death in the United States. Errors involve medicines, surgery, diagnosis, equipment, and laboratory reports. They can occur anywhere in the healthcare system including hospitals, clinics, outpatient surgery centers, physicians' and nurse practitioners' offices, pharmacies, and the individual's home.

**Manifestations of Cellular Injury**

1. An important manifestation of cell injury is the resultant metabolic disturbances of intracellular accumulation (infiltration) of abnormal amounts of various substances. Two categories of accumulations are (1) normal cellular substances, such as water, proteins, lipids, and carbohydrate excesses; and (2) abnormal substances, either endogenous (e.g., from abnormal metabolism) or exogenous (e.g., a virus).

2. Most accumulations are attributed to four types of mechanisms, all abnormal: (1) An endogenous substance is produced in excess or at an increased rate; (2) an abnormal substance, often the result of a mutated gene, accumulates; (3) an endogenous substance is not effectively catabolized; and (4) a harmful exogenous substance accumulates because of inhalation, ingestion, or infection.

3. Accumulations harm cells by “crowding” the organelles and by causing excessive (and sometimes harmful) metabolites to be produced during their catabolism. The metabolites are released into the cytoplasm or expelled into the extracellular matrix.

4. Cellular swelling, the accumulation of excessive water in the cell, is caused by the failure of transport mechanisms and is a sign of many types of cellular injury. Oncosis is a type of cellular death resulting from cellular swelling.

5. Accumulations of organic substances—lipids, carbohydrates, glycogen, proteins,
pigments—are caused by disorders in which (1) cellular uptake of the substance exceeds the cell's capacity to catabolize (digest) or use it or (2) cellular anabolism (synthesis) of the substance exceeds the cell's capacity to use or secrete it.

6. Dystrophic calcification (accumulation of calcium salts) is always a sign of pathologic change because it occurs only in injured or dead cells. Metastatic calcification, however, can occur in uninjured cells in individuals with hypercalcemia.

7. Disturbances in urate metabolism can result in hyperuricemia and deposition of sodium urate crystals in tissue—leading to a painful disorder called gout.

8. Systemic manifestations of cellular injury include fever, leukocytosis, increased heart rate, pain, and serum elevations of enzymes in the plasma.

**Cellular Death**

1. Cellular death has historically been classified as necrosis and apoptosis. Necrosis is characterized by rapid loss of the plasma membrane structure, organelle swelling, mitochondrial dysfunction, and the lack of features of apoptosis. Apoptosis is known as regulated or programmed cell death and is characterized by “dropping off” of cellular fragments, called apoptotic bodies. It is now understood that under certain conditions necrosis is regulated or programmed, hence the new term *programmed necrosis*, or necroptosis.

2. There are four major types of necrosis: coagulative, liquefactive, caseous, and fatty. Different types of necrosis occur in different tissues.

3. Structural signs that indicate irreversible injury and progression to necrosis are the dense clumping and disruption of genetic material and the disruption of the plasma and organelle membranes.

4. Apoptosis, a distinct type of sublethal injury, is a process of selective cellular self-destruction that occurs in both normal and pathologic tissue changes.

5. Death by apoptosis causes loss of cells in many pathologic states including (1) severe cell injury, (2) accumulation of misfolded proteins, (3) infections, and (4) obstruction in tissue ducts.

6. Excessive accumulation of misfolded proteins in the ER leads to a condition
known as endoplasmic reticulum stress. ER stress results in apoptotic cell death and this mechanism has been linked to several degenerative diseases of the CNS and other organs.

7. Excessive or insufficient apoptosis is known as dysregulated apoptosis.

8. Autophagy means “eating of self,” and as a recycling factory it is a self-destructive process and a survival mechanism. When cells are starved or nutrient deprived, the autophagic process institutes cannibalization and recycles the digested contents. Autophagy can maintain cellular metabolism under starvation conditions and remove damaged organelles under stress conditions, improving the survival of cells. Autophagy declines and becomes less efficient as the cell ages, thus contributing to the aging process.

9. Gangrenous necrosis, or gangrene, is tissue necrosis caused by hypoxia and the subsequent bacterial invasion.

**Aging and Altered Cellular and Tissue Biology**

1. It is difficult to determine the physiologic (normal) from the pathologic changes of aging. Investigators are focused on genetic, epigenetic, inflammatory, oxidative stress, and metabolic origins of aging.

2. Important factors in aging include increased damage to the cell, reduced capacity to divide, reduced ability to repair damaged DNA, and increased likelihood of defective protein balance or homeostasis.

3. Frailty is a common clinical syndrome in older adults, leaving a person vulnerable to falls, functional decline, disability, disease, and death. Sarcopenia and cachexia are common as a consequence of aging.

**Somatic Death**

1. Somatic death is death of the entire organism. Postmortem change is diffuse and does not involve the inflammatory response.

2. Manifestations of somatic death include cessation of respiration and circulation, gradual lowering of body temperature, dilation of the pupils, loss of elasticity and transparency in the skin, stiffening of the muscles (rigor mortis), and discoloration
of the skin (livor mortis). Signs of putrefaction are obvious about 24 to 48 hours after death.

The cells of the body live in a fluid environment with electrolyte and acid-base concentrations maintained within a narrow range. Changes in electrolyte concentration affect the electrical activity of nerve and muscle cells and cause shifts of fluid from one compartment to another. Alterations in acid-base balance disrupt cellular functions. Fluid fluctuations also affect blood volume and cellular function. Disturbances in these functions are common and can be life-threatening. Understanding how alterations occur and how the body compensates or corrects the disturbance is important for comprehending many pathophysiologic conditions.
Distribution of Body Fluids and Electrolytes

The sum of fluids within all body compartments constitutes total body water (TBW)—about 60% of body weight in adults (Table 5-1). The volume of TBW is usually expressed as a percentage of body weight in kilograms. One liter of water weighs 2.2 lb (1 kg). The rest of the body weight is composed of fat and fat-free solids, particularly bone.

*NOTE: Total body water is a percentage of body weight.

Body fluids are distributed among functional compartments, or spaces, and provide a transport medium for cellular and tissue function. Intracellular fluid (ICF) comprises all the fluid within cells, about two thirds of TBW. Extracellular fluid (ECF) is all the fluid outside the cells (about one third of TBW) and includes the interstitial fluid (the space between cells and outside the blood vessels) and the intravascular fluid (blood plasma) (Table 5-2). The total volume of body water for a 70-kg person is about 42 liters. Other ECF compartments include lymph and transcellular fluids, such as synovial, intestinal, and cerebrospinal fluid; sweat; urine; and pleural, peritoneal, pericardial, and intraocular fluids.

Electrolytes and other solutes are distributed throughout the intracellular and extracellular fluid (Table 5-3). Note that the extracellular fluid contains a large amount of sodium and chloride and a small amount of potassium, whereas the opposite is true of the intracellular fluid. The concentrations of phosphates and magnesium are greater in the intracellular fluid and the concentration of calcium is greater in the extracellular fluid. These differences are important for the
maintenance of electroneutrality between the extracellular and intracellular compartments, the transmission of electrical impulses, and the movement of water among body compartments (see Chapter 1).

ECF, Extracellular fluid; ICF, intracellular fluid.

Although the amount of fluid within the various compartments is relatively constant, solutes (e.g., salts) and water are exchanged between compartments to maintain their unique compositions. The percentage of TBW varies with the amount of body fat and age. Because fat is water repelling (hydrophobic), very little water is contained in adipose (fat) cells. Individuals with more body fat have proportionately less TBW and tend to be more susceptible to dehydration.

The distribution and the amount of TBW change with age (see the Pediatric Considerations and Geriatric Considerations boxes), and although daily fluid intake may fluctuate widely, the body regulates water volume within a relatively narrow range. Water obtained by drinking, water ingested in food, and water derived from oxidative metabolism are the primary sources of body water. Normally, the largest amounts of water are lost through renal excretion, with lesser amounts lost through the stool and vaporization from the skin and lungs (insensible water loss) (Table 5-4).

Water Movement Between Plasma and Interstitial Fluid

The distribution of water and the movement of nutrients and waste products between the capillary and interstitial spaces occur as a result of changes in hydrostatic pressure (pushes water) and osmotic/oncotic pressure (pulls water) at the arterial and venous ends of the capillary (see Figure 1-24). Water, sodium, and glucose readily move across the capillary membrane. The plasma proteins normally do not cross the capillary membrane and maintain effective osmolality by generating plasma oncotic pressure (particularly albumin).

As plasma flows from the arterial to the venous end of the capillary, four forces determine if fluid moves out of the capillary and into the interstitial space (filtration) or if fluid moves back into the capillary from the interstitial space (reabsorption). These forces acting together are described as net filtration or Starling forces:

1. **Capillary hydrostatic pressure (blood pressure)** facilitates the outward movement of water from the capillary to the interstitial space.

2. **Capillary (plasma) oncotic pressure** osmotically attracts water from the interstitial space back into the capillary.

3. **Interstitial hydrostatic pressure** facilitates the inward movement of water from the interstitial space into the capillary.

4. **Interstitial oncotic pressure** osmotically attracts water from the capillary into the interstitial space.

The forces moving fluid back and forth across the capillary wall are summarized below:
Net filtration = \((\text{Forces favoring filtration}) - (\text{Forces opposing filtration})\)

Forces favoring filtration = Capillary hydrostatic pressure and interstitial oncotic pressure

Forces opposing filtration = Capillary oncotic pressure and interstitial hydrostatic pressure

At the arterial end of the capillary, hydrostatic pressure exceeds capillary oncotic pressure and fluid moves into the interstitial space (filtration). At the venous end of the capillary, capillary oncotic pressure exceeds capillary hydrostatic pressure and fluids are attracted back into the circulation (reabsorption). Interstitial hydrostatic pressure promotes the movement of about 10% of the interstitial fluid along with small amounts of protein into the lymphatics, which then returns to the circulation. Because albumin does not normally cross the capillary membrane, interstitial oncotic pressure is normally minimal. Figure 5-1 illustrates net filtration.
FIGURE 5-1  Net Filtration—Fluid Movement between Plasma and Interstitial Space. The movement of fluid between the vascular, interstitial spaces and the lymphatics is the result of net filtration of fluid across the semipermeable capillary membrane. Capillary hydrostatic pressure is the primary force for fluid movement out of the arteriolar end of the capillary and into the interstitial space. At the venous end, capillary oncotic pressure (from plasma proteins) attracts water back into the vascular space. Interstitial hydrostatic pressure promotes the movement of fluid and proteins into the lymphatics. Osmotic pressure accounts for the movement of fluid between the interstitial space and the intracellular space. Normally, intracellular and extracellular fluid osmotic pressures are equal (280 to 294 mOsm) and water is equally distributed between the interstitial and intracellular compartments.

Water Movement Between ICF and ECF

Water moves between ICF and ECF compartments primarily as a function of osmotic forces (see Chapter 1 for definitions). Water moves freely by diffusion
through the lipid bilayer cell membrane and through **aquaporins**, a family of water channel proteins that provide permeability to water.\(^1\) Sodium is responsible for the ECF osmotic balance, and potassium maintains the ICF osmotic balance. The osmotic force of ICF proteins and other nondiffusible substances is balanced by the active transport of ions out of the cell. Water crosses cell membranes freely, so the osmolality of TBW is normally at equilibrium. Normally the ICF is not subject to rapid changes in osmolality, but when ECF osmolality changes, water moves from one compartment to another until osmotic equilibrium is reestablished (see Figure 5-7, p. 120).
Alterations in Water Movement

Edema

Edema is excessive accumulation of fluid within the interstitial spaces. The forces favoring fluid movement from the capillaries or lymphatic channels into the tissues are increased capillary hydrostatic pressure, decreased plasma oncotic pressure, increased capillary membrane permeability, and lymphatic channel obstruction (Figure 5-2).

Pathophysiology

Capillary hydrostatic pressure increases as a result of venous obstruction or salt and water retention. Venous obstruction causes hydrostatic pressure to increase behind the obstruction, pushing fluid from the capillaries into the interstitial spaces. Thrombophlebitis (inflammation of veins), hepatic obstruction, tight clothing around the extremities, and prolonged standing are common causes of venous obstruction. Congestive heart failure, renal failure, and cirrhosis of the liver are associated with excessive salt and water retention, which cause plasma volume
overload, increased capillary hydrostatic pressure, and edema.

Since plasma albumin acts like a magnet to attract water, the loss or diminished production (e.g., from liver disease or protein malnutrition) contributes to decreased plasma oncotic pressure. Plasma proteins are lost in glomerular diseases of the kidney, serous drainage from open wounds, hemorrhage, burns, and cirrhosis of the liver. The decreased oncotic attraction of fluid within the capillary causes filtered capillary fluid to remain in the interstitial space, resulting in edema.

Capillaries become more permeable with inflammation and immune responses, especially with trauma such as burns or crushing injuries, neoplastic disease, and allergic reactions. Proteins escape from the vascular space and produce edema through decreased capillary oncotic pressure and interstitial fluid protein accumulation.

The lymphatic system normally absorbs interstitial fluid and a small amount of proteins. When lymphatic channels are blocked or surgically removed, proteins and fluid accumulate in the interstitial space, causing lymphedema. For example, lymphedema of the arm or leg occurs after surgical removal of axillary or femoral lymph nodes, respectively, for treatment of carcinoma. Inflammation or tumors may cause lymphatic obstruction, leading to edema of the involved tissues.

**Clinical manifestations**

Edema may be localized or generalized. *Localized edema* is usually limited to a site of trauma, as in a sprained finger. Another kind of localized edema occurs within particular organ systems and includes cerebral, pulmonary, and laryngeal edema; pleural effusion (fluid accumulation in the pleural space); pericardial effusion (fluid accumulation within the membrane around the heart); and ascites (accumulation of fluid in the peritoneal space). Edema of specific organs, such as the brain, lung, or larynx, can be life-threatening. *Generalized edema* is manifested by a more uniform distribution of fluid in interstitial spaces. Dependent edema, in which fluid accumulates in gravity-dependent areas of the body, might signal more generalized edema. Dependent edema appears in the feet and legs when standing and in the sacral area and buttocks when supine (lying on back). It can be identified by pressing on tissues overlying bony prominences. A pit left in the skin indicates edema (hence the term *pitting edema*) (Figure 5-3).
Edema usually is associated with weight gain, swelling and puffiness, tight-fitting clothes and shoes, limited movement of affected joints, and symptoms associated with the underlying pathologic condition. Fluid accumulations increase the distance required for nutrients and waste products to move between capillaries and tissues. Blood flow may be impaired also. Therefore wounds heal more slowly, and with prolonged edema the risks of infection and pressure sores over bony prominences increase. As edematous fluid accumulates, it is trapped in a “third space” (i.e., the interstitial space, pleural space, pericardial space) and is unavailable for metabolic processes or perfusion. Dehydration can develop as a result of this sequestering. Such sequestration occurs with severe burns, where large amounts of vascular fluid are lost to the interstitial spaces, reducing plasma volume and causing shock (see Chapter 24).

**Evaluation and treatment**

Specific conditions causing edema require diagnosis. Edema may be treated symptomatically until the underlying disorder is corrected. Supportive measures include elevating edematous limbs, using compression stockings, avoiding prolonged standing, restricting salt intake, and taking diuretics. Administration of
IV albumin can be required in severe cases.

**Quick Check 5-1**

1. How does an increase in capillary hydrostatic pressure cause edema?
2. How does a decrease in capillary oncotic pressure cause edema?
Sodium, Chloride, and Water Balance

The kidneys and hormones have a central role in maintaining sodium and water balance. Because water follows the osmotic gradients established by changes in salt concentration, sodium concentration and water balance are intimately related. Sodium concentration is regulated by renal effects of aldosterone (see Figure 18-18). Water balance is regulated primarily by antidiuretic hormone (ADH; also known as vasopressin).

Sodium (Na\(^+\)) accounts for 90% of the ECF cations (positively charged ions) (see Table 5-3). Along with its constituent anions (negatively charged ions) chloride and bicarbonate, sodium regulates extracellular osmotic forces and therefore regulates water balance. Sodium is important in other functions, including maintenance of neuromuscular irritability for conduction of nerve impulses (in conjunction with potassium and calcium; see Figure 1-29), regulation of acid-base balance (using sodium bicarbonate and sodium phosphate), participation in cellular chemical reactions, and transport of substances across the cellular membrane.

The kidney, in conjunction with neural and hormonal mediators, maintains normal serum sodium concentration within a narrow range (135 to 145 mEq/L) primarily through renal tubular reabsorption. Hormonal regulation of sodium (and potassium) balance is mediated by aldosterone, a mineralocorticoid synthesized and secreted from the adrenal cortex as a component of the renin-angiotensin-aldosterone system. Aldosterone secretion is influenced by circulating blood volume, by blood pressure, and by plasma concentrations of sodium and potassium. When circulating blood volume or blood pressure is reduced, or sodium levels are depressed or potassium levels are increased, renin, an enzyme secreted by the juxtaglomerular cells of the kidney, is released. Renin stimulates the formation of angiotensin I, an inactive polypeptide. Angiotensin-converting enzyme (ACE) in pulmonary vessels converts angiotensin I to angiotensin II, which stimulates the secretion of aldosterone and antidiuretic hormone (see below) and also causes vasoconstriction. The aldosterone promotes renal sodium and water reabsorption and excretion of potassium, increasing blood volume (Figure 5-4; also see Figure 29-9). Vasoconstriction elevates the systemic blood pressure and restores renal perfusion (blood flow). This restoration inhibits the further release of renin.
Natriuretic peptides are hormones primarily produced by the myocardium. Atrial natriuretic hormone (ANH) is produced by the atria. B-type natriuretic peptide (BNP) is produced by the ventricles. Urodilatin (an ANP analog) is synthesized within the kidney. Natriuretic peptides are released when there is an increase in transmural atrial pressure (increased volume), which may occur with congestive heart failure or when there is an increase in mean arterial pressure (Figure 5-5). They are natural antagonists to the renin-angiotensin-aldosterone system. Natriuretic peptides cause vasodilation and increase sodium and water excretion, decreasing blood pressure. Natriuretic peptides are sometimes called a “third factor” in sodium regulation. (Increased glomerular filtration rate is thus the first factor and aldosterone the second factor.)

**Chloride** ($\text{Cl}^-$) is the major anion in the ECF and provides electroneutrality, particularly in relation to sodium. Chloride transport is generally passive and follows the active transport of sodium so that increases or decreases in chloride concentration are proportional to changes in sodium concentration. Chloride
concentration tends to vary inversely with changes in the concentration of bicarbonate \((\text{HCO}_3^-)\), the other major anion.

**Water balance** is regulated by the secretion of ADH (also known as vasopressin). ADH is secreted when plasma osmolality increases or circulating blood volume decreases and blood pressure drops (Figure 5-6). Increased plasma osmolality occurs with water deficit or sodium excess in relation to total body water. The increased osmolality stimulates hypothalamic osmoreceptors. In addition to causing thirst, these osmoreceptors signal the posterior pituitary gland to release ADH. Thirst stimulates water drinking and ADH increases water reabsorption into the plasma from the distal tubules and collecting ducts of the kidney (see Chapter 29). The reabsorbed water decreases plasma osmolality, returning it toward normal, and urine concentration increases.
With fluid loss (dehydration) from vomiting, diarrhea, or excessive sweating, a decrease in blood volume and blood pressure often occurs. **Volume-sensitive receptors** and **baroreceptors** (nerve endings that are sensitive to changes in volume and pressure) also stimulate the release of ADH from the pituitary gland and stimulate thirst. The volume receptors are located in the right and left atria and thoracic vessels; baroreceptors are found in the aorta, pulmonary arteries, and carotid sinus. ADH secretion also occurs when atrial pressure drops, as occurs with decreased blood volume and with the release of angiotensin II (see Figure 29-9). The reabsorption of water mediated by ADH then promotes the restoration of plasma volume and blood pressure (see Figure 5-6).

2. How do hormones regulate salt and water balance?
3. What are aquaporins?
Alterations in Sodium, Chloride, and Water Balance

Alterations in sodium and water balance are closely related. Sodium imbalances occur with gains or losses of body water. Water imbalances develop with gains or losses of salt. In general, these alterations can be classified as changes in tonicity, the change in the concentration of solutes in relation to water: isotonic, hypertonic, or hypotonic (Table 5-5 and Figure 5-7; also see Figure 1-25). Changes in tonicity also alter the volume of water in the intracellular and extracellular compartments, resulting in isovolemia, hypervolemia, or hypovolemia.

Isotonic Alterations

Isotonic alterations are the most common and occur when TBW changes are accompanied by proportional changes in the concentrations of electrolytes (see Figure 5-7). Isotonic fluid loss causes dehydration and hypovolemia. For example, if an individual loses pure plasma or ECF, fluid volume is depleted but the concentration and type of electrolytes and the osmolality remain in the normal range (280 to 294 milliosmoles [mOsm]). Causes include hemorrhage, severe
wound drainage, excessive diaphoresis (sweating), and inadequate fluid intake. There is loss of extracellular fluid volume with weight loss, dryness of skin and mucous membranes, decreased urine output, and symptoms of hypovolemia. Indicators of hypovolemia include a rapid heart rate, flattened neck veins, and normal or decreased blood pressure. In severe states, hypovolemic shock can occur (see Chapter 24). Isotonic fluids containing electrolytes and glucose are given orally, intravenously (i.e., 0.9% saline solution or 5% dextrose in 0.225% saline solution), or, in some cases, subcutaneously (hypodermoclysis).

**Isotonic fluid excess** causes hypervolemia. Common causes include excessive administration of intravenous fluids, hypersecretion of aldosterone, or the effects of drugs such as cortisone (which causes renal reabsorption of sodium and water). As plasma volume expands, hypervolemia develops with weight gain. The diluting effect of excess plasma volume leads to decreased hematocrit and decreased plasma protein concentration. The neck veins may distend, and the blood pressure increases. Increased capillary hydrostatic pressure leads to edema formation. Ultimately, pulmonary edema and heart failure may develop. Diuretics are commonly used for treatment.

**Hypertonic Alterations**

**Hypertonic fluid alterations** develop when the osmolality of the ECF is elevated above normal (greater than 294 mOsm). The most common causes are increased concentration of ECF sodium (hypernatremia) or deficit of ECF water, or both. In both instances, ECF hypertonicity attracts water from the intracellular space, causing ICF dehydration (see Figure 5-7).

**Hypernatremia**

**Pathophysiology**

**Hypernatremia** occurs when serum sodium levels exceed 145 mEq/L. Increased levels of serum sodium cause hypertonicity. Hypernatremia can be isovolemic, hypovolemic, or hypervolemic depending on the accompanying ECF water volume. **Isovolemic hypernatremia** is the most common and occurs when there is a loss of free water with a near normal body sodium concentration. Causes include inadequate water intake; excessive sweating (sweat is hypotonic), fever, or respiratory tract infections, which increase the respiratory rate and enhance water loss from the lungs; burns; vomiting; diarrhea; and central or nephrogenic diabetes insipidus (lack of ADH or inadequate renal response to ADH). Infants with severe diarrhea are vulnerable and have increased risk because they cannot communicate
thirst. Insufficient water intake occurs particularly in individuals who are comatose, confused, or immobilized or are receiving gastric feedings. **Dehydration** refers to water deficit but also is commonly used to indicate both sodium and water loss (isotonic or isoosmolar dehydration).^5^ 

**Hypovolemic hypernatremia** occurs where there is loss of sodium accompanied by a relatively greater loss of body water. Causes include use of loop diuretics, osmotic diuresis (i.e., from hyperglycemia related to uncontrolled diabetes mellitus or use of mannitol), or failure of the kidneys to concentrate urine.

**Hypervolemic hypernatremia** is rare and occurs when there is increased total body water and a greater increase in total body sodium level, resulting in hypervolemia. Causes include infusion of hypertonic saline solutions (e.g., as sodium replacement for treatment of salt depletion, which can occur with renal impairment, heart failure, or gastrointestinal [GI] losses); oversecretion of adrenocorticotropic hormone (ACTH) or aldosterone (e.g., Cushing syndrome, adrenal hyperplasia); and near salt water drowning.\(^6\) High amounts of dietary sodium rarely cause hypernatremia in a healthy individual because the sodium is eliminated by the kidneys.

Because chloride follows sodium, **hyperchloremia** (elevation of serum chloride concentration greater than 105 mEq/L) often accompanies hypernatremia, as well as plasma bicarbonate deficits (such as in metabolic acidosis)^7^ (see p. 127). There are no specific symptoms or treatment for chloride excess.

**Clinical manifestations**

When there is excessive sodium intake or decreased sodium loss in relation to water, water is osmotically redistributed to the hypertonic extracellular space, resulting in hypervolemia, and intracellular dehydration ensues. Clinical manifestations include thirst, weight gain, bounding pulse, and increased blood pressure. Central nervous system signs are the most serious and are related to alterations in membrane potentials and shrinking of brain cells (sodium cannot cross brain capillaries because of their tight endothelial junctions). Signs include muscle twitching and hyperreflexia (hyperactive reflexes), confusion, coma, convulsions, and cerebral hemorrhage from stretching of veins. Hypernatremia with marked water deficit is manifested by signs and symptoms of intracellular and extracellular dehydration with volume depletion (**Box 5-1**).

**Box 5-1**

**Signs and Symptoms of Dehydration**
Increased serum sodium concentration

Thirst

Headache

Weight loss

Oliguria and concentrated urine

Hard stools

Decreased skin turgor

Dry mucous membranes

Decreased sweating and tears

Elevated temperature

Soft eyeballs

Sunken fontanels in infants

Prolonged capillary refill time

Tachycardia

Weak pulses

Low blood pressure

Postural hypotension

Hypovolemic shock

Confusion

Coma

**Evaluation and treatment**

Serum sodium levels are greater than 147 mEq/L and urine specific gravity will be
greater than 1.030. The history and physical examination provide information about underlying disorders and events. The treatment of hypernatremia and water deficit is to give oral fluids or isotonic salt-free fluid (5% dextrose in water) until the serum sodium level returns to normal. Fluid replacement must be given slowly to prevent cerebral edema. Serum sodium levels need to be monitored. Hypervolemia or hypovolemia requires treatment of the underlying clinical condition.

**Hypotonic Alterations**

**Hypotonic fluid imbalances** occur when the osmolality of the ECF is less than 280 mOsm (see Figure 5-7). The most common causes are sodium deficit or water excess. Either leads to *intracellular overhydration* (cellular edema) and cell swelling. When there is a sodium deficit, the osmotic pressure of the ECF decreases and water moves into the cell where the osmotic pressure is greater. The plasma volume then decreases, leading to symptoms of hypovolemia. With water excess, increases in both the ICF and ECF volume occur, causing symptoms of hypervolemia and water intoxication with cerebral and pulmonary edema.

**Hyponatremia**

**Pathophysiology**

**Hyponatremia** develops when the serum sodium concentration falls below 135 mEq/L. Hyponatremia occurs when there is loss of sodium, inadequate intake of sodium, or dilution of sodium by water excess. Sodium depletion usually causes hypoosmolality with movement of water into cells with rupture of cell membranes. **Isovolemic hyponatremia** occurs when there is loss of sodium without a significant loss of water (pure sodium deficit). Causes can include syndrome of inappropriate antidiuretic hormone (SIADH [see Chapter 19], which enhances water retention), hypothyroidism, pneumonia, and glucocorticoid deficiency. Inadequate intake of dietary sodium is rare but possible in individuals on low-sodium diets, particularly with use of diuretics.

**Hypervolemic hyponatremia** occurs when total body sodium level increases. The increased sodium leads to an increase in total body water and dilution of sodium in the extracellular space. Causes include congestive heart failure, cirrhosis of the liver, and nephrotic syndrome. Edema is present.

**Hypovolemic hyponatremia** occurs with a loss of total body water, but there is a greater loss of body sodium. The extracellular volume is decreased. Causes include prolonged vomiting, severe diarrhea, inadequate secretion of aldosterone (e.g., adrenal insufficiency), and renal losses from diuretics.
Dilutional hyponatremia (water intoxication) occurs when there is intake of large amounts of free water or replacement of fluid loss with intravenous 5% dextrose in water, which dilutes sodium. The glucose is metabolized to carbon dioxide and water, leaving a hypotonic solution with a diluting effect. Excessive sweating stimulates thirst and intake of large amounts of free water (as can occur in endurance athletes), which dilutes sodium. Some individuals with psychogenic disorders develop water intoxication from compulsive water drinking. Other causes can include tap water enemas, near fresh water drowning, and use of selective serotonin reuptake inhibitors (SSRIs). When the body is functioning normally, it is almost impossible to produce an excess of TBW because water balance is regulated by the kidneys.

Hypochloremia, a low level of serum chloride (less than 97 mEq/L), usually occurs with hyponatremia or an elevated bicarbonate concentration, as in metabolic alkalosis (see p. 127). Sodium deficit related to restricted intake, use of diuretics, vomiting, or nasogastric suction is accompanied by chloride deficiency. Cystic fibrosis is characterized by hypochloremia (see Chapter 28). Treatment of the underlying cause is required.

Clinical manifestations
The serum sodium concentration will be less than 135 mEq/L. Sodium depletion usually causes hypoosmolality with movement of water into cells. The hematocrit is reduced from the dilutional effect of water excess in dilutional hyponatremia. The high amount of intracellular solutes compared to the low amount of extracellular solutes as a result of the hyponatremia causes an intracellular osmotic shift of water, resulting in cell swelling. The most life-threatening consequence is cerebral edema and increased intracranial pressure. Neurologic changes include lethargy, confusion, apprehension, seizures, and coma. A decrease in sodium concentration changes the cell's ability to depolarize and repolarize normally, altering the action potential in neurons and muscle (see Chapter 1). Muscle twitching, depressed reflexes, and weakness are common. Nausea and vomiting are more common with less severe hyponatremia (i.e., decreases between 120 and 130 mEq/L). Hypovolemic hyponatremia has signs of hypotension, tachycardia, and decreased urine output. Hypervolemic hyponatremia is accompanied by weight gain, edema, ascites, and jugular vein distention. Hyponatremia is a major cause of morbidity and mortality in intensive care units and in the elderly (see Health Alert: Hyponatremia and the Elderly).
Hyponatremia and the Elderly

Hyponatremia is the most common of the electrolyte disorders and prevalence is highest among elderly hospitalized individuals. Isovolemic hyponatremia caused by SIADH is thought to be the most common cause and can occur with central nervous system injury, pulmonary disease, malignancies, nausea, pain, and aging changes. Other contributing factors include use of thiazide diuretics, proton pump inhibitors, age-related decrease in thirst with dehydration, and diminished urine concentrating ability. Hyponatremia contributes to cognitive deficits, gait disturbances, falls, fractures, long-term hospitalization, the need for long-term care, and death. The elderly need to be assessed for risk, implementation of preventive strategies, and early intervention.

SIADH, Syndrome of inappropriate antidiuretic hormone.

Evaluation and treatment

The cause of hyponatremia must be determined and treatment planned accordingly. Small amounts of intravenous hypertonic sodium chloride (i.e., 3% sodium chloride) can be given when neurologic manifestations are severe but must be given slowly to prevent osmotic demyelination syndrome in the brain. Restriction of water intake is required in most cases of dilutional hyponatremia because body sodium levels may be normal or increased even though serum sodium levels are low. Arginine vasopressin (ADH) receptor antagonists (vaptans) are a class of drugs used for the treatment of hypervolemic and euvolemic hyponatremia. Serum sodium concentration must be monitored.

2. What are some causes of hypernatremia?
3. What is the most severe complication of hyponatremia?
Alterations in Potassium and Other Electrolytes

Potassium

Potassium ($K^+$) is the major intracellular electrolyte and is essential for normal cellular functions. Total body potassium content is about 4000 mEq, with most of it (98%) located in the cells. The ICF concentration of potassium is 150 to 160 mEq/L; the ECF potassium concentration is 3.5 to 5.0 mEq/L. The difference in concentration is maintained by a sodium-potassium adenosinetriphosphatase active transport system ($Na^+-K^+$ ATPase pump) (see Figure 1-26).

As the predominant ICF ion, potassium exerts a major influence on the regulation of ICF osmolality and fluid balance as well as on intracellular electrical neutrality in relation to hydrogen ($H^+$) and sodium. Potassium is required for glycogen and glucose deposition in liver and skeletal muscle cells. It also maintains the resting membrane potential, as reflected in the transmission and conduction of nerve impulses (see Figure 1-29), the maintenance of normal cardiac rhythms, and the contraction of skeletal muscle and smooth muscle.

Dietary potassium moves rapidly into cells after ingestion. However, the distribution of potassium between intracellular and extracellular fluids is influenced by several factors. Insulin, aldosterone, epinephrine, and alkalosis facilitate the shift of potassium into cells. Insulin deficiency, aldosterone deficiency, acidosis, cell lysis, and strenuous exercise facilitate the shift of potassium out of cells. Glucagon blocks entry of potassium into cells, and glucocorticoids promote potassium excretion. Potassium also will move out of cells along with water when there is increased ECF osmolarity.

Although potassium is found in most body fluids, the kidney is the most efficient regulator of potassium balance. Potassium is freely filtered by the renal glomerulus, and 90% is reabsorbed by the proximal tubule and loop of Henle. In the distal tubules, principal cells secrete potassium and intercalated cells reabsorb potassium. These cells determine the amount of potassium excreted from the body. The gut may also sense the amount of $K^+$ ingested and stimulate renal $K^+$ excretion independent of aldosterone.11

The potassium concentration in the distal tubular cells is determined primarily by the plasma concentration in the peritubular capillaries. When plasma potassium concentration increases from increased dietary intake or shifts of potassium from the ICF to the ECF occur, potassium is secreted into the urine by the distal tubules. Decreased levels of plasma potassium result in decreased distal tubular secretion,
although approximately 5 to 15 mEq per day will continue to be lost. Changes in the rate of filtrate (urine) flow through the distal tubule also influence the concentration gradient for potassium secretion. When the urine flow rate is high, as with the use of diuretics, potassium concentration in the distal tubular urine is lower, leading to the secretion of potassium into the urine.

Changes in pH and thus in hydrogen ion concentration also affect potassium balance. During acute acidosis, hydrogen ions accumulate in the ICF and potassium shifts out of the cell to the ECF to maintain a balance of cations across the cell membrane. This occurs in part because of a decrease in sodium-potassium ATPase pump activity. Decreased ICF potassium results in decreased secretion of potassium by the distal tubular cells, contributing to hyperkalemia. In acute alkalosis, intracellular fluid levels of hydrogen diminish and potassium shifts into the cell; in addition, the distal tubular cells increase their secretion of potassium, further contributing to hypokalemia.\(^\text{12}\)

Besides conserving sodium, \textit{aldosterone} also regulates potassium concentration. Elevated plasma potassium concentration causes the release of renin by renal juxtaglomerular cells and the adrenal secretion of aldosterone through the renin-angiotensin-aldosterone system. Aldosterone then stimulates the release of potassium into the urine by the distal renal tubules. Aldosterone also increases the secretion of potassium from sweat glands.

Insulin helps regulate plasma potassium levels by stimulating the sodium-potassium ATPase pump, thus promoting the movement of potassium into liver and muscle cells, particularly after eating. Insulin can also be used to treat hyperkalemia. Dangerously low levels of plasma potassium can result when insulin is given while potassium levels are depressed. Potassium balance is especially significant in the treatment of conditions requiring insulin administration, such as insulin-dependent diabetes mellitus.

\textbf{Potassium adaptation} is the ability of the body to adapt to increased levels of potassium intake over time. A sudden increase in potassium may be fatal, but if the intake of potassium is slowly increased by amounts of more than 120 mEq per day, the kidney can increase the urinary excretion of potassium and maintain potassium balance.

\section*{Hypokalemia}

\section*{Pathophysiology}

Potassium deficiency, or \textit{hypokalemia}, develops when the serum potassium concentration falls to less than 3.5 mEq/L. Because cellular and total body stores of potassium are difficult to measure, changes in potassium balance are described,
although not always accurately, by the plasma concentration. Generally, lowered serum potassium level indicates loss of total body potassium. With potassium loss from the ECF, the concentration gradient change favors movement of potassium from the cell to the ECF. The ICF/ECF concentration ratio is maintained, but the amount of total body potassium is depleted.

Factors contributing to the development of hypokalemia include reduced intake of potassium, increased entry of potassium into cells, and increased losses of body potassium. Dietary deficiency of potassium is more common in elderly individuals with both low protein intake and inadequate intake of fruits and vegetables and in individuals with alcoholism or anorexia nervosa (see Health Alert: Potassium Intake: Hypertension and Stroke). Reduced potassium intake generally becomes a problem when combined with other causes of potassium depletion.

**Health Alert**

**Potassium Intake: Hypertension and Stroke**

Enriched dietary intake of potassium is associated with lower risk of hypertension and stroke. The American diet often exceeds recommendations for sodium intake and a deficiency in potassium intake. There is increased risk of high blood pressure, cardiovascular disease, and mortality when the plasma ratio of sodium concentration to potassium concentration is high. Potassium attenuates the effects of high dietary salt with reduction in blood pressure, stroke rates, and cardiovascular disease risk. The exact mechanism of how potassium affects blood pressure is unknown but is thought to be related to renal handling of sodium, endothelial cell function, decreased vascular resistance, and reduced oxidative stress. A large prospective study of older women showed they were found to have lower risk of ischemic but not hemorrhagic stroke associated with higher intakes of potassium, especially in women without hypertension. Lower risk of mortality was found in all women with higher intakes of potassium. Increased dietary intake of potassium is recommended for most individuals without impaired renal handling of potassium.

ECF hypokalemia can develop without losses of total body potassium. For example, potassium shifts from the ECF to the ICF in exchange for hydrogen to maintain plasma acid-base balance during respiratory or metabolic alkalosis.
Insulin promotes cellular uptake of potassium and insulin administration may cause an ECF potassium deficit.

Potassium shifts from the ICF to the ECF in conditions such as diabetic ketoacidosis, in which the increased hydrogen ion concentration in the ECF causes $\text{H}^+$ to shift into the cell in exchange for potassium. A normal level of potassium is maintained in the plasma, but potassium continues to be lost in the urine, causing a deficit in the amount of total body potassium. Severe, even fatal, hypokalemia may occur if insulin is administered without also providing potassium supplements. Thus total body potassium depletion becomes evident when insulin treatment and rehydration therapy are initiated. Potassium replacement is instituted cautiously to prevent hyperkalemia.

Losses of potassium from body stores are usually caused by gastrointestinal and renal disorders. Diarrhea, intestinal drainage tubes or fistulae, and laxative abuse also result in hypokalemia. Normally, only 5 to 10 mEq of potassium and 100 to 150 ml of water are excreted in the stool each day. With diarrhea, fluid and electrolyte losses can be voluminous, with several liters of fluid and 100 to 200 mEq of potassium lost per day. Vomiting or continuous nasogastric suctioning often is associated with potassium depletion, partly because of the potassium lost from the gastric fluid but principally because of renal compensation for volume depletion and the metabolic alkalosis (elevated bicarbonate levels) that occurs from sodium, chloride, and hydrogen ion losses. The loss of fluid and sodium stimulates the secretion of aldosterone, which in turn causes renal losses of potassium.

Renal potassium losses occur with increased secretion of potassium by the distal tubule. Use of potassium-wasting diuretics, excessive aldosterone secretion, increased distal tubular flow rate, and low plasma magnesium concentration all may contribute to urinary losses of potassium. The elevated flow of bicarbonate at the distal tubule during alkalosis also contributes to renal excretion of potassium because the increased tubular lumen electronegativity attracts potassium. Many diuretics inhibit the reabsorption of sodium chloride, causing the diuretic effect. The distal tubular flow rate then increases, promoting potassium excretion. If sodium loss is severe, the compensating aldosterone secretion may further deplete potassium stores. Primary hyperaldosteronism with excessive secretion of aldosterone from an adrenal adenoma (tumor) also causes potassium wasting. Many kidney diseases reduce the ability to conserve sodium. The disordered sodium reabsorption produces a diuretic effect, and the increased distal tubule flow rate favors the secretion of potassium. Magnesium deficits increase renal potassium secretion and promote hypokalemia. Certain antibiotics (i.e., carbenicillin disodium and amphotericin B) are known to cause hypokalemia by increasing the rate of potassium excretion. Rare hereditary defects in renal potassium transport (e.g.,
Bartter and Gitelman syndromes) also can cause hypokalemia.

**Clinical manifestations**

Mild losses of potassium are usually asymptomatic. Severe loss of potassium results in neuromuscular and cardiac manifestations. Neuromuscular excitability decreases, causing skeletal muscle weakness, smooth muscle atony, cardiac dysrhythmias, glucose intolerance, and impaired urinary concentrating ability.\(^\text{13}\)

Symptoms occur in relation to the rate of potassium depletion. Because the body can accommodate slow losses of potassium, the decrease in ECF concentration may allow potassium to shift from the intracellular space, restoring the potassium concentration gradient toward normal, with less severe neuromuscular changes. With acute and severe losses of potassium, changes in neuromuscular excitability are more profound. Skeletal muscle weakness occurs initially in the larger muscles of the legs and arms and ultimately affects the diaphragm and depresses ventilation. Paralysis and respiratory arrest can occur with severe losses. Loss of smooth muscle tone is manifested by constipation, intestinal distention, anorexia, nausea, vomiting, and paralytic ileus (paralysis of the intestinal muscles).

The cardiac effects of hypokalemia are related also to changes in membrane excitability. As ECF potassium concentration decreases, the resting membrane potential becomes more negative (i.e., from \(-90\) millivolts to \(−100\) millivolts [hypopolarization]). Because potassium contributes to the repolarization phase of the action potential, hypokalemia delays ventricular repolarization. Various dysrhythmias may occur, including sinus bradycardia, atrioventricular block, and paroxysmal atrial tachycardia. The characteristic changes in the electrocardiogram (ECG) reflect *delayed repolarization*. For instance, the amplitude of the T wave decreases, the amplitude of the U wave increases, and the ST segment is depressed (Figure 5-8). In severe states of hypokalemia, P waves peak, the QT interval is prolonged, and T wave inversions may be seen. Hypokalemia enhances the therapeutic effect of digitalis and increases the risk of digitalis toxicity.
A wide range of metabolic dysfunctions may result from potassium deficiency (Table 5-6). Carbohydrate metabolism is affected because hypokalemia depresses insulin secretion and alters hepatic and skeletal muscle glycogen synthesis. Renal function is impaired, with a decreased ability to concentrate urine. Polyuria (increased urine) and polydipsia (increased thirst) are associated with decreased
responsiveness to ADH. Long-term potassium deficits lasting more than 1 month may damage renal tissue, with interstitial fibrosis and tubular atrophy.

**Evaluation and treatment**

The diagnosis of hypokalemia is significantly related to the medical history and the identification of disorders associated with potassium loss or shifts of extracellular potassium to the intracellular space. Treatment involves an estimation of total body potassium losses and correction of acid-base imbalances. Further losses of potassium should be prevented and the individual should be encouraged to eat foods rich in potassium. The maximal rate of oral replacement is 40 to 80 mEq/day if renal function is normal. A maximal safe rate of intravenous replacement is 20 mEq/hr. Because potassium is irritating to blood vessels, a maximal concentration of 40 mEq/L should be used. Serum potassium values are monitored until normokalemia is achieved.

**Hyperkalemia**

**Pathophysiology**

Elevation of ECF potassium concentration greater than 5.5 mEq/L constitutes
Hyperkalemia. Because of efficient renal excretion, increases in total body potassium level are relatively rare. Acute increases in serum potassium level are handled quickly through increased cellular uptake and renal excretion of body potassium excesses.

Hyperkalemia may be caused by increased intake, a shift of potassium from cells to the ECF, decreased renal excretion, or drugs that decrease renal potassium excretion (i.e., ACE inhibitors, angiotensin receptor blockers, and aldosterone antagonists). If renal function is normal, slow, long-term increases in potassium intake are usually well tolerated through potassium adaptation, although short-term potassium loading can exceed renal excretion rates. Dietary excesses of potassium are uncommon but accidental ingestion of potassium salt substitutes can cause toxicity. Use of stored whole blood and intravenous boluses of potassium penicillin G or replacement potassium can precipitate hyperkalemia, particularly with impaired renal function. Potassium moves from the ICF to the ECF with cell trauma or a change in cell membrane permeability, acidosis, insulin deficiency, or cell hypoxia. Burns, massive crushing injuries, and extensive surgeries can cause release of potassium to the ECF as a result of cell trauma. If renal function is sustained, potassium is excreted. As cell repair begins, hypokalemia develops without an adequate replacement of potassium.

In acidosis, ECF hydrogen ions shift into cells in exchange for ICF potassium and sodium; hyperkalemia and acidosis therefore often occur simultaneously. Because insulin promotes cellular entry of potassium, insulin deficits, which occur with such conditions as diabetic ketoacidosis, are accompanied by hyperkalemia. Hypoxia can lead to hyperkalemia by diminishing the efficiency of cell membrane active transport, resulting in the escape of potassium to the ECF. Digitalis overdose (toxicity) may cause hyperkalemia by inhibiting the Na⁺-K⁺ ATPase pump, and thus allowing potassium to remain outside the cell,

Decreased renal excretion of potassium commonly is associated with hyperkalemia. Renal failure that results in oliguria (urine output of 30 ml/hr or less) is accompanied by elevations of serum potassium level. The severity of hyperkalemia is related to the amount of potassium intake, the degree of acidosis, and the rate of renal cell damage. Decreases in the secretion or renal effects of aldosterone also can cause decreases in the urinary excretion of potassium. For example, Addison disease (a disease of adrenal cortical insufficiency) results in decreased production and secretion of aldosterone (and other steroids) and thus contributes to hyperkalemia.

Clinical manifestations
Symptoms vary with the severity of hyperkalemia. During mild attacks, increased
neuromuscular irritability may be manifested as restlessness, intestinal cramping, and diarrhea. Severe hyperkalemia decreases the resting membrane potential (i.e., from −90 millivolts to −70 millivolts [hyperpolarization]) and causes muscle weakness, loss of muscle tone, and paralysis. In mild states of hyperkalemia, there is more rapid repolarization, reflected in the ECG as narrow and taller T waves with a shortened QT interval. Severe hyperkalemia causes delayed cardiac conduction and prevents repolarization of heart muscle. Severe hyperkalemia depresses the ST segment, prolongs the PR interval, and widens the QRS complex because of decreased conduction velocity from inactivated sodium channels (see Figure 5-8). Bradydysrhythmias and delayed conduction are common in hyperkalemia; severe hyperkalemia can cause ventricular fibrillation or cardiac arrest.15

As with hypokalemia, changes in the ratio of intracellular to extracellular potassium concentration contribute to the symptoms of hyperkalemia (see Table 5-6). The neuromuscular effects of hyperkalemia are related to the increase in rate of repolarization and the presence of other contributing factors, such as acidosis and calcium balance. Long-term increases in ECF potassium concentration result in shifts of potassium into the cell, because the tendency is to maintain a normal ratio of ICF to ECF potassium concentrations. Acute elevations of extracellular potassium concentration affect neuromuscular irritability because this ratio is disrupted. Increases in extracellular fluid calcium concentration can override the neuromuscular effects of hyperkalemia because calcium is also a cation and affects the threshold potential (see Chapter 1).

**Evaluation and treatment**

Hyperkalemia should be investigated when there is a history of renal disease, massive trauma, insulin deficiency, Addison disease, use of potassium salt substitutes, or metabolic acidosis. The acuity of the onset of symptoms may be related to the underlying cause.

Management of hyperkalemia includes treating the contributing causes and correcting the potassium excess. When serum potassium levels are dangerously high, calcium gluconate can be administered to restore normal neuromuscular irritability and to stabilize the resting cardiac membrane potential by making the threshold potential less negative. Administration of glucose (which readily stimulates insulin secretion) or administration of both glucose and insulin for diabetic individuals facilitates cellular entry of potassium. Sodium bicarbonate corrects metabolic acidosis and lowers serum potassium concentration. Oral or rectal administration of cation exchange resins, which exchange sodium for potassium in the intestine, can be effective. Dialysis effectively removes potassium when renal failure has occurred.
Quick Check 5-4

1. What role does potassium play in the body? What metabolic dysfunctions occur in potassium deficiency? In potassium excess?

2. Explain how a person can have normal total body potassium levels but still exhibit hypokalemia.

3. What is the most prominent ECG change associated with hyperkalemia? With hypokalemia?

Other Electrolytes—Calcium, Phosphate, and Magnesium

The specifics of balance for the other body electrolytes—calcium (Ca$^{++}$), phosphate (PO$_4^{3-}$), and magnesium (Mg$^{++}$)—are summarized in Table 5-7. Parathyroid hormone and vitamin D are important for the regulation of these minerals$^{16}$ (see Chapter 18).
TABLE 5-7
Alterations in Calcium, Phosphate, and Magnesium

Acid-Base Balance

Acid-base balance must be regulated within a narrow range for the body to function normally. Slight changes in amounts of hydrogen and changes in pH can significantly alter biologic processes in cells and tissues. Hydrogen ion is needed to maintain membrane integrity and the speed of metabolic enzyme reactions. Most pathologic conditions disturb acid-base balance, producing circumstances possibly more harmful than the disease process itself.

Hydrogen Ion and pH

The concentration of hydrogen ions in body fluids is very small—approximately 0.0000001 mg/L. This number, which may be expressed as $10^{-7}$ mg/L, is indicated as pH 7.0. The symbol $pH$ represents the acidity or alkalinity of a solution. As the pH changes 1 unit (e.g., from pH 7.0 to pH 6.0), the $[H^+]$ ([H$^+$] = hydrogen ion concentration) changes tenfold. The greater the [H$^+$], the more acidic the solution and the lower the pH. The lower the [H$^+$], the more alkaline or basic the solution and the higher the pH. In biologic fluids, a pH of less than 7.4 is defined as acidic and a pH greater than 7.4 is defined as alkaline or basic (Table 5-8).

Body acids are formed as end products of protein, carbohydrate, and fat metabolism and acids can release hydrogen ion. Acids must be balanced by the amount of basic substances in the body to maintain normal pH. The lungs, kidneys, and bones are the major organs involved in regulating acid-base balance. The systems work together to regulate short- and long-term changes in acid-base status.

Body acids exist in two forms: **volatile** (can be eliminated as CO$_2$ gas) and **nonvolatile** (can be eliminated by the kidney). The volatile acid is carbonic acid ($H_2CO_3$), a weak acid (i.e., it does not release its hydrogen easily). In the presence of the enzyme carbonic anhydrase, it readily dissociates into carbon dioxide (CO$_2$) and
water (H₂O). The carbon dioxide is then eliminated by pulmonary ventilation.

**Nonvolatile acids** are sulfuric, phosphoric, and other organic acids. They are **strong acids** (readily release their hydrogens). Nonvolatile acids are secreted into the urine by the renal tubules in amounts of about 60 to 100 mEq of hydrogen per day or about 1 mEq per kilogram of body weight.

**Buffer Systems**

**Buffering** occurs in response to changes in acid-base status. **Buffers** can absorb excessive hydrogen ion (H⁺) (acid) or hydroxyl ion (OH⁻) (base) and prevent a significant change in pH. The buffer systems are located in both the ICF and the ECF compartments, and they function at different rates (Table 5-9). The most important plasma buffer systems are carbonic acid–bicarbonate and the protein hemoglobin (Figure 5-9). Phosphate and protein are the most important intracellular buffers and provide a first line of defense. Ammonia and phosphate can attach hydrogen ions and are important renal buffers.

CO₂, Carbon dioxide; Hb⁺, hemoglobin; HCO₃⁻, bicarbonate; H₂CO₃, carbonic acid; HHb, hydrogenated hemoglobin; HPO₄²⁻, dibasic phosphate; H₂PO₄⁻, monobasic phosphate; HPr, hydrogenated protein; Pr⁻, protein.
FIGURE 5-9 Integration of pH Control Mechanisms (example for acidosis). CO₂ is produced in tissue cells and diffuses to plasma, where it is transported as dissolved CO₂, or it combines with water to form carbonic acid (H₂CO₃), or it combines with protein from which hydrogen has...
been released. Most of the CO₂ diffuses into the red blood cells and combines with water to form H₂CO₃. The H₂CO₃ dissociates to form hydrogen ion (H⁺) and bicarbonate (HCO₃⁻). Hydrogen combines with hemoglobin that has released its oxygen to form HHb, which buffers the hydrogen and makes venous blood slightly more acidic than arterial blood. The increase in H⁺ coupled with elevated CO₂ levels results in HHbCO₃⁻ and an increase in the respiratory rate and secretion of H⁺ by the kidneys.

Carbonic Acid–Bicarbonate Buffering

The carbonic acid–bicarbonate buffer pair operates in both the lung and the kidney and is a major extracellular buffer. The lungs are a second line of defense and can relatively quickly (within seconds to minutes) decrease the amount of carbonic acid by blowing off carbon dioxide and leaving water. The kidneys are a third line of defense (hours to days) and can reabsorb bicarbonate (a type of base) or regenerate new bicarbonate from carbon dioxide and water. The relationship between bicarbonate (HCO₃⁻) and carbonic acid (H₂CO₃) is usually expressed as a ratio. Normal bicarbonate level is about 24 mEq/L, and normal carbonic acid level is about 1.2 mEq/L (when the arterial CO₂ partial pressure [Paco₂] is 40 mm Hg), producing a 20 : 1 (24/1.2) ratio and the normal pH of 7.4 (Figure 5-10). These two systems are very effective together because the lungs can adjust acid concentration rapidly by ventilation and bicarbonate is easily reabsorbed or regenerated by the kidney tubules, although more slowly.
Renal and respiratory adjustments to primary changes in pH are known as **compensation**. The respiratory system compensates for changes in pH by increasing or decreasing the concentration of carbon dioxide (carbonic acid) by changing ventilation. The renal system compensates by producing more acidic or more alkaline urine. The values for PaCO₂ and bicarbonate will vary from normal levels in an attempt to maintain a ratio of 20 : 1. **Correction** occurs when the values for both components of the buffer pair (carbonic acid and bicarbonate) return to normal levels.

**Protein Buffering**

Both intracellular and extracellular proteins have negative charges and can serve as buffers for hydrogen, but because most proteins are inside cells, they are primarily an intracellular buffer system. Hemoglobin (Hb) is an excellent intracellular blood buffer because it can bind with hydrogen ion (H⁺) (forming HHb) and carbon dioxide (forming HHbCO₂). Hemoglobin bound to hydrogen ion becomes a weak acid. Hemoglobin not saturated with oxygen (venous blood) is a better buffer than...
hemoglobin saturated with oxygen (arterial blood). The pH control mechanism is illustrated in Figure 5-9.

**Renal Buffering**

The distal tubule of the kidney regulates acid-base balance by secreting hydrogen into the urine and reabsorbing bicarbonate into the plasma. Dibasic phosphate ($\text{HPO}_4^{2-}$) and ammonia ($\text{NH}_3$) are two important renal buffers because they can attach hydrogen ions and be secreted into the urine. The renal buffering of hydrogen ions requires the use of carbon dioxide ($\text{CO}_2$) and water ($\text{H}_2\text{O}$) to form carbonic acid ($\text{H}_2\text{CO}_3$). The enzyme carbonic anhydrase catalyzes the reaction. The hydrogen in the carbonic acid is then secreted from the tubular cell and buffered in the lumen by phosphate and ammonia (i.e., forms $\text{H}_2\text{PO}_4^-$ and $\text{NH}_4^+$). The remaining bicarbonate is reabsorbed. The end effect is the addition of new bicarbonate to the plasma, which contributes to the alkalinity of the plasma because the hydrogen ion is excreted from the body (Figure 5-11).
FIGURE 5-11 Renal Excretion of Acid. 1. Conservation of filtered bicarbonate. Filtered bicarbonate combines with secreted hydrogen ion in the presence of carbon anhydrase (CA) to form carbonic acid (H₂CO₃), which then dissociates to water (H₂O) and carbon dioxide (CO₂); both diffuse into the epithelial cell. The CO₂ and H₂O combine to form H₂CO₃ in the presence of CA, and the resulting bicarbonate ion (HCO₃⁻) is reabsorbed into the capillary. 2. Formation of titratable acid. Hydrogen ion is secreted and combines with dibasic phosphate (H₂PO₄⁻) to form monobasic phosphate (HPO₄²⁻). The secreted hydrogen ion is formed from the dissociation of H₂CO₃, and the remaining HCO₃⁻ is reabsorbed into the capillary. 3. Formation of ammonium. Ammonia (NH₃) is produced from glutamine in the epithelial cell and diffuses to the tubular
lumen, where it combines with $H^+$ to form ammonium ion ($\text{NH}_4^+$). Once $\text{NH}_4^+$ has been formed, it cannot return to the epithelial cell (diffusional trapping), and the bicarbonate remaining in the epithelial cell is reabsorbed into the capillary.

**Acid-Base Imbalances**

Pathophysiologic changes in the concentration of hydrogen ion in the blood lead to acid-base imbalances.\(^{18,19}\) In **acidemia** the pH of arterial blood is less than 7.4. A systemic increase in hydrogen ion concentration or a loss of base is termed **acidosis.** In **alkalemia** the pH of arterial blood is greater than 7.4. A systemic decrease in hydrogen ion concentration or an excess of base is termed **alkalosis.** These changes may be caused by metabolic or respiratory processes. Figure 5-10 summarizes the relationship among pH, the partial pressure of carbon dioxide (respiratory regulation), and the concentration of bicarbonate (renal regulation) during alkalosis and acidosis. Acid-base imbalances are assessed using measurement of arterial blood gases, which includes the reporting of pH, $\text{Paco}_2$, and $\text{HCO}_3^-$. The medical history and clinical symptoms are important in determining the cause of the disorder. Figure 5-12 summarizes the relationships among pH, $\text{Pco}_2$, and bicarbonate during different acid-base alterations.
FIGURE 5-12 Primary and Compensatory Acid-Base Changes. A systematic approach can be used to interpret the cause of an acid-base imbalance. 1, Is the pH low or high? 2, If the pH is low (acidemia), is the cause respiratory (high PaCO$_2$) or metabolic (low HCO$_3^-$) ? 3, If the pH is high (alkalemia), is the cause respiratory (low PaCO$_2$) or metabolic (high HCO$_3^-$) ? 4, Is there compensation for the primary acid-base disorder? (a) HCO$_3^-$ will be ≥24 mEq/L if there is renal compensation for a primary respiratory acidosis; (b) PaCO$_2$ will be <40 mm Hg if there is respiratory compensation of a primary metabolic acidosis; (c) HCO$_3^-$ will be <24 mEq/L if there is renal compensation for primary respiratory alkalosis; (d) PaCO$_2$ will be >40 mm Hg if there is respiratory compensation for primary metabolic alkalosis. NOTE: Examine the pH first to determine if there is acidemia or alkalemia. Then examine the changes in HCO$_3^-$ and PaCO$_2$. 1, HCO$_3^-$ will be elevated when there is primary metabolic alkalosis or renal compensation for primary respiratory acidosis. 2, HCO$_3^-$ will be decreased when there is primary metabolic acidosis or renal compensation for primary respiratory alkalosis. 3, PaCO$_2$ will be elevated when there is primary respiratory acidosis or respiratory compensation for primary metabolic alkalosis. 4, PaCO$_2$ will be decreased when there is primary respiratory alkalosis or respiratory compensation for metabolic acidosis. H$_2$CO$_3$, Carbonic acid; HCO$_3^-$, bicarbonate; PaCO$_2$, arterial partial pressure of carbon dioxide.

**Metabolic Acidosis**

In *metabolic acidosis* the concentrations of non–carbonic acids increase or bicarbonate is lost from extracellular fluid or cannot be regenerated by the kidney.
(Table 5-10). This can occur either quickly, as in lactic acidosis caused by poor perfusion or hypoxemia, or slowly over an extended time, as in renal failure, diabetic ketoacidosis, or starvation (anion gap acidosis). There is a decrease in the 20:1 ratio of $\text{HCO}_3^-$ to $\text{H}_2\text{CO}_3$.

*Anion gap refers to anions not usually measured in laboratory reports (e.g., sulfate, phosphate, and lactate). The anions usually measured are chloride ($\text{Cl}^-$) and bicarbonate ($\text{HCO}_3^-$). When the sum of the concentrations of measured anions (e.g., chloride and bicarbonate) is subtracted from the sum of the concentrations of measured cations (e.g., sodium and potassium), there is a “gap” of approximately 10 to 12 mEq/L; this is the normal anion gap. An elevated anion gap provides clues to the cause of the acidosis (i.e., to the addition of endogenously or exogenously generated acids). In a normal anion gap acidosis, chloride is retained to replace lost bicarbonate.

The buffering systems normally compensate for excess acid and maintain arterial pH within normal range. When acidosis is severe, buffers become depleted and cannot compensate, and the ratio of the concentrations of bicarbonate to carbonic acid decreases to less than 20:1 (see Figure 5-10). An increase in the plasma concentration of chloride out of proportion of sodium causes hyperchloremic acidosis (nonanion gap acidosis). The specific type of acidosis can be determined by examining the serum anion gap (see Table 5-10).

Metabolic acidosis is manifested by changes in the function of the neurologic, respiratory, gastrointestinal, and cardiovascular systems. Early symptoms include headache and lethargy, which progress to confusion and coma in severe acidosis. The respiratory system's efforts to compensate for the increase in metabolic acids result in what are termed Kussmaul respirations (a form of hyperventilation), which are deep and rapid. This represents the body's attempt to increase pH by expelling carbon dioxide, which decreases carbonic acid concentration. Other symptoms include anorexia, nausea, vomiting, diarrhea, and abdominal discomfort. Death can result in the most severe and prolonged cases preceded by dysrhythmias and hypotension. The underlying condition must be diagnosed to establish effective treatment.
Metabolic Alkalosis
When excessive loss of metabolic acids occurs, bicarbonate concentration increases, causing metabolic alkalosis\(^{21}\) (see Figure 5-12). When acid loss is caused by vomiting, renal compensation is not very effective because loss of chloride (an anion) in hydrochloric acid (HCl) stimulates renal retention of bicarbonate (an anion). The result is known as hypochloremic metabolic alkalosis.\(^{21}\) Hyperaldosteronism also can lead to alkalosis as a result of sodium bicarbonate retention and loss of hydrogen and potassium. Diuretics may produce a mild alkalosis because they promote greater excretion of sodium, potassium, and chloride than of bicarbonate.

Some common signs and symptoms of metabolic alkalosis are weakness, muscle cramps, hyperactive reflexes, tetany, confusion, convulsions, and atrial tachycardia. Respirations may be shallow and slow ventilation as the lungs attempt to compensate by increasing carbon dioxide retention. The manifestations vary with the cause and severity of the alkalosis. The symptoms of hyperactive reflexes and tetany occur because alkalosis increases binding of Ca\(^{++}\) to plasma proteins, thus decreasing ionized calcium concentration. The decreased ionized calcium concentration causes excitable cells to become hypopolarized, initiating an action potential more easily and causing muscle contraction.

Treatments are related to the underlying cause of the condition. With hypochloremic alkalosis or contraction alkalosis with volume depletion, a sodium chloride solution is required for correction because chloride must be replaced before bicarbonate can be excreted by the kidney.

Respiratory Acidosis

Respiratory acidosis occurs when there is alveolar hypoventilation, resulting in an excess of carbon dioxide in the blood (hypercapnia). The arterial carbon dioxide tension (or pressure) (Pa\textsubscript{CO}_2) is >45 mm Hg and the pH is less than 7.35 (see Figure 5-12). A decrease in alveolar ventilation in relation to the metabolic production of carbon dioxide produces respiratory acidosis by an increase in the concentration of carbonic acid. Respiratory acidosis can be acute or chronic.\(^{22}\) Common causes include depression of the respiratory center (e.g., from drugs or head injury), paralysis of the respiratory muscles, disorders of the chest wall (e.g., kyphoscoliosis or broken ribs), and disorders of the lung parenchyma (e.g., pneumonia, pulmonary edema, emphysema, asthma, bronchitis). Renal compensation occurs by elimination of hydrogen ion and retention of bicarbonate.

The signs and symptoms seen often include headache, blurred vision, breathlessness, restlessness, and apprehension followed by lethargy, disorientation,
muscle twitching, tremors, convulsions, and coma. Respiratory rate is rapid at first and gradually becomes depressed as the respiratory center adapts to increasing levels of carbon dioxide. The skin may be warm and flushed because the elevated carbon dioxide concentration causes vasodilation. The restoration of adequate alveolar ventilation is necessary to remove the excess \( \text{CO}_2 \) (\( \text{H}_2\text{CO}_3 \)).

**Respiratory Alkalosis**

Respiratory alkalosis occurs when there is alveolar hyperventilation (deep, rapid respirations). Excessive reduction in plasma carbon dioxide levels (hypocapnia) decrease carbonic acid concentration\(^{23,24}\) The \( \text{Paco}_2 \) is <35 mm Hg and the pH is greater than normal (see Figure 5-12). Respiratory alkalosis can be chronic or acute. Hypoxemia (caused by pulmonary disease, congestive heart failure, or high altitudes), hypermetabolic states (e.g., fever, anemia, thyrotoxicosis), early salicylate intoxication, hysteria, cirrhosis, and gram-negative sepsis stimulate hyperventilation. Improper use of mechanical ventilators also can cause iatrogenic (treatment-related) respiratory alkalosis, and secondary alkalosis may develop as a result of hyperventilation stimulated by metabolic or respiratory acidosis. The kidneys compensate by decreasing hydrogen excretion and bicarbonate reabsorption.

The central and peripheral nervous systems are stimulated by respiratory alkalosis, causing dizziness, confusion, tingling of extremities (paresthesias), convulsions, and coma. Cerebral vasoconstriction reduces cerebral blood flow. Carpopedal spasm (spasm of muscles in the fingers and toes), tetany, and other symptoms of hypocalcemia (see Table 5-7, p. 126) are similar to those of metabolic alkalosis. The underlying disturbance must be treated, particularly hypoxemia.

**Quick Check 5-5**

1. What is the difference between compensation and correction of acid-base disturbances?

2. What two chemicals are altered in metabolic acid-base disturbances?

3. How do alterations in carbon dioxide concentration influence acid-base status?

**Pediatric Considerations**
Distribution of Body Fluids

Newborn Infants

At birth TBW represents about 75% to 80% of body weight and decreases to about 67% during the first year of life. Physiologic loss of body water amounting to 5% of body weight occurs as an infant adjusts to a new environment. Infants are particularly susceptible to significant changes in TBW because of a high metabolic rate and greater body surface area, as compared to adults. Consequently, they have a greater fluid intake and output in relation to their body size. Renal mechanisms of fluid and electrolyte conservation may not be mature enough to counter abnormal losses related to vomiting or diarrhea, thereby allowing dehydration to occur. Symptoms of dehydration include increased thirst, decreased urine output, decreased body weight, decreased skin elasticity, sunken fontanels, absent tears, dry mucous membranes, increased heart rate, and irritability.

Children and Adolescents

TBW slowly decreases to 60% to 65% of body weight. At adolescence the percentage of TBW approaches adult levels and differences according to gender appear. Males have a greater percentage of body water because of increased muscle mass, and females have more body fat because of the influence of estrogen and thus less water.

Geriatric Considerations

Distribution of Body Fluids

The further decline in the percentage of TBW in the elderly is in part the result of a decreased free fat mass and decreased muscle mass, as well as a reduced ability to regulate sodium and water balance. Kidneys are less efficient in producing either a concentrated or a diluted urine, and sodium-conserving responses are sluggish. Thirst perception also may decline and loss of cognitive function can influence access to beverages. Healthy older adults can adequately maintain their hydration status. When disease is present, a decrease in TBW, dehydration, and hypernatremia can become life-threatening.
Did You Understand?

Distribution of Body Fluids

1. Body fluids are distributed among functional compartments and are classified as intracellular fluid (ICF) and extracellular fluid (ECF).

2. The sum of all fluids is the total body water (TBW), which varies with age and amount of body fat.

3. Water moves between the ICF and ECF compartments principally by osmosis.

4. Water moves between the plasma and interstitial fluid by osmosis (pulling of water) and hydrostatic pressure (pushing of water), which occur across the capillary membrane.

5. Movement across the capillary wall is called net filtration and is described according to Starling law (the balance between hydrostatic and osmotic forces).

Alterations in Water Movement

1. Edema is a problem of fluid distribution that results in accumulation of fluid within the interstitial spaces.

2. The pathophysiologic process that leads to edema is related to an increase in forces favoring fluid filtration from the capillaries or lymphatic channels into the tissues.

3. Edema is caused by arterial dilation, venous or lymphatic obstruction, increased vascular volume, loss of plasma proteins, or increased capillary permeability.

4. Edema may be localized or generalized and usually is associated with weight gain, swelling and puffiness, tighter-fitting clothes and shoes, and limited movement of the affected area.

Sodium, Chloride, and Water Balance

1. There is an intimate relationship between the balance of sodium and water levels; chloride levels are generally proportional to changes in sodium levels.
2. Water balance is regulated by the sensation of thirst and by antidiuretic hormone (ADH), which is secreted in response to an increase in plasma osmolality or a decrease in circulating blood volume.

3. Sodium balance is regulated by aldosterone, which increases reabsorption of sodium from the urine into the blood by the distal tubule of the kidney.

4. Renin and angiotensin are enzymes that promote secretion of aldosterone and thus regulate sodium and water balance.

5. Natriuretic hormones are involved in decreasing tubular reabsorption and promoting urinary excretion of sodium.

**Alterations in Sodium, Water, and Chloride Balance**

1. Alterations in sodium and water balance may be classified as isotonic, hypertonic, or hypotonic.

2. Isotonic alterations occur when changes in TBW are accompanied by proportional changes in electrolytes.

3. Hypertonic alterations develop when the osmolality of the ECF is elevated above normal, usually because of an increased concentration of ECF sodium or a deficit of ECF water.

4. Hypernatremia (sodium levels more than 145 mEq/L) may be caused by an acute increase in sodium level or a loss of water.

5. Hypernatremia can be isovolemic, hypovolemic, or hypervolemic depending on accompanying changes in the level of body water.

6. Hypernatremia with marked water deficit is manifested by hypovolemia and dehydration.

7. Hyperchloremia is caused by an excess of sodium or a deficit of bicarbonate.

8. Hypotonic alterations occur when the osmolality of the ECF is less than normal.

9. Hyponatremia (serum sodium concentration less than 135 mEq/L) usually causes movement of water into cells.
10. Hyponatremia may be caused by sodium loss, inadequate sodium intake, or
dilution of the body's sodium level with excess water.

11. Hyponatremia can be isovolemic, hypervolemic or hypovolemic, or dilutional
depending on accompanying changes in the amount of body water.

12. Hypochloremia usually is the result of hyponatremia or elevated bicarbonate
concentrations.

**Alterations in Potassium and Other Electrolytes**

1. Potassium is the predominant ICF ion; it regulates ICF osmolality, maintains the
resting membrane potential, and is required for deposition of glycogen in liver and
skeletal muscle cells.

2. Potassium balance is regulated by the kidney, by aldosterone and insulin
secretion, and by changes in pH.

3. Potassium adaptation allows the body to accommodate slowly to increased levels
of potassium intake.

4. Hypokalemia (serum potassium concentration less than 3.5 mEq/L) indicates loss
of total body potassium, although ECF hypokalemia can develop without losses of
total body potassium, and plasma potassium levels may be normal or elevated when
total body potassium is depleted.

5. Hypokalemia may be caused by reduced potassium intake, a shift of potassium
from the ECF to the ICF, increased aldosterone secretion, increased renal excretion,
and alkalosis.

6. Hyperkalemia (potassium levels that are greater than 5.5 mEq/L) may be caused
by increased potassium intake, a shift of potassium from the ICF to the ECF, or
decreased renal excretion.

7. Calcium is an ion necessary for bone and teeth formation, blood coagulation,
hormone secretion and cell receptor function, and membrane stability.

8. Phosphate acts as a buffer in acid-base regulation and provides energy for muscle
contraction.
9. Calcium and phosphate concentrations are rigidly controlled by parathyroid hormone (PTH), vitamin D, and calcitonin.

10. Hypocalcemia (serum calcium concentration less than 8.5 mg/dl) is related to inadequate intestinal absorption, deposition of calcium into bone or soft tissue, blood administration, or decreased PTH and vitamin D levels.

11. Hypercalcemia (serum calcium concentration greater than 12 mg/dl) can be caused by a number of diseases, including hyperparathyroidism, bone metastases, sarcoidosis, and excess vitamin D.

12. Hypophosphatemia is usually caused by intestinal malabsorption and increased renal excretion of phosphate.

13. Hyperphosphatemia develops with acute or chronic renal failure when there is significant loss of glomerular filtration.

14. Magnesium is a major intracellular cation and is regulated principally by PTH.

15. Magnesium functions in enzymatic reactions and often interacts with calcium at the cellular level.

16. Hypomagnesemia (serum magnesium concentrations less than 1.5 mEq/L) may be caused by malabsorption syndromes.

17. Hypermagnesemia (serum magnesium concentrations greater than 2.5 mEq/L) is rare and usually is caused by renal failure.

**Acid-Base Balance**

1. Hydrogen ions, which maintain membrane integrity and the speed of enzymatic reactions, must be concentrated within a narrow range if the body is to function normally.

2. Hydrogen ion concentration, [H⁺], is expressed as pH, which represents the negative logarithm (i.e., 10⁻⁻) of hydrogen ions in solution (i.e., 0.0000001 mg/L).

3. Different body fluids have different pH values; values less than 7.4 are more acidic and values greater than 7.4 are more basic.
4. The renal and respiratory systems, together with the body's buffer systems, are the principal regulators of acid-base balance.

5. Buffers are substances that can absorb excessive acid or base without a significant change in pH.

6. Buffers exist as acid-base pairs; the principal plasma buffers are carbonic acid ($H_2CO_3$), bicarbonate ($HCO_3^-$), protein (hemoglobin), and phosphate.

7. The lungs and kidneys act to compensate for primary changes in pH by increasing or decreasing ventilation and by producing more acidic or more alkaline urine.

8. Correction is a process different from compensation; correction occurs when the values for both components of the buffer pair return to normal as the primary disorder is treated or resolves.

9. Acid-base imbalances are caused by changes in the concentration of hydrogen ion in the blood; an increase causes acidosis, and a decrease causes alkalosis.

10. An abnormal increase or decrease in bicarbonate concentration causes metabolic alkalosis or metabolic acidosis; changes in the rate of alveolar ventilation and removal of carbon dioxide produce respiratory acidosis or respiratory alkalosis.

11. Metabolic acidosis is caused by an increase in the levels of non–carbonic acids or by the loss of bicarbonate from the extracellular fluid.

12. Metabolic alkalosis occurs with an increase in bicarbonate concentration, which is usually caused by loss of metabolic acids from conditions such as vomiting or gastrointestinal suctioning or by excessive bicarbonate intake, hyperaldosteronism, and diuretic therapy.

13. Respiratory acidosis occurs with decreased alveolar ventilation, which in turn causes hypercapnia (an increase in carbon dioxide concentration) and increased carbonic acid concentration.

14. Respiratory alkalosis occurs with alveolar hyperventilation and excessive reduction of carbon dioxide level, or hypopcapnia with decreases in carbonic acid concentration.

The human body is continually exposed to a large variety of conditions that result in damage, such as sunlight, pollutants, agents that can cause physical trauma, and infectious agents (viruses, bacteria, fungi, parasites). Damage can also arise from within, such as cancers. The damage may be at the level of a single cell, which can be easily repaired, or may be at the level of multiple cells or tissues or organs, which can result in disease and potentially the death of the individual. To protect us from these conditions, the body has developed a highly sophisticated, multilevel system of interactive defense mechanisms.
Human Defense Mechanisms

The human body has developed several means of protecting itself from injury and infection. **Innate immunity**, also known as natural or native immunity, includes natural barriers (physical, mechanical, and biochemical) and inflammation. Innate barriers form the first line of defense at the body's surfaces and are in place at birth to prevent damage by substances in the environment and thwart infection by pathogenic microorganisms. Surface barriers may also harbor a group of microorganisms known as the “normal flora” that can protect us from pathogens. If the surface barriers are breached, the second line of defense, the **inflammatory response**, is activated to protect the body from further injury, prevent infection of the injured tissue, and promote healing. The inflammatory response is a rapid activation of biochemical and cellular mechanisms that are relatively nonspecific, with similar responses being initiated against a wide variety of causes of tissue damage. The third line of defense, **adaptive immunity** (also known as acquired or specific immunity), is induced in a relatively slower and more specific process and targets particular invading microorganisms for the purpose of eradicating them. Adaptive immunity also involves “memory,” which results in a more rapid response during future exposure to the same microorganism. Comparisons among defense mechanisms are described in Table 6-1. The information presented in this chapter introduces the components and processes of innate immunity and sets the stage for Chapter 7, which presents an overview of adaptive immunity, and Chapter 8, which discusses processes of infection and alterations in immune defenses.

Innate Immunity

**Innate immunity** includes natural barriers (physical, mechanical, and biochemical) that form the first line of defense at the body's surfaces and are in place at birth. Surface barriers also may harbor a group of frequently benign microorganisms known as the “normal microbiome” that can protect us from pathogenic microorganisms. Innate immunity in the newborn and changes associated with aging are reviewed in the *Pediatric* and *Geriatric Considerations* boxes.

**First Line of Defense: Physical and Biochemical Barriers and the Human Microbiome**

**Physical Barriers**

The physical barriers that cover the external parts of the human body offer considerable protection from damage and infection. These barriers are composed of tightly associated epithelial cells of the skin and of the linings of the gastrointestinal, genitourinary, and respiratory tracts (*Figure 6-1*). When pathogens attempt to penetrate this physical barrier, they may be removed by mechanical means—sloughed off with dead skin cells as they are routinely replaced, expelled by coughing or sneezing, vomited from the stomach, or flushed from the urinary tract by urine. Epithelial cells of the upper respiratory tract also produce mucus and have hair-like cilia that trap and move pathogens upward to be expelled by coughing or sneezing. Additionally, the low temperature (such as on the skin) and the low pH (such as of the skin and stomach) generally inhibit microorganisms, most of which routinely require temperatures near 37°C (98.6°F) and pH near neutral for efficient growth.
Epithelial Cell–Derived Chemicals

Epithelial cells secrete an array of substances that protect against infection,
including mucus, perspiration (or sweat), saliva, tears, and earwax. These can trap potential invaders and contain substances that will kill microorganisms. Perspiration, tears, and saliva contain an enzyme (lysozyme) that attacks the cell walls of gram-positive bacteria. Sebaceous glands in the skin also secrete fatty acids and lactic acid that kill bacteria and fungi. These glandular secretions create an acidic (pH 3 to 5) and inhospitable environment for most bacteria.

Epithelial cell secretions also contain small-molecular-weight antimicrobial peptides that kill or inhibit the growth of disease-causing bacteria, fungi, and viruses. These are generally positively charged polypeptides of approximately 15 to 95 amino acids. More than a thousand antimicrobial peptides have been found, but the best studied are cathelicidins and defensins.

Several cathelicidins have been discovered in other species, but only one is currently known to function in humans. Bacteria have cholesterol-free cell membranes into which cathelicidin can insert and disrupt the membrane, killing the bacteria. Cathelicidin is produced by epithelial cells of the skin, gut, urinary tract, and respiratory tract, and is stored in neutrophils, mast cells, and monocytes and can be released during inflammation.

In contrast, many different human defensins have been identified. Defensin molecules can be further subdivided into α (at least six identified in humans) and β types (at least six identified, but perhaps up to 40 different molecules). The α-defensins often require activation by proteolytic enzymes, whereas the β-defensins are synthesized in active forms. Given the similarity in their chemical charges, defensins may kill bacteria in the same way as cathelicidin. The α-defensins are particularly rich in the granules of neutrophils and may contribute to the killing of bacteria by those cells. They are also found in Paneth cells lining the small intestine, where they protect against a variety of disease-causing microorganisms. The β-defensins are found in epithelial cells lining the respiratory, urinary, and intestinal tracts, as well as in the skin. In addition to antibacterial properties, β-defensins may also help protect epithelial surfaces from infection with adenovirus (one of the causes of the common cold) and human immunodeficiency virus (HIV). Both classes of antimicrobial peptides also can activate cells of the next levels of defense: innate and acquired immunity.

The lung also produces and secretes a family of glycoproteins, collectins, which includes surfactant proteins A through D and mannose-binding lectin. Collectins react with carbohydrates on the surface of a wide array of pathogenic microorganisms and help cells of the innate immune system (macrophages) to recognize and kill the microorganism. Mannose-binding lectin (MBL) recognizes a sugar commonly found on the surface of microbes and is a powerful activator of a plasma protein system (complement) resulting in damage to bacteria or increased
recognition by macrophages.

The Normal Microbiome

The body’s surfaces are colonized with an array of microorganisms, the normal microbiome previously known as normal flora. Each surface (the skin and the mucous membranes of the eyes, upper and lower gastrointestinal tracts, upper respiratory tract, urethra, and vagina) is colonized by a combination of bacteria and fungi that is unique to the particular location and individual\(^2\) (Table 6-2). The microorganisms in the microbiome do not normally cause disease, and although their relationship with humans has been referred to as commensal (to the benefit of one organism without affecting the other), the relationship may be more mutualistic (to the benefit of both organisms). Using the colon for an example, at birth the lower gut is relatively sterile but colonization with bacteria begins quickly, with the number, diversity, and concentration increasing progressively during the first year of life.

</tbody>
</table>

The normal microbiome benefits us in many ways; bacteria in the gastrointestinal (GI) tract produce (1) enzymes that facilitate the digestion and utilization of many molecules in the human diet, such as fatty acids and large polysaccharides; (2)
usable metabolites (e.g., vitamin K, B vitamins); and (3) antibacterial factors that prevent colonization by pathogenic microorganisms (see Chapter 8) For instance, members of the normal microbiome in the colon produce chemicals (ammonia, phenols, indoles, and other toxic materials) and proteins (bacteriocins) that are toxic to more pathogenic microorganisms. They also compete with pathogens for nutrients and block attachment to the epithelium, which is an obligatory first step in the infectious process by most pathogens. Additionally, the normal microbiome of the gut helps train the adaptive immune system by inducing growth of gut-associated lymphoid tissue (where most cells of the adaptive immune system reside) and the development of both local and systemic adaptive immunity. Bidirectional communication between the brain and GI tract (brain-gut axis) is influenced by GI bacteria with importance for cognitive function, behavior, pain modulation, and stress responses.3

Prolonged treatment with broad-spectrum antibiotics can alter the normal microbiome, decreasing its protective activity, and lead to an overgrowth of pathogenic microorganisms. In the intestine, overgrowth of the yeast Candida albicans or the bacteria Clostridium difficile (a cause of pseudomembranous colitis, an infection of the colon) may occur. The bacterium Lactobacillus is a major constituent of the normal gastrointestinal and vaginal microbiome in healthy women.4 This microorganism produces a variety of chemicals (e.g., hydrogen peroxide, lactic acid, bacteriocins) that help prevent infections of the vagina and urinary tract by other bacteria and yeast. Prolonged antibiotic treatment can diminish colonization with Lactobacillus and increase the risk for urologic or vaginal infections, such as vaginosis.

The mutualistic relationship with the microbiome is maintained through the physical integrity of the skin and mucosal epithelium and other mechanisms that protect the microbiome from the immune and inflammatory systems. Some members of the normal bacterial microbiome are opportunistic; opportunistic microorganisms can cause disease if the individual's defenses are compromised. These microorganisms are normally controlled by the innate and adaptive immune systems and contribute to our defenses. For example, Pseudomonas aeruginosa is a member of the normal microbiome of the skin and produces a toxin that protects against infections with staphylococcal and other bacteria. However, severe burns compromise the integrity of the skin and may lead to life-threatening systemic infections with Pseudomonas.

Quick Check 6-1
1. How do physical and mechanical barriers contribute to defense mechanisms?

2. What are antimicrobial peptides?

3. What two types of defensins contribute to the biochemical barrier?

4. What is the normal bacterial flora? What is its role in defense?

5. What are opportunistic microorganisms?

**Second Line of Defense: Inflammation**

Whereas the physical and chemical barriers of the innate immune system are relatively static, **inflammation** is programmed to respond to cellular or tissue damage, whether the damaged tissue is septic or sterile. The response is a rapid initiation of an interactive system of humoral (soluble in the blood) and cellular systems designed to limit the extent of tissue damage, destroy contaminating infectious microorganisms, initiate the adaptive immune response, and begin the healing process.

The **inflammatory response** (1) occurs in tissues with a blood supply (vascularized); (2) is activated *rapidly* (within seconds) after damage occurs; (3) depends on the activity of both cellular and chemical components; and (4) is *nonspecific*, meaning that it takes place in approximately the same way regardless of the type of stimulus or whether exposure to the same stimulus has occurred in the past.

Inflammation will be activated by virtually any injury to vascularized tissues, including infection or tissue necrosis (e.g., ischemia, trauma, physical or chemical injury, foreign bodies, immune reactions). The classic or cardinal signs of acute inflammation were described in the first century by a Roman named Celsus and included rubor (redness), calor (heat), tumor (swelling), and dolor (pain). A fifth sign, functio laesa (loss of function), was added later. Microscopic inflammatory changes occur within seconds in the microcirculation (arterioles, capillaries, and venules) near the site of an injury and include the following processes (Figure 6-2):

1. **Vasodilation** (increased size of the blood vessels), which causes slower blood velocity and increases blood flow to the injured site

2. **Increased vascular permeability** (the blood vessels become porous from contraction of endothelial cells) and leakage of fluid out of the vessel (exudation), causing swelling (edema) at the site of injury; as plasma moves outward, blood in
the microcirculation becomes more viscous and flows more slowly, and the increased blood flow and increasing concentration of red cells at the site of inflammation cause locally increased redness (erythema) and warmth

3. White blood cell adherence to the inner walls of vessels and their migration through enlarged junctions between the endothelial cells lining the vessels into the surrounding tissue
Compared with the normal circulation, inflammation is characterized by:

1. Dilation of the blood vessels and increased blood flow, leading to erythema and warmth;
2. Increased vascular permeability with leakage of plasma from the vessels, leading to edema;
3. Movement of leukocytes from the vessels into the site of injury.

(From Kumar V et al: Robbins and Cotran pathological basis of disease, ed 8, Philadelphia, 2009, Saunders.)
Each of the characteristic changes associated with inflammation is the direct result of the activation and interactions of a host of chemicals and cellular components found in the blood and tissues. The vascular changes deliver leukocytes (particularly neutrophils), plasma proteins, and other biochemical mediators to the site of injury, where they act in concert. Some of these chemical mediators activate pain fibers. The tissue injury, pain, and swelling contribute to loss of function. Figure 6-3 summarizes the process of inflammation. The lymphatic vessels drain the extravascular fluid to the lymph nodes and may, themselves, become secondarily inflamed; lymphangitis of the lymph vessels and lymphadenitis of the nodes, which become hyperplastic, enlarged, and frequently painful.

Figure 6-3  Acute Inflammatory Response. Inflammation is usually initiated by cellular injury and may be complicated by infection. Mast cell degranulation, the activation of three plasma systems, and the release of subcellular components from the damaged cells occur as a consequence. These systems are interdependent, so that induction of one (e.g., mast cell degranulation) can result in the induction of the other two. The result is the development of the characteristic microscopic and clinical hallmarks of inflammation. The figure numbers refer to additional figures in which more detailed information may be found on that portion of the response.

There are several benefits of inflammation, including the following:
1. Prevents infection and further damage by invading microorganisms. The inflammatory exudate dilutes toxins produced by bacteria and released from dying cells. The activation of plasma protein systems (e.g., complement and clotting systems) helps contain and destroy bacteria. The influx of phagocytes (e.g., neutrophils, macrophages) destroys cellular debris and microorganisms.

2. Limits and controls the inflammatory process. The influx of plasma protein systems (e.g., clotting system), plasma enzymes, and cells (e.g., eosinophils) prevents the inflammatory response from spreading to areas of healthy tissue.

3. Interacts with components of the adaptive immune system to elicit a more specific response to contaminating pathogen(s) through the influx of macrophages and lymphocytes that destroy pathogens.

4. Prepares the area of injury for healing and repair through removal of bacterial products, dead cells, and other products of inflammation (e.g., by way of channels through the epithelium or drainage by lymphatic vessels).

   Fluid and debris that accumulate at an inflamed site are drained by lymphatic vessels. This process also facilitates the development of acquired immunity because microbial antigens in lymphatic fluid pass through the lymph nodes, where they encounter lymphocytes.

---

**Quick Check 6-2**

1. Why are innate immunity and inflammation described as “nonspecific”?

2. How are the five classic superficial symptoms of inflammation related to the process of inflammation?

3. Describe the basic steps in acute inflammation.

4. What are the benefits of inflammation?

---

**Plasma Protein Systems and Inflammation**

Three key plasma protein systems are essential to an effective inflammatory response (Figure 6-4). These are the complement system, the clotting system, and the kinin system. Although each system has a unique role in inflammation, they have
many similarities. Each system consists of multiple proteins found in the blood, usually in inactive forms; several are enzymes that circulate as proenzymes. Each system contains a few proteins that can be activated early in inflammation. Activation of the first components results in sequential activation of other components of the system, leading to a biologic function that helps protect the individual. This sequential activation is referred to as a cascade. Thus, we occasionally refer to the complement cascade, the clotting cascade, or the kinin cascade. In some cases, activation of a particular protein in the system may require that it be enzymatically cut into two pieces of different size. Usually the larger fragment continues the cascade by activating the next component, and the smaller fragment frequently has potent proinflammatory activities.
FIGURE 6-4  Plasma Protein Systems in Inflammation: Complement, Clotting, and Kinin Systems. Each plasma protein system consists of a family of proteins that are activated in sequence to create potent biologic effects. The complement system can be activated by three mechanisms, each of which results in proteolytic activation of C3. The fragments of C3 activation, C3a and C3b, are major components of inflammation. C3a is a potent anaphylatoxin, which induces degranulation of mast cells. C3b can bind to the surface or cells, such as bacteria, and either serve as an opsonin for phagocytosis or proteolytically activate the next component of the complement cascade, C5. The smaller fragment of C5 activation is C5a, a powerful anaphylatoxin, and is also chemotactic for neutrophils, attracting them to the site of inflammation. The larger fragment, C5b, activates the components of the membrane attack complex (C5-C9), which damage the bacterial membrane and kill the bacteria. The clotting system can be activated by the tissue factor (extrinsic) pathway and the contact activation (intrinsic) pathway. All routes of clotting initiation lead to activation of factor X and thrombin. Thrombin is an enzyme that proteolytically activates fibrinogen to form fibrin and small fibrinopeptides (FPs). Fibrin polymerizes to form a clot, and the FP are highly active as chemotactic factors and cause increased vascular permeability. The Xlla produced by the clotting system can also be activated by kallikrein of the kinin system (red arrow). Prekallikrein is enzymatically converted to kininogen, which activates bradykinin. Bradykinin functions similar to histamine and increases vascular permeability. Bradykinin can also stimulate nerve endings to cause pain. FP, Fibrinopeptide; TF, tissue factor.

Complement System

The complement system consists of a large number of proteins (sometimes called complement factors) that together constitute about 10% of the total circulating serum protein. Activation of the complement system produces several factors that can destroy pathogens directly or can activate or increase the activity of many other components of the inflammatory and adaptive immune response. Factors produced
during activation of the complement system are among the body's most potent defenders, particularly against bacterial infection.

The most important function of the complement cascade is activation of C3 and C5, which results in a variety of molecules that are (1) opsonins, (2) chemotactic factors, or (3) anaphylatoxins.\(^5\) **Opsonins** coat the surface of bacteria and increase their susceptibility to being phagocytosed (eaten) and killed by inflammatory cells, such as neutrophils and macrophages. **Chemotactic factors** diffuse from a site of inflammation and attract phagocytic cells to that site. **Anaphylatoxins** induce rapid degranulation of mast cells (i.e., release of histamine that induces vasodilation and increased capillary permeability), a major cellular component of inflammation. The most potent complement products are C3b (opsonin), C3a (anaphylatoxin), and C5a (anaphylatoxin, chemotactic factor). Activation of terminal complement components C5b through C9 (membrane attack complex, or MAC) results in a complex that creates pores in the outer membranes of cells or bacteria. The pores disrupt the cell's membrane and permit water to enter, causing the death of the cell.

Three major pathways control the activation of complement (see Figure 6-4). The **classical pathway** is primarily activated by antibodies, which are proteins of the acquired immune system. Antibodies must first bind to their targets, called antigens, which can be proteins or carbohydrates from bacteria or other infectious agents. Antibodies activate the first component of complement, C1, which leads to activation of other complement components, leading to activation of C3 and C5. Thus, antibodies of the acquired immune response can use the complement system to kill bacteria and activate inflammation.

The **alternative pathway** is activated by several substances found on the surface of infectious organisms (e.g., lipopolysaccharides [endotoxin] on the bacterial surface or yeast cell wall carbohydrates [zymosan]). This pathway uses unique proteins (factor B, factor D, and properdin) to form a complex that activates C3. C3 activation leads to C5 activation and convergence with the classical pathway. Thus, the complement system can be directly activated by certain infectious organisms without antibody being present.

The **lectin pathway** is similar to the classical pathway but is independent of antibody. It is activated by several plasma proteins, particularly mannose-binding lectin (MBL). MBL binds to bacterial polysaccharides containing the carbohydrate mannose and activates complement through two proteins that are similar to C1—MASP-1 (mannose-binding lectin-associated serine protease) and MASP-2.\(^6\) Thus, infectious agents that do not activate the alternative pathway may be susceptible to complement through the lectin pathway.

In summary, the complement cascade can be activated by at least three different means, and its products have four functions: (1) opsonization (C3b), (2)
anaphylatoxic activity resulting in mast cell degranulation (C3a, C5a), (3) leukocyte chemotaxis (C5a), and (4) cell lysis (C5b-C9; membrane attack complex [MAC]).

**Clotting System**

The *clotting (coagulation) system* is a group of plasma proteins that, when activated sequentially, form a blood clot. A *blood clot* is a meshwork of protein (fibrin) strands that contains platelets (the primary cellular initiator of clotting) and traps other cells, such as erythrocytes, phagocytes, and microorganisms. Clots (1) plug damaged vessels and stop bleeding, (2) trap microorganisms and prevent their spread to adjacent tissues, and (3) provide a framework for future repair and healing. Specific details and illustrations of the clotting system are presented in Chapter 20 (also see Figure 20-18) and only the relationship between clotting and inflammation is presented here.

The clotting system can be activated by many substances that are released during tissue injury and infection, including collagen, proteinases, kallikrein, and plasmin, as well as by bacterial products such as endotoxins. Like the complement cascade, the coagulation cascade can be activated through different pathways that converge and result in the formation of a clot (see Figure 6-4). The *tissue factor (extrinsic) pathway* is activated by *tissue factor (TF)* (also called *tissue thromboplastin*) that is released by damaged endothelial cells in blood vessels and reacts with activated factor VII (VIIa). The *contact activation (intrinsic) pathway* is activated when the vessel wall is damaged and Hageman factor (factor XII) in plasma contacts negatively-charged subendothelial substances. The pathways converge at factor X. Activation of factor X begins a common pathway leading to activation of fibrin that polymerizes to form a fibrin clot.

As with the complement system, activation of the clotting system produces protein fragments known as fibrinopeptides (FPs) A and B that enhance the inflammatory response. Fibrinopeptides are released from fibrinogen when fibrin is produced. Both fibrinopeptides (especially fibrinopeptide B) are chemotactic for neutrophils and increase vascular permeability by enhancing the effects of bradykinin (formed from the kinin system) on endothelial cells.

**Kinin System**

The third plasma protein system, the *kinin system* (see Figure 6-4), interacts closely with the coagulation system. Both the clotting and kinin systems can be initiated through activation of *Hageman factor (factor XII)* to factor XIIa. Another name for factor XIIa is *prekallikrein* activator because it enzymatically activates the first component of the kinin system, prekallikrein. The final product of the kinin system
is a small-molecular-weight molecule, \textit{bradykinin}, which is produced from a larger precursor molecule, \textit{kininogen}. Bradykinin causes dilation of blood vessels, acts with prostaglandins to induce pain, causes smooth muscle cell contraction, and increases vascular permeability.

\textbf{Control and Interaction of Plasma Protein Systems}

The three plasma protein systems are highly interactive so that activation of one results in production of a large number of very potent, biologically active substances that further activate the other systems. Very tight regulation of these processes is essential for the following two reasons.

1. The inflammatory process is critical for an individual's survival; thus efficient activation must be guaranteed regardless of the cause of tissue injury. Interaction among the plasma systems may result in activation of the entire inflammatory response regardless of which system is activated initially.

2. The biochemical mediators generated during these processes are potent and potentially detrimental to the individual, and their actions must be strictly confined to injured or infected tissues.

Therefore, multiple mechanisms are available to either activate or inactivate (regulate) these plasma protein systems. For instance, the plasma that enters the tissues during inflammation (edema) contains enzymes that destroy mediators of inflammation. \textit{Carboxypeptidase} inactivates the anaphylatoxic activities of C3a and C5a, and kininases degrade kinins. \textit{Histaminase} degrades histamine and kallikrein and down-regulates the inflammatory response.

The formation of clots also activates a \textit{fibrinolytic system} that is designed to limit the size of the clot and remove the clot after bleeding has ceased. Thrombin of the clotting system activates \textit{plasminogen} in the blood to form the enzyme plasmin. The primary activity of \textit{plasmin} is to degrade fibrin polymers in clots. However, plasmin can also activate the complement cascade through components C1, C3, and C5 and the kinin cascade by activating factor XII and producing prekallikrein activator.

Another example of a common regulator is \textit{C1 esterase inhibitor (C1 inh)}. C1 inh inhibits complement activation through C1 (classical pathway), MASP-2 (lectin pathway), and C3b (alternative pathway). It is also a major inhibitor of the clotting and kinin pathway components (e.g., kallikrein, factor XIIa). A genetic defect in C1 inh \textit{(C1 inh deficiency)} results in \textit{hereditary angioedema}, which is a self-limiting edema of cutaneous and mucosal layers resulting from stress, illness, or relative
minor or unapparent trauma. The disease is characterized by hyperactivation of all three plasma protein systems, although excessive production of bradykinin appears to be the principal cause of increased vascular permeability.

Many cells are protected from inadvertent complement system damage by factors linked to the external surface of the plasma membrane. Two examples are decay accelerating factor (DAF) and CD59; DAF prevents activation of C3 and CD59 inhibits the membrane attack complex.

Quick Check 6-3

1. What are the three most important products of the complement system?

2. How is the coagulation cascade activated? How is it related to the plasma kinin cascade?

3. What factors control the plasma protein systems of inflammation?

Cellular Components of Inflammation

Inflammation is a process in vascular tissue; thus the cellular components can be found in the blood or in tissue surrounding the blood vessels. The blood vessels are lined with endothelial cells, which under normal conditions actively maintain blood flow. During inflammation the vascular endothelium becomes a principal coordinator of blood clotting and the passage of cells and fluid into the tissue. The tissues close to the vessels contain mast cells, which are probably the most important activators of inflammation, and dendritic cells, which connect the innate and acquired immune responses. The blood contains a complex mixture of cells (Figure 6-5 and see Chapter 20). Blood cells are divided into erythrocytes (red blood cells), platelets, and leukocytes (white blood cells). Erythrocytes carry oxygen to the tissues and platelets are small cell fragments involved in blood clotting. Leukocytes are subdivided into granulocytes (containing many enzyme-filled cytoplasmic granules), monocytes, and lymphocytes. Granulocytes are the most common leukocytes and are classified by the type of stains needed to visualize enzyme-containing granules in their cytoplasm (basophils, eosinophils, and neutrophils). Monocytes are precursors of macrophages that are found in the tissue. Various forms of lymphocytes participate in the innate immune response (e.g., natural killer [NK] cells) and the acquired immune response (B and T cells).
Cells of both innate and acquired immune systems respond to molecules produced at a site of cellular damage and are recruited to that site to augment the protective response. These molecules originate from destroyed or damaged cells, contaminating microbes, activation of the plasma protein systems, or secretions by other cells of the innate or acquired immune systems. Each cell has a set of cell surface receptors that specifically bind these molecules, resulting in activation of intracellular signaling pathways and activation of the cell itself. Activation may result in the cell gaining a function critical to the inflammatory response or the induction of the release of additional cellular products that increase inflammation, or both. Most of these inflammatory cells and protein systems, along with the substances they produce, act at the site of tissue injury to confine the extent of damage; kill microorganisms; remove the cellular debris; and activate healing,
tissue regeneration (a process known as resolution), or repair.

**Cellular Receptors**

As will be discussed in Chapter 7, B and T lymphocytes of the adaptive immune system have evolved surface receptors (i.e., the T-cell receptor, or TCR, and the B-cell receptor, or BCR) that bind a large spectrum of antigens. Cells involved in innate resistance have evolved a different set of receptors that recognize a much more limited array of specific molecules (ligands). These are referred to as pattern recognition receptors (PRRs). PRRs recognize two types of molecular patterns: molecules that are expressed by infectious agents, either found on their surface or released as soluble molecules (pathogen-associated molecular patterns, or PAMPs); or products of cellular damage (damage-associated molecular patterns, or DAMPs). Thus cells of the innate immune system can respond to both sterile (through DAMPs) and septic (through PAMPs and DAMPs) tissue damage. It is estimated that at least 100 different PRRs are expressed that recognize more than 1000 different molecules.

PRRs are generally expressed on cells in tissues near the body's surface (i.e., skin, respiratory tract, gastrointestinal tract, genitourinary tract) where they monitor the environment for products of cellular damage and potentially infectious microorganisms. Classes of cellular PRRs primarily differ in the specificity of ligands they bind. PRRs can be found as cell surface receptors that bind extracellular ligands, in endosomes in contact with ingested microbes and other materials, in the cytosol where they bind intracellular materials resulting from cellular damage, or secreted into the extracellular environment. An example of a secreted PRR is mannose-binding lectin of the lectin pathway of complement activation (see p. 139).

**Toll-like receptors (TLRs)** primarily recognize a large variety of PAMPs located on the microorganism's cell wall or surface (e.g., bacterial lipopolysaccharide [LPS], peptidoglycans, lipoproteins, yeast zymosan, viral coat proteins), other surface structures (e.g., bacterial flagellin), or microbial nucleic acid (e.g., bacterial DNA, viral double-stranded RNA).

Ten different TLRs have been described in humans (Table 6-3). They are expressed on the surface of many cells that have direct and early contact with potential pathogenic microorganisms, including mucosal epithelial cells, mast cells, neutrophils, macrophages, dendritic cells, and some subpopulations of lymphocytes. TLRs are linked to pathways that produce two groups of transcription factors: NF-κB, which controls synthesis and release of cytokines; and interferon regulatory factors (IRFs), which control the production of anti-viral type I interferons.

**Complement receptors** are found on many cells of the innate and acquired immune responses (e.g., granulocytes, monocytes/macrophages, lymphocytes, mast cells, erythrocytes, platelets), as well as some epithelial cells. They recognize several fragments produced through activation of the complement system, particularly C3a, C5a, and C3b.

**Scavenger receptors** are primarily expressed on macrophages and facilitate recognition and phagocytosis of bacterial pathogens, as well as damaged cells and altered soluble lipoproteins associated with vascular damage (e.g., high-density lipoprotein [HDL], acetylated low-density lipoprotein [LDL], oxidized LDL). More than eight receptors have been identified. Some scavenger receptors (e.g., SR-PSOX) recognize the cell membrane phospholipid phosphatidylserine (PS). PS is normally sequestered on the cytoplasmic surface of the cell membrane, but is externalized under a very limited variety of conditions, including erythrocyte senescence and cellular apoptosis. Thus macrophages, through this receptor, can identify and remove old red blood cells and cells undergoing apoptosis.

**NOD-like receptors (NLRs)** are cytoplasmic receptors that recognize products of microbes and damaged cells. At least 22 NLRs have been identified in humans. NOD-1 and NOD-2 are cytoplasmic and recognize fragments of peptidoglycans from intracellular bacteria and initiate production of proinflammatory mediators, such as tumor necrosis factor (TNF) and interleukin-6 (IL-6). Other NLRs associate with intracellular multiprotein complexes called **inflammasomes**. Inflammasomes primarily bind cellular stress-related molecules, a type of DAMP, and control the production of the inflammatory cytokines interleukin-1β (IL-1β) and IL-18.
Cellular Products

To elicit an effective inflammatory (or adaptive immune) response, intercellular communication and cooperation are necessary. **Cytokines** constitute a large family of small-molecular-weight soluble intercellular-signaling molecules that are secreted, bind to specific cell membrane receptors, and regulate innate or adaptive immunity (Figure 6-6). Cytokines may be either **proinflammatory** or **anti-inflammatory** in nature, depending on whether they tend to induce or inhibit the inflammatory response. These molecules usually diffuse over short distances, but some effects occur over long distances, such as the systemic induction of fever by some cytokines (i.e., endogenous pyrogens) that are produced at an inflammatory site. Binding of cytokines to a target cell often induces synthesis of additional cellular products. For example, binding of the cytokine TNF-α to a cell may result in synthesis and release of IL-1.
A large number of cytokines have been described and are classified into several families. The terms lymphokines and monokines refer respectively to cytokines secreted from lymphocytes or monocytes, although cytokines are secreted by many different types of cells. Chemokines are members of a special family of cytokines that are chemotactic and primarily attract leukocytes to sites of inflammation. Chemokines are synthesized by many cell types, including macrophages, fibroblasts, and endothelial cells, in response to proinflammatory cytokines, such as TNF-α. To date, more than 50 different human chemokines have been described.
Examples include those that primarily attract macrophages (e.g., monocyte/macrophage chemotactic proteins [MCP-1, MCP-2, and MCP-3]), macrophage inflammatory proteins ([MIP-α and MIP-1β]), or neutrophils (e.g., interleukin-8 [IL-8]).

**Interleukins (ILs)** are produced predominantly by macrophages and lymphocytes in response to stimulation of PRRs or by other cytokines. More than 30 interleukins have been identified. Their effects include the following:

1. Alteration of adhesion molecule expression on many types of cells
2. Attraction of leukocytes to a site of inflammation (chemotaxis)
3. Induction of proliferation and maturation of leukocytes in the bone marrow
4. General enhancement or suppression of inflammation
5. Development of the acquired immune response

Two major proinflammatory ILs are interleukin-1 and interleukin-6, which cooperate closely with another cytokine, tumor necrosis factor-alpha. **Interleukin-1 (IL-1)** is produced in two forms, IL-1α and IL-1β, mainly by macrophages. IL-1 activates monocytes, other macrophages, and lymphocytes, thereby enhancing both innate and acquired immunity, and acts as a growth factor for many cells. It has several effects on neutrophils, including induction of proliferation (resulting in an increase in the number of circulating neutrophils), attraction to an inflammatory site (chemotaxis), and increased cellular respiration and lysosomal enzyme activity (both effects resulting in increased cellular killing of bacteria). IL-1 is an endogenous pyrogen (i.e., fever-causing cytokine) that reacts with receptors on cells of the hypothalamus and affects the body’s thermostat, resulting in fever.

**Interleukin-6 (IL-6)** is produced by macrophages, lymphocytes, fibroblasts, and other cells. IL-6 directly induces hepatocytes (liver cells) to produce many of the proteins needed in inflammation (acute-phase reactants, discussed later in this chapter). IL-6 also stimulates growth and differentiation of blood cells in the bone marrow and the growth of fibroblasts (required for wound healing).

Although not classified as an interleukin, **tumor necrosis factor-alpha (TNF-α)** is secreted by macrophages and other cells (e.g., mast cells) in response to stimulation of TLRs. TNF-α induces a multitude of proinflammatory effects, particularly on the vascular endothelium and macrophages. When secreted in large amounts, TNF-α has systemic effects that include the following:
1. Inducing fever by acting as an endogenous pyrogen

2. Causing increased synthesis of inflammation-related serum proteins by the liver

3. Causing muscle wasting (cachexia) and intravascular thrombosis in cases of severe infection and cancer.

Very high levels of TNF-α can be lethal and are probably responsible for fatalities from shock caused by gram-negative bacterial infections.

Some cytokines are anti-inflammatory and diminish the inflammatory response. The most important are interleukin-10 and transforming growth factor-beta. **Interleukin-10 (IL-10)** is primarily produced by lymphocytes and suppresses the growth of other lymphocytes and the production of proinflammatory cytokines by macrophages, leading to down-regulation of both inflammatory and acquired immune responses. **Transforming growth factors**, including **transforming growth factor-beta (TGF-β)**, are produced by many cells in response to inflammation and induce cell division and differentiation of other cell types, such as immature blood cells.

**Interferons (IFNs)** are members of a family of cytokines that protect against viral infections and modulate the inflammatory response. (Mechanisms of viral infection are described in Chapter 8.) Type I interferons (primarily IFN-α, IFN-β) are produced and released by virally infected cells in response to viral double-stranded RNA and other viral PAMPs. These IFNs do not kill viruses directly but instead are secreted and induce antiviral proteins and protection in neighboring healthy cells. Type II interferon (IFN-γ) is produced primarily by lymphocytes; it activates macrophages, resulting in increased capacity to kill infectious agents (including viruses and bacteria), and enhances the development of acquired immune responses against viruses.

**Mast Cells and Basophils**

The mast cell is probably the most important cellular activator of the inflammatory response. **Mast cells** are filled with granules and located in the loose connective tissues close to blood vessels near the body's outer surfaces (i.e., in the skin and lining the gastrointestinal and respiratory tracts). **Basophils** are found in the blood and probably function in the same way as tissue mast cells. A great number of stimuli activate mast cells to release potent soluble inducers of inflammation. These are released by (1) **degranulation** (the release of the contents of mast cell granules) and (2) **synthesis** (the new production and release of mediators in response to a stimulus) (Figure 6-7).
FIGURE 6-7 Mast Cell and Mast Cell Degranulation and Synthesis of Biologic Mediators During Inflammation. A, Colorized photomicrograph of mast cell; dense red granules contain histamine and other biologically active substances. Among these are histamine, which is a major initiator of vascular changes, and a variety of chemotactic factors. B, Mast cell degranulation (left) and synthesis (right). Histamine and other biologically active substances are released immediately after stimulation of mast cells. (A from Roitt IM et al: Immunology, ed 3, St Louis, 1993, Mosby.)
Degranulation.

In response to a stimulus, biochemical mediators in the mast cell granules, including histamine, chemotactic factors, and cytokines (e.g., tumor necrosis factor-alpha [TNF-α], IL-4), are released within seconds and exert their effects immediately. **Histamine** is a small-molecular-weight molecule with potent effects on many other cells, particularly those that control the circulation. Histamine, along with serotonin (found in many cells, but not human mast cells), is called a vasoactive amine. These molecules cause temporary, rapid constriction of smooth muscle and dilation of the postcapillary venules, which results in increased blood flow into the microcirculation. Histamine also causes increased vascular permeability resulting from retraction of endothelial cells lining the capillaries and increased adherence of leukocytes to the endothelium. Histamine affects cells by binding to histamine H1 and H2 receptors on the target cell surface (Figure 6-8). Antihistamines are drugs that block the binding of histamine to its receptors, resulting in decreased inflammation.

![Figure 6-8](image)

**FIGURE 6-8** Effects of Histamine Through H1 and H2 Receptors. The effects depend on (1) the density and affinity of H1 or H2 receptors on the target cell and (2) the identity of the target cell. *ATP*, Adenosine triphosphate; *cAMP*, cyclic adenosine monophosphate; *cGMP*, cyclic guanosine monophosphate; *GTP*, guanosine triphosphate.

Binding of histamine to the *H1 receptor* is essentially proinflammatory; that is, it promotes inflammation. On the other hand, binding to the *H2 receptor* is generally anti-inflammatory because it results in suppression of leukocyte function. The H1
receptor is present on smooth muscle cells, especially those of the bronchi, and causes bronchial smooth muscle to contract (bronchoconstriction) when stimulated. Both types of receptors are distributed among many different cells and are often present on the same cells and may act in an antagonistic fashion. For instance, stimulation of H1 receptors on neutrophils results in augmentation of neutrophil chemotaxis, whereas H2 receptor stimulation results in its inhibition. The H2 receptor is especially abundant on parietal cells of the stomach mucosa and induces the secretion of gastric acid as part of the normal physiology of the stomach. The role of histamine receptors and hypersensitivity is discussed in Chapter 8.

Mast cell granules also contain chemotactic factors, two of which are neutrophil chemotactic factor (NCF) and eosinophil chemotactic factor of anaphylaxis (ECF-A). Chemotaxis is directional movement of cells along a chemical gradient formed by a chemotactic factor. Neutrophils are the predominant cell needed to kill bacteria in the early stages of inflammation. Eosinophils help regulate the inflammatory response. Both cells are discussed in more detail later in this chapter.

**Synthesis of mediators.**

Activated mast cells initiate synthesis of other mediators of inflammation. These include leukotrienes, prostaglandins, and platelet-activating factor, which are produced from lipids (arachidonic acid) in the plasma membrane. Leukotrienes (slow-reacting substances of anaphylaxis [SRS-A]) are sulfur-containing lipids produced by lipoxygenase that initiate histamine-like effects: smooth muscle contraction and increased vascular permeability. Leukotrienes appear to be important in the later stages of the inflammatory response because they stimulate slower and more prolonged inflammatory responses than does histamine.

**Prostaglandins** cause increased vascular permeability, neutrophil chemotaxis, and pain by direct effects on nerves. They are long-chain, unsaturated fatty acids produced by the action of the enzyme cyclooxygenase (COX) on arachidonic acid; prostaglandins are classified into groups (E, D, A, F, and B) according to their structure with numeral subscripts designating the number of double bonds. Prostaglandins E1 and E2 cause increased vascular permeability and smooth muscle contraction. COX exists in two different forms: COX-1 is found in most tissues and COX-2 is associated with inflammation. Aspirin and other nonsteroidal anti-inflammatory drugs inhibit both COX-1 and COX-2, but inhibition of COX-1 causes complications, such as gastrointestinal toxicity. Selective COX-2 inhibitors are now available.

**Platelet-activating factor (PAF)** is produced by removal of a fatty acid from the plasma membrane phospholipids by phospholipase A2. Although mast cells are a
major source of PAF, this molecule also can be produced by neutrophils, monocytes, endothelial cells, and platelets. The biologic activity of PAF is virtually identical to that of leukotrienes, namely, causing endothelial cell retraction to increase vascular permeability, leukocyte adhesion to endothelial cells, and platelet activation.

**Endothelium**

The lining of blood vessels consists of a layer of endothelial cells that adhere to an underlying matrix of connective tissue that contains a variety of proteins, including collagen, fibronectin, and laminins. **Endothelial cells** regulate circulating components of the inflammatory system and maintain normal blood flow by preventing spontaneous activation of platelets and members of the clotting system. Nitric oxide (NO) produced from arginine and prostacyclin (PGI₂) from arachidonic acid maintain blood flow and pressure and inhibit platelet activation. PGI₂ and NO are synergistic. NO is released continually to relax vascular smooth muscle and suppress the effects of low levels of cytokines, thus maintaining vascular tone. PGI₂ production varies a great deal and is increased when additional regulation is needed.

Damage to the endothelial cell lining of the vessel exposes the subendothelial connective tissue matrix, which is prothrombogenic and initiates platelet activation and formation of clots (the contact activation [intrinsic] clotting pathway). Proinflammatory mediators (e.g., histamine, prostacyclin, and many others) affect the endothelium, resulting in adherence of leukocytes to the vessel surface, invasion of leukocytes into the tissue, and efflux of plasma from the vessel.

**Platelets**

Platelets are anucleate cytoplasmic fragments formed from megakaryocytes. They circulate in the bloodstream until vascular injury occurs resulting in platelet activation by many products of tissue destruction and inflammation, including collagen, thrombin, and platelet-activating factor. Activated platelets (1) interact with components of the coagulation cascade to stop bleeding; (2) degranulate, releasing biochemical mediators such as serotonin, which has vascular effects similar to those of histamine; and (3) synthesize thromboxane A₂ (TXA₂) from prostaglandin H₂. TXA₂ is a potent vasoconstrictor and inducer of platelet aggregation. Prolonged use of low-dose aspirin preferentially suppresses production of TXA₂ without interfering with the production of anti-inflammatory PGI₂ by the endothelium. Platelets also release growth factors that promote wound
Phagocytes

The primary role of most granulocytes (neutrophils, eosinophils, basophils) and monocytes/macrophages is phagocytosis—the process by which a cell ingests and disposes of damaged cells and foreign material, including microorganisms.

Neutrophils.

The neutrophil, or polymorphonuclear neutrophil (PMN), is a member of the granulocytic series of white blood cells and is named for the characteristic staining pattern of its granules as well as its multilobed nucleus. Neutrophils are the predominant phagocytes in the early inflammatory site, arriving within 6 to 12 hours after the initial injury. Several inflammatory mediators (e.g., some bacterial proteins, complement fragments C3a and C5a, and mast cell neutrophil chemotactic factor) specifically and rapidly attract neutrophils from the circulation and activate them.17

Because the neutrophil is a mature cell that is incapable of division and sensitive to acidic environments, it is short lived at the inflammatory site and becomes a component of the purulent exudate, or pus, which is removed from the body through the epithelium or drained from the infected site via the lymphatic system. (The lymphatic system is described in Chapter 23.) The primary roles of the neutrophil are removal of debris and dead cells in sterile lesions, such as burns, and destruction of bacteria in nonsterile lesions.

Eosinophils.

Another population of granulocytes is the eosinophil. Although eosinophils are only mildly phagocytic, they have two specific functions: (1) serve as the body's primary defense against parasites, and (2) help regulate vascular mediators released from mast cells. The role of eosinophils in resistance to parasites occurs in collaboration with specific antibodies produced by the acquired immune system (discussed in Chapter 7).18

Regulation of mast cell–derived inflammatory mediators is critical to control inflammation. The acute inflammatory response is needed only in a circumscribed area and for a limited time. Therefore, control mechanisms are necessary to prevent biochemical mediators from evoking more inflammation than necessary. Mast cell eosinophil chemotactic factor–A (ECF-A) attracts eosinophils to the site of inflammation. Eosinophil lysosomal granules contain enzymes that degrade vasoactive molecules, thereby controlling the vascular effects of inflammation.
Histaminase degrades histamine, and arylsulfatase B degrades leukotrienes.

**Basophils.**

The baseline is the least prevalent granulocyte in the blood. It is very similar to mast cells in the content of its granules and, in addition, is an important source of the cytokine IL-4, which is a key regulator of the adaptive immune response. Although often associated with allergies and asthma, its primary role is yet unknown.

**Monocytes and macrophages.**

Monocytes are the largest normal blood cells (14 to 20 µm in diameter). Monocytes are produced in the bone marrow, enter the circulation, and migrate to the inflammatory site where they develop into macrophages. Monocytes also appear to be the precursors of macrophages that are found in tissues (tissue macrophages) including Kupffer cells in the liver, alveolar macrophages in the lungs, and microglia in the brain. Macrophages are generally larger (20 to 40 µm) and are more active as phagocytes than their monocytic precursors. Macrophages, particularly those residing in the tissues, are often important cellular initiators of the inflammatory response.

Monocyte-derived macrophages from the circulation may appear at the inflammatory site as soon as 24 hours after the initial neutrophil infiltration, but usually arrive 3 to 7 days later. Neutrophils and monocytes/macrophages differ chiefly in the following ways:

1. **Speed:** Neutrophils arrive at the injury site first, whereas macrophages move more sluggishly.

2. **Active life span:** Macrophages survive and divide in the acidic inflammatory site, whereas neutrophils cannot.

3. **Chemotactic factors:** Neutrophils and macrophages are not attracted by the same factors, such as macrophage chemotactic factor, which is released by neutrophils.

4. **Enzymatic content of their lysosomes, or digestive vacuoles:** Neutrophils have a more active NADPH oxidase and produce more hydrogen peroxide; macrophage phagolysosomes are more acidic, favoring the activity of acidic proteases and other enzymes.

5. **Role in the immune response:** Macrophages, but not neutrophils, are involved in
activation of the adaptive immune system.

6. Role in wound repair: Macrophages are the primary cells that infiltrate tissue in wounds, remove cells and cellular debris, promote angiogenesis, and produce cytokines and growth factors that suppress further inflammation and initiate healing by promoting epithelial cell division, activating fibroblasts, and promoting synthesis of extracellular matrix and collagen.

The bactericidal activity of macrophages can increase markedly with the help of inflammatory cytokines produced by cells of the acquired immune system (subsets of T lymphocytes) or cells activated through Toll-like receptors (TLRs). Macrophage activation results in two subpopulations of cells. M1 macrophages are activated through TLRs by substances found in sites of inflammation and have greater bacterial killing capacity. M2 macrophages are activated by lymphocyte-produced cytokines and are primarily involved in healing and repair.

Several bacteria are resistant to killing by granulocytes and can even survive inside macrophages. Microorganisms, such as *Mycobacterium tuberculosis* (tuberculosis), *Mycobacterium leprae* (leprosy), *Salmonella typhi* (typhoid fever), *Brucella abortus* (brucellosis), and *Listeria monocytogenes* (listeriosis), can remain dormant or multiply inside the phagolysosomes of macrophages.

**Dendritic cells.**

Dendritic cells provide one of the major links between the innate and acquired immune responses. They are the primary phagocytic cells located in the peripheral organs and skin, where molecules released from infectious agents are encountered, recognized through PRRs, and internalized through phagocytosis. Dendritic cells then migrate through the lymphatic vessels to lymphoid tissue, such as lymph nodes, and interact with T lymphocytes to generate an acquired immune response. Through the production of a family of cytokines, they guide development of a subset of T cells (helper cells) that coordinate the development of functional B and T cells (discussed in Chapter 7).

**Phagocytosis.**

The two most important phagocytes are neutrophils and macrophages. Both cells are circulating in the blood and must first leave the circulation and migrate to the site of inflammation before initiating phagocytosis (Figure 6-9). Many products of inflammation affect expression of surface molecules involved in cell-to-cell adherence. Both leukocytes and endothelial cells begin expressing molecules
(selectins and integrins) that increase adhesion, or stickiness, causing the leukocytes to adhere more avidly to the endothelial cells in the walls of the capillaries and venules in a process called **margination**, or **pavementing**. Leukocyte-endothelial interactions lead to **diapedesis**, or emigration of the cells through the inter-endothelial junctions that have loosened in response to inflammatory mediators.\(^\text{22}\)
Process of Phagocytosis. The process that results in phagocytosis is characterized by three interrelated steps: adherence and diapedesis, tissue invasion by chemotaxis, and phagocytosis. 

A. Adherence, margination, diapedesis, and chemotaxis. The primary phagocyte in the blood is the neutrophil, which usually moves freely within the vessel (1). At sites of inflammation, the neutrophil progressively develops increased adherence to the endothelium, leading to accumulation along the vessel wall (margination or pavementing) (2). At sites of endothelial cell retraction the neutrophil exits the blood by means of diapedesis (3).

Chemotaxis. In the tissues, the neutrophil detects chemotactic factor gradients through surface receptors (1) and migrates towards higher concentrations of the factors (2). The high concentration of chemotactic factors at the site of inflammation immobilizes the neutrophil (3).

B. Specific receptors for recognition and attachment. 

C. Phagocytosis. Opsonized microorganisms bind to the surface of a phagocyte through specific receptors (1). The microorganism is ingested into a phagocytic vacuole, or phagosome (2). Lysosomes fuse with the phagosome, resulting in the formation of a phagolysosome (3). During this process the microorganism is exposed to products of the lysosomes, including a variety of enzymes and products of the hexose-monophosphate shunt (e.g., $\text{H}_2\text{O}_2$, $\text{O}_2^-$). The microorganism is killed and digested (4). Ab, Antibody; AbR, antibody receptor; C3b, complement component C3b; C3bR, complement C3b receptor; PAMP, pathogen-associated molecular pattern; PRR, pattern recognition receptor.

Once inside the tissue, leukocytes undergo a process of directed migration (chemotaxis) by which they are attracted to the inflammatory site by chemotactic
The primary chemotactic factors include many bacterial products, neutrophil chemotactic factor produced by mast cells, the chemokine IL-8, complement fragments C3a and C5a, and products of the clotting and kinin systems. Red blood cells cannot repair themselves and are phagocytized by macrophages at the end of their lifespan (Figure 6-10).

**FIGURE 6-10** Phagocytosis of Red Blood Cell. This scanning electron micrographs shows the progressive steps in phagocytosis. A, Red blood cells (R) attach to the surface of a macrophage (M). B, Part of the macrophage (M) membrane starts to enclose the red cell (R). C, The red blood cells are almost totally engulfed by the macrophage. (Modified from King DW et al: General pathology: principles and dynamics, Philadelphia, 1983, Lea & Febiger.)
At the inflammatory site, the process of phagocytosis involves five steps: (1) recognition and adherence of the phagocyte to its target, (2) engulfment (ingestion or endocytosis), (3) formation of a phagosome, (4) fusion of the phagosome with lysosomal granules within the phagocyte, and (5) destruction of the target. Throughout the process, both the target and the digestive enzymes are isolated within membrane-bound vesicles. Isolation protects the phagocyte itself from the harmful effects of the target microorganisms, as well as its own enzymes.

Most phagocytes can trap and engulf bacteria using PRRs, although the process is relatively slow. **Opsonization** greatly enhances adherence by acting as a glue to tighten the affinity of adherence between the phagocyte and the target cell. The most efficient opsonins are antibodies and C3b produced by the complement system. Antibodies are made against antigens on the surface of bacteria and are highly specific to that particular microorganism. Certain bacterial and fungal polysaccharide coatings activate the alternative and lectin pathways of complement activation, which deposits C3b on the bacterial surface and increases phagocytosis. The surface of phagocytes contains a variety of specific receptors that will strongly bind to opsonins. These include complement receptors that bind to C3b and Fc receptors that bind to a site on antibody molecules.

**Engulfment** (endocytosis) is carried out by small pseudopods that extend from the plasma membrane and surround the adherent microorganism, forming an intracellular phagocytic vacuole, or phagosome (see Figures 6-9 and 6-10). After the formation of the phagosome, lysosomes converge, fuse with the phagosome, and discharge their contents, creating a phagolysosome. Destruction of the bacterium takes place within the phagolysosome and is accomplished by both oxygen-dependent and oxygen-independent mechanisms.

**Oxygen-dependent killing mechanisms** result from the production of toxic oxygen species. Phagocytosis is accompanied by a burst of oxygen uptake by the phagocyte; this is termed the **respiratory burst** and results from a shift in much of the cell's glucose metabolism to the **hexose-monophosphate shunt**, which produces nicotinamide adenine dinucleotide phosphate (NADPH). A membrane-associated enzyme, NADPH oxidase, uses NADPH to generate superoxide (O$_2^-$), hydrogen peroxide (H$_2$O$_2$), and other reactive oxygen species that can be highly damaging to bacteria. Hydrogen peroxide also can collaborate with the lysosomal enzyme **myeloperoxidase** and halide anions (Cl$^-$ and Br$^-$) to form acids that kill bacteria and fungi.

**Oxygen-independent mechanisms** of microbial killing include (1) the acidic pH (3.5 to 4.0) of the phagolysosome, (2) cationic proteins that bind to and damage target cell membranes, (3) enzymatic attack of the microorganism's cell wall by lysozyme and other enzymes, and (4) inhibition of bacterial growth by lactoferrin.
binding of iron.

When a phagocyte dies at an inflammatory site, it frequently lyses (breaks open) and releases its cytoplasmic contents into the tissue. For instance, contents of neutrophil primary granules (lysozyme, hydrolases, neutral proteases) and secondary granules (lysozyme, collagenase, gelatinase) can digest the connective tissue matrix, causing much of the tissue destruction associated with inflammation.\(^{24}\) The destructive effects of many enzymes and reactive oxygen molecules released by dying phagocytes are minimized by natural inhibitors found in the blood, such as superoxide dismutase (breaks down superoxide), catalase (breaks down hydrogen peroxide), and the antiproteinases \(\alpha_1\)-antitrypsin and \(\alpha_2\)-macroglobulin (both produced by the liver). An inherited deficiency of \(\alpha_1\)-antitrypsin often leads to chronic lung damage and emphysema as a result of inflammation. (The pulmonary effects of \(\alpha_1\)-antitrypsin deficiency are described in Chapter 27.)

**Natural Killer Cells and Lymphocytes**

The main function of **natural killer (NK) cells** is recognition and elimination of cells infected with viruses, although they also are somewhat effective at elimination of other abnormal cells, specifically cancer cells.\(^{25}\) NK cells seem to be more efficient in this role when they encounter an infected cell within the circulatory system as opposed to within tissues. NK cells have inhibitory and activating receptors that allow differentiation between infected or tumor cells and normal cells. If the NK cell binds to a target cell through activating receptors, it produces several cytokines and toxic molecules that can kill the target.\(^{26}\) NK cells and lymphocytes, which are the principal cells of the adaptive immune response, will be discussed in much more detail in Chapter 7.

**Quick Check 6-4**

1. What are pattern recognition receptors?

2. What are cytokines? How do cytokines promote inflammation?

3. What products do the mast cells release during inflammation, and what are their effects?

4. What phagocytic cell types are involved in the acute inflammatory response? What is the role of each?
5. What are the four steps in the process of phagocytosis?
Acute and Chronic Inflammation

Inflammation can be divided into phases of acute and chronic inflammation. The acute inflammatory response is self-limiting—that is, it continues only until the threat to the host is eliminated. This usually takes 8 to 10 days from onset to healing. If the acute inflammatory response proves inadequate, a chronic inflammation may develop and persist for weeks or months. If healing has not been initiated, inflammation may progress to a granulomatous response that is designed to contain the cause of tissue damage so it no longer poses any harm to the individual. The characteristics of the early (i.e., acute) inflammatory response differ from those of the later (i.e., chronic) response, and each phase involves different biochemical mediators and cells that function together. Depending on the successful containment of tissue damage and infection, the acute and chronic phases may lead to healing without progression to the next phase.

Local Manifestations of Acute Inflammation

The cells and plasma protein systems of the inflammatory response interact to produce all the characteristics of inflammation, whether local or systemic (discussed in the next section), as well as determine the duration of inflammation, either acute or chronic. All the local characteristics of acute inflammation (i.e., swelling, pain, heat, and redness [erythema]) result from vascular changes and the subsequent leakage of circulating components into the tissue.

The exudate of inflammation results from increased vascular permeability and varies in composition, depending on the stage of the inflammatory response and, to some extent, the injurious stimulus. In early or mild inflammation, the exudate may be watery (serous exudate) with very few plasma proteins or leukocytes, such as the fluid in a blister. In more severe or advanced inflammation, the exudate may be thick and clotted (fibrinous exudate), such as in the lungs of individuals with pneumonia. If a large number of leukocytes accumulate, as in persistent bacterial infections, the exudate consists of pus and is called a purulent (suppurative) exudate. Purulent exudate is characteristic of walled-off lesions (cysts or abscesses). If bleeding occurs, the exudate is filled with erythrocytes and is described as a hemorrhagic exudate.

Systemic Manifestations of Acute Inflammation

The three primary systemic changes associated with the acute inflammatory response are fever, leukocytosis (a transient increase in the levels of circulating
leukocytes), and increased levels of circulating plasma proteins.

**Fever**

*Fever* is partially induced by specific cytokines (e.g., IL-1, released from neutrophils and macrophages). These are known as *endogenous pyrogens* to differentiate them from pathogen-produced *exogenous pyrogens*. *Pyrogens* act directly on the hypothalamus, the portion of the brain that controls the body's thermostat. (Mechanisms of temperature regulation and fever are discussed in Chapter 14.) A fever can be beneficial because some microorganisms (e.g., those that cause syphilis or gonococcal urethritis) are highly sensitive to small increases in body temperature. On the other hand, fever may have harmful side effects because it may enhance the host's susceptibility to the effects of endotoxins associated with gram-negative bacterial infections (bacterial toxins are described in Chapter 8).

**Leukocytosis**

*Leukocytosis* is an increase in the number of circulating white blood cells (greater than 11,000/ml in adults). During many infections, leukocytosis may be accompanied by a *left shift* in the ratio of immature to mature neutrophils, so that the more immature forms of neutrophils, such as band cells, metamyelocytes, and occasionally myelocytes, are present in relatively greater than normal proportions. (Chapter 20 contains a more complete discussion of the development and maturation of blood cells.) Production of immature leukocytes increases primarily from proliferation and release of granulocyte and monocyte precursors in the bone marrow, which is stimulated by several products of inflammation.

**Plasma Protein Synthesis**

The synthesis of many plasma proteins, mostly products of the liver, is increased during inflammation. These proteins, which can be either proinflammatory or anti-inflammatory in nature, are referred to as *acute-phase reactants* (Table 6-4). Acute-phase reactants reach maximal circulating levels within 10 to 40 hours after the start of inflammation. IL-1 is indirectly responsible for the synthesis of acute-phase reactants through the induction of IL-6, which directly stimulates liver cells to synthesize most of these proteins.
Common laboratory tests for inflammation measure levels of acute-phase reactants. For example, an increase in blood levels of acute-phase reactants, primarily fibrinogen, is associated with an increased adhesion among erythrocytes and a corresponding increase in the sedimentation rate. The erythrocyte sedimentation rate is a measurement of the rate at which red blood cells sediment in a tube over a prescribed time span (usually an hour). Although increased erythrocyte sedimentation is a nonspecific reaction, it is considered a good indicator of an acute inflammatory response.

### Chronic Inflammation

Superficially, the difference between acute and chronic inflammation is duration; **chronic inflammation** lasts 2 weeks or longer, regardless of cause. Chronic inflammation is sometimes preceded by an unsuccessful acute inflammatory response (Figure 6-11). For example, if bacterial contamination or foreign objects (e.g., dirt, wood splinter, silica, and glass) persist in a wound, an acute response may be prolonged beyond 2 weeks. Pus formation, suppuration (purulent discharge), and incomplete wound healing may characterize this type of chronic inflammation.
Chronic inflammation usually becomes chronic because of the persistence of an infection, an antigen, or a foreign body in the wound. Chronic inflammation is characterized by the persistence of many of the processes of acute inflammation. In addition, large amounts of neutrophil degranulation and death, the activation of lymphocytes, and the concurrent activation of fibroblasts result in the release of mediators that induce the infiltration of more lymphocytes and monocytes/macrophages and the beginning of wound healing and tissue repair. For more detailed information on each portion of the response, see the figures referenced in this illustration.

Chronic inflammation can occur also as a distinct process without previous acute inflammation. Some microorganisms (e.g., mycobacteria that cause tuberculosis) have cell walls with a very high lipid and wax content, making them relatively insensitive to breakdown by phagocytes. Other microorganisms (e.g., those that cause leprosy, syphilis, and brucellosis) can survive within the macrophage and avoid removal by the acute inflammatory response. Other microorganisms produce toxins that damage tissue and cause persistent inflammation even after the organism is killed. Finally, chemicals, particulate matter, or physical irritants (e.g., inhaled dusts, wood splinters, and suture material) can cause a prolonged inflammatory response.

Chronic inflammation is characterized by a dense infiltration of lymphocytes and macrophages. If macrophages are unable to protect the host from tissue damage, the body attempts to wall off and isolate the infected area, thus forming a granuloma (Figure 6-12). For example, infections caused by some bacteria (listeriosis, brucellosis), fungi (histoplasmosis, coccidiodomycosis), and parasites (leishmaniasis, schistosomiasis, toxoplasmosis) can result in granuloma formation. TNF-α primarily drives granuloma formation. Some macrophages differentiate into large epithelioid cells, which specialize in taking up debris and other small
particles. Other macrophages fuse into multinucleated giant cells, which are active phagocytes that can engulf very large particles—larger than those that can be engulfed by a single macrophage. These two types of specialized cells form the center of the granuloma, which is surrounded by a wall of lymphocytes. The granuloma itself is often encapsulated by fibrous deposits of collagen and may become cartilaginous or possibly calcified by deposits of calcium carbonate and calcium phosphate.

The classic granuloma associated with tuberculosis is characterized by a wall of epithelioid cells surrounding a cheeselike proteinaceous center derived from dead and decaying tissue (caseous necrosis) and mycobacteria. Decay of cells within the granuloma results in the release of acids and the enzymatic contents of lysosomes from dead phagocytes. In this inhospitable environment, the cellular debris is broken down into its basic constituents, and a clear fluid may remain (liquefaction necrosis). Eventually, this fluid diffuses out and leaves a hollow, thick-walled structure that has replaced normal tissue and reduced the function of the lung.
1. Describe how acute inflammation differs from chronic inflammation. What characteristics do they share?

2. List the types of exudate produced in inflammation.
Wound Healing

The conclusion of inflammation is healing and repair. The most favorable outcome is a return to normal structure and function if damage is minor, no complications occur, and destroyed tissues are capable of regeneration (replacement of damaged tissue with healthy tissue, such as occurs in the epithelia of the skin and intestines and in some organs, such as the liver) (Figure 6-13). This restoration is called resolution and may take up to 2 years, and local production of IL-10 appears to play a critical role. Resolution may not be possible if extensive damage is present, the tissue is not capable of regeneration, infection results in abscess or granuloma formation, or fibrin persists in the lesion. In those cases, repair takes place instead of resolution. Repair is the replacement of destroyed tissue with scar tissue. Scar tissue is composed primarily of collagen that fills in the lesion and restores strength but cannot carry out the physiologic functions of destroyed tissue, resulting in loss of function.
Wound healing involves processes that (1) fill in, (2) seal, and (3) shrink the wound. These characteristics of healing vary in importance and duration among different types of wounds. A clean incision, such as a paper cut or a sutured surgical wound, heals primarily through the process of collagen synthesis. Because this type of wound has minimal tissue loss and close apposition of the wound edges, very little sealing (epithelialization) and shrinkage (contraction) are required. Wounds that heal under conditions of minimal tissue loss are said to heal by primary intention (see Figure 6-13).
Other wounds do not heal as easily. Healing of an open wound, such as a stage IV pressure ulcer (decubitus ulcer), requires a great deal of tissue replacement so that epithelialization, scar formation, and contraction take longer and healing occurs through secondary intention (see Figure 6-13). Healing by either primary or secondary intention may occur at different rates for different types of tissue injury.

Epidermal wounds that heal by secondary intention and unsutured internal lesions are not completely restored by healing. At best, repaired tissue regains 80% of its original tensile strength. Only epithelial, hepatic (liver), and bone marrow cells are capable of the complete mitotic regeneration of the normal tissue known as compensatory hyperplasia. In fibrous connective tissue, such as joints and ligaments, normal healing results in replacement of the original tissue with new tissue that does not have exactly the same structure or function as that of the original. Some tissues heal without replacement of cells. For example, damage resulting from myocardial infarction heals with a scar composed of fibrous tissue rather than with cardiac muscle.

Wound healing occurs in three overlapping phases: inflammation, proliferation and new tissue formation, and remodeling and maturation.

**Phase I: Inflammation**

The early phase of wound healing, the transition from acute inflammation to healing, begins almost immediately. The inflammatory phase includes coagulation or hemostasis and the infiltration of cells that participate in wound healing, including platelets, neutrophils, and macrophages (Figure 6-14). The fibrin mesh of the blood clot acts as a scaffold for cells that participate in healing. Platelets contribute to clot formation and, as they degranulate, release growth factors that initiate proliferation of undamaged cells. Neutrophils clear the wound of debris and bacteria and are later replaced by macrophages. Macrophages are essential to wound healing because they clear debris, release wound healing mediators and growth factors, recruit fibroblasts, and help promote formation of a new blood supply (angiogenesis) during the proliferative phase of wound healing.
Phase II: Proliferation and New Tissue Formation

The proliferative phase begins 3 to 4 days after the injury and continues for as long as 2 weeks. The wound is sealed and the fibrin clot is replaced by normal tissue or scar tissue during this phase. The **proliferative phase** is characterized by macrophage invasion of the dissolving clot and recruitment and proliferation of fibroblasts (connective tissue cells), followed by fibroblast collagen synthesis, epithelialization, contraction of the wound, and cellular differentiation. Macrophages secrete a variety of biochemical mediators that promote healing, including:

1. Transforming growth factor-beta (TGF-β) stimulates fibroblasts entering the lesion to synthesize and secrete the collagen precursor procollagen.
2. **Angiogenesis factors**, such as vascular endothelial growth factor (VEGF) and fibroblast growth factor-2 (FGF-2), stimulate vascular endothelial cells to form capillary buds that grow into the lesion; decreased pH and decreased wound oxygen tension also promote angiogenesis.\(^{30}\)

3. **Matrix metalloproteinases (MMPs)** degrade and remodel extracellular matrix proteins (e.g., collagen and fibrin) at the site of injury.\(^{31}\)

    Granulation tissue grows into the wound from surrounding healthy connective tissue and consists of invasive cells, new lymphatic vessels, and new capillaries derived from capillaries in the surrounding tissue, giving the granulation tissue a red, granular appearance. During this process the healing wound must be protected. Epithelialization is the process by which epithelial cells grow into the wound from surrounding healthy tissue.\(^{32}\) Epithelial cells migrate under the clot or scab using MMPs to unravel collagen. Migrating epithelial cells contact similar cells from all sides of the wound and seal it. The epithelial cells remain active, undergoing differentiation to give rise to the various epidermal layers (see Chapter 41). Epithelialization of a skin wound can be hastened if the wound is kept moist, preventing the fibrin clot from becoming a scab.

    **Fibroblasts** are important cells during healing because they secrete collagen and other connective tissue proteins. Fibroblasts are stimulated by macrophage-derived TGF-β to proliferate, enter the lesion, and deposit connective tissue proteins in débrided areas about 6 days after the fibroblasts have entered the lesion. **Collagen** is the most abundant protein in the body.\(^{33}\) It contains high concentrations of the amino acids glycine, proline, and lysine, many of which are enzymatically modified. Modification of proline and lysine requires several cofactors that are absolutely necessary for proper collagen polymerization and function. These include iron, ascorbic acid (vitamin C), and molecular oxygen (O\(_2\)); absence of any of these results in impaired wound healing. As healing progresses, collagen molecules are cross-linked by intermolecular covalent bonds to form collagen fibrils that are further cross-linked to form collagen fibers. The complete process takes several months.

    In granulation tissue, TGF-β induces some fibroblasts to transition into **myofibroblasts**, specialized cells responsible for wound contraction.\(^{34}\) Myofibroblasts have features of both smooth muscle cells and fibroblasts. They appear microscopically similar to fibroblasts but differ in that their cytoplasm contains bundles of parallel fibers similar to those found in smooth muscle cells. **Wound contraction** occurs as extensions from the plasma membrane of myofibroblasts establish connections between neighboring cells, contract their
fibers, and exert tension on the neighboring cells while anchoring themselves to the wound bed. Wound contraction is necessary for closure of all wounds, especially those that heal by secondary intention. Contraction is noticeable 6 to 12 days after injury.

**Phase III: Remodeling and Maturation**

Tissue remodeling and maturation begins several weeks after injury and is normally complete within 2 years. During this phase, there is continuation of cellular differentiation, scar formation, and scar remodeling. The fibroblast is the major cell of tissue remodeling with the deposition of collagen into an organized matrix. Tissue regeneration and wound contraction continue in the remodeling and maturation phase—a phase for recovering normal tissue structure that can persist for years. For wounds that heal by scarring, scar tissue is remodeled and capillaries disappear, leaving the scar avascular. Within 2 to 3 weeks after maturation has begun, the scar tissue has gained about two thirds of its eventual maximal strength.

**Dysfunctional Wound Healing**

Dysfunctional wound healing and impaired epithelialization may occur during any phase of the healing process. The cause of dysfunctional wound healing includes ischemia, excessive bleeding, excessive fibrin deposition, a predisposing disorder such as diabetes mellitus, obesity, wound infection, inadequate nutrients, numerous drugs, and tobacco smoke.35

Oxygen-deprived (ischemic) tissue is susceptible to cellular death and infection, which prolongs inflammation and delays healing. Ischemia reduces energy production and impairs collagen synthesis and the tensile strength of regenerating connective tissue.

Healing is prolonged if there is excessive bleeding. Large clots increase the amount of space that granulation tissue must fill and serve as mechanical barriers to oxygen diffusion. Accumulated blood is an excellent culture medium for bacteria and promotes infection, thereby prolonging inflammation by increasing exudation and pus formation. Decreased blood volume also inhibits inflammation because of vessel constriction rather than the dilation required to deliver inflammatory cells, nutrients, and oxygen to the site of injury.

Obesity delays wound healing because of impaired leukocyte function and predisposition to infection, decreases in the number of growth factors, and increases in the levels of proinflammatory cytokines. Additionally, there is dysregulation in collagen synthesis and a decrease in angiogenesis.36
Excessive fibrin deposition is detrimental to healing. Fibrin released in response to injury must eventually be reabsorbed to prevent organization into fibrous adhesions. Adhesions formed in the pleural, pericardial, or abdominal cavities can bind organs together by fibrous bands and distort or strangulate the affected organ.

Persons with diabetes are at risk for prolonged wound healing. Wounds are often ischemic because of the potential for small-vessel diseases that impair the microcirculation and alter (glycosylated) hemoglobin, which has an increased affinity for oxygen and thus does not readily release oxygen in tissues. Consequences of hyperglycemia also include suppression of macrophages and increased risk for wound infection.

Wound infection is caused by the infiltration of pathogens. Pathogens damage cells, stimulate the continued release of inflammatory mediators, consume nutrients, and delay wound healing.

Optimal nutrition is important during all phases of healing because metabolic needs increase. Leukocytes need glucose to produce adenosine 5′-triphosphate (5′-ATP) necessary for chemotaxis, phagocytosis, intercellular killing, and initiation of healing; therefore the wounds of persons with diabetes who receive insufficient insulin heal poorly. Hypoproteinemia impairs fibroblast proliferation and collagen synthesis. Prolonged lack of vitamins A and C results in poorly formed connective tissue and greatly impaired healing because they are cofactors required for collagen synthesis. Other nutrients, including iron, zinc, manganese, and copper, are also required as cofactors for collagen synthesis. Malnutrition increases risk for wound infection, delays healing, and reduces wound tensile strength.

Medications, including antineoplastic (anticancer) agents, nonsteroidal anti-inflammatory drugs (NSAIDs), and steroids, delay wound healing. Antineoplastic agents slow cell division and inhibit angiogenesis. Although NSAIDs inhibit prostaglandin production and suppress acute inflammation and relieve pain, they also can delay wound healing, particularly bone formation, and may contribute to the formation of excessive scarring. Steroids prevent macrophages from migrating to the site of injury and inhibit release of collagenase and plasminogen activator. Steroids also inhibit fibroblast migration into the wound during the proliferative phase and delay epithelialization. Toxic agents in tobacco smoke (i.e., nicotine, carbon monoxide, and hydrogen cyanide) delay wound healing and increase the risk for wound infection.

Dysfunctional collagen synthesis may involve excessive production of collagen, leading to a hypertrophic scar or keloid. A hypertrophic scar is raised but remains within the original boundaries of the wound and tends to regress over time (Figure 6-15, A). A keloid is a raised scar that extends beyond the original boundaries of the wound, invades surrounding tissue, and is likely to recur after
surgical removal (Figure 6-15, B). A familial tendency to keloid formation has been observed, with a greater incidence in blacks than whites.

Wound Disruption

A potential complication of wounds that are sutured closed is **dehiscence**, in which the wound pulls apart at the suture line. Dehiscence generally occurs 5 to 12 days after suturing, when collagen synthesis is at its peak. Approximately half of dehiscence occurrences are associated with wound infection, but they also may be the result of sutures breaking because of excessive strain. Obesity increases the risk for dehiscence because adipose tissue is difficult to suture. Wound dehiscence
usually is heralded by increased serous drainage from the wound and a patient's perception that “something gave way.” Prompt surgical attention is required.

**Impaired Contraction**

Wound contraction, although necessary for healing, may become excessive, resulting in a deformity or **contracture of scar tissue**. Burns of the skin are especially susceptible to contracture development, particularly at joints, resulting in loss of movement around the joints. Internal contractures include duodenal strictures caused by dysfunctional healing of a peptic ulcer; esophageal strictures caused by chemical burns, such as lye ingestion; or abdominal adhesions caused by surgery, infection, or radiation. Contracture may occur in cirrhosis of the liver, constricting vascular flow and contributing to the development of portal hypertension and esophageal varices. Proper positioning, range-of-motion exercises, and surgery are among the physical means used to overcome excessive skin contractures. Surgery is performed to release internal contractures.

**Quick check 6-6**

1. How does regeneration of tissue differ from repair of tissue?

2. What does it mean to heal by primary intention?

3. What is the role of fibroblasts in wound healing?

4. Describe various ways wound healing may be dysfunctional.

**Pediatric Considerations**

**Age-Related Factors Affecting Innate Immunity in the Newborn Child**

- Newborn physiologic immunity acquired from mother through placenta and breast milk.

- Newborns have transiently depressed inflammatory responses.

- Neutrophils are incapable of chemotaxis, lacking fluidity in the plasma membrane.
• Complement levels are diminished, especially components of the alternative pathways (e.g., factor B), particularly in premature newborns.

• Monocyte/macrophage numbers are normal but chemotaxis of monocytes is delayed.

• There is a tendency for infections associated with chemotactic defects, for example, cutaneous abscesses caused by staphylococci and cutaneous candidiasis.

• There are diminished oxidative and bacterial responses in those stressed by in utero infection or respiratory insufficiency.

• There is a tendency to develop severe overwhelming sepsis and meningitis when infected by bacteria against which no maternal antibodies are present.

• The establishment of the gut microbiome is facilitated by breast milk.

• Cesarean delivered newborns have reduced gut microbial diversity.

---

**Geriatric Considerations**

**Age-Related Factors Affecting Innate Immunity in the Elderly**

• Normal numbers of cells of innate immunity but possible diminished function (e.g., decreased phagocytic activity, decreased antibody production, and altered cytokine synthesis)

• Increased incidence of chronic inflammation, possibly related to increased production of proinflammatory mediators

• At risk for impaired healing and infection associated with chronic illness (e.g., diabetes mellitus, peripheral vascular disease, or cardiovascular disease) and decreased phagocytosis.

• Use of medications interfering with healing (e.g., anti-inflammatory steroids)

• Loss of subcutaneous fat, diminishing layers of protection against injury

• Atrophied epidermis, including underlying capillaries, which decreases perfusion and increases risk of hypoxia in wound bed
• Aging of the immune system, diminishing the effectiveness of vaccines
Did You Understand?

**Innate Immunity**

1. Neonates often have transiently depressed inflammatory function, particularly neutrophil chemotaxis and alternative complement pathway activity.

2. Elderly persons are at risk for impaired wound healing, usually because of chronic illnesses.

3. There are three layers of human defense: barriers; innate immunity, which includes the inflammatory response; and adaptive (acquired) immunity.

4. Physical barriers are the first lines of defense that prevent damage to the individual and prevent invasion by pathogens; these include the skin and mucous membranes.

5. Antibacterial peptides (cathelicidins, defensins, collectins, and mannose-binding lectin) in mucous secretions, perspiration, saliva, tears, and other secretions provide a biochemical barrier against pathogenic microorganisms.

6. The skin and mucous membranes are colonized by commensal or mutualistic microorganisms that provide protection by releasing chemicals that facilitate immune responses, prevent colonization by pathogens, and facilitate digestion in the gastrointestinal tract.

7. The second line of defense is the inflammatory response, a rapid and nonspecific protective response to cellular injury from any cause. It can occur only in vascularized tissue.

8. The macroscopic hallmarks of inflammation are redness, swelling, heat, pain, and loss of function of the inflamed tissues.

9. The microscopic hallmarks of inflammation are vasodilation, increased capillary permeability, and an accumulation of fluid and cells at the inflammatory site.

10. Inflammation is mediated by three key plasma protein systems: the complement system, the clotting system, and the kinin system. The components of all three systems are a series of inactive proteins that are activated sequentially.
11. The complement system can be activated by antigen-antibody reactions (through the classical pathway) or by other products, especially bacterial polysaccharides (through the lectin pathway or the alternative pathway), resulting in the production of biologically active fragments that recruit phagocytes, activate mast cells, and destroy pathogens.

12. The most biologically potent products of the complement system are C3b (opsonin), C3a (anaphylatoxin), and C5a (anaphylatoxin, chemotactic factor).

13. The clotting system stops bleeding, localizes microorganisms, and provides a meshwork for repair and healing.

14. Bradykinin is the most important product of the kinin system and causes vascular permeability, smooth muscle contraction, and pain.

15. Control of inflammation regulates inflammatory cells and enzymes and localizes the inflammatory response to the area of injury or infection.

16. Carboxypeptidase, histaminase, and C1 esterase inhibitor are inactivating enzymes, and the fibrinolytic system and plasmin facilitate clot degradation after bleeding is stopped.

17. Many different types of cells are involved in the inflammatory process including mast cells, endothelial cells, platelets, phagocytes (neutrophils, eosinophils, monocytes and macrophages, dendritic cells), natural killer (NK) cells, and lymphocytes.

18. Most cells express plasma membrane pattern recognition receptors (PRRs) that recognize molecules produced by infectious microorganisms (pathogen-associated molecular patterns, or PAMPs), or products of cellular damage (damage-associated molecular patterns, or DAMPs). Toll-like receptors (TLRs) and NOD-like receptors are expressed on many inflammatory cells, recognize PAMPs and DAMPs, and promote release of cytokines and inflammatory mediators that eliminate damaged cells and protect against invasion by microbes.

19. The cells of the innate immune system secrete many biochemical mediators (cytokines) that are responsible for activating other cells and regulating the inflammatory response; these cytokines include chemokines, interleukins, interferons, and other molecules.
20. Chemokines induce chemotaxis of leukocytes, fibroblasts, and other cells to promote phagocytosis and wound healing.

21. Interleukins are produced primarily by lymphocytes and macrophages and promote or inhibit inflammation by activating growth and differentiation of leukocytes and lymphocytes.

22. The most important proinflammatory interleukins are interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor-alpha (TNF-α). Interleukins 6 and 10 down-regulate the inflammatory response.

23. Interferons are produced by cells that are infected by viruses. Once released from infected cells, interferons can stimulate neighboring healthy cells to produce substances that prevent viral infection.

24. The most important activator of the inflammatory response is the mast cell, which is located in connective tissue near capillaries and initiates inflammation by releasing biochemical mediators (histamine, chemotactic factors) from preformed cytoplasmic granules and synthesizing other mediators (prostaglandins, leukotrienes, and platelet-activating factor) in response to a stimulus. Basophils are found in the blood and function similar to mast cells.

25. Histamine is the major vasoactive amine released from mast cells. It causes dilation of capillaries and retraction of endothelial cells lining the capillaries, which increases vascular permeability.

26. The endothelial cells lining the circulatory system (vascular endothelium) normally regulate circulating components of the inflammatory system and maintain normal blood flow by preventing spontaneous activation of platelets and members of the clotting system.

27. During inflammation the endothelium expresses receptors that help leukocytes leave the vessel and retract to allow fluid to pass into the tissues.

28. Platelets interact with the coagulation cascade to stop bleeding and release a number of mediators that promote and control inflammation.

29. The polymorphonuclear neutrophil (PMN), the predominant phagocytic cell in the early inflammatory response, exits the circulation by diapedesis through the retracted endothelial cell junctions and moves to the inflammatory site by
chemotaxis.

30. Eosinophils release products that control the inflammatory response and are the principal cell that kills parasitic organisms.

31. The macrophage, the predominant phagocytic cell in the late inflammatory response, is highly phagocytic, is responsive to cytokines, and promotes wound healing.

32. Dendritic cells connect the innate and acquired immune systems by collecting antigens at the site of inflammation and transporting them to sites, such as the lymph nodes, where immunocompetent B and T cells reside and are transformed into functional cells.

33. Phagocytosis is a multistep cellular process for the elimination of pathogens and foreign debris. The steps include recognition and attachment, engulfment, formation of a phagosome and phagolysosome, and destruction of pathogens or foreign debris. Phagocytic cells engulf microorganisms and enclose them in phagocytic vacuoles (phagolysosomes), within which toxic products (especially metabolites of oxygen) and degradative lysosomal enzymes kill and digest the microorganisms.

34. Opsonins, such as antibody and complement component C3b, coat microorganisms and make them more susceptible to phagocytosis by binding them more tightly to the phagocyte.

**Acute and Chronic Inflammation**

1. Acute inflammation is self-limiting and usually resolves within 8 to 10 days.

2. Local manifestations of inflammation are the result of the vascular changes associated with the inflammatory process, including vasodilation and increased capillary permeability. The symptoms include redness, heat, swelling, and pain.

3. The principal systemic effects of inflammation are fever and increases in levels of circulating leukocytes (leukocytosis) and plasma proteins (acute-phase reactants [i.e., IL-1 and IL-6]).

4. Chronic inflammation can be a continuation of acute inflammation that lasts 2 weeks or longer. It also can occur as a distinct process without much preceding acute inflammation.
5. Chronic inflammation is characterized by a dense infiltration of lymphocytes and macrophages. The body may wall off and isolate the infection to protect against tissue damage by formation of a granuloma.

### Wound Healing

1. Resolution (regeneration) is the return of tissue to nearly normal structure and function. Repair is healing by scar tissue formation.

2. Damaged tissue proceeds to resolution (restoration of the original tissue structure and function) if little tissue has been lost or if injured tissue is capable of regeneration. This is called healing by primary intention.

3. Tissues that sustained extensive damage or those incapable of regeneration heal by the process of repair resulting in the formation of a scar. This is called healing by secondary intention.

4. Resolution and repair occur in two separate phases: the reconstructive phase in which the wound begins to heal and the maturation phase in which the healed wound is remodeled.

5. Dysfunctional wound healing can be related to ischemia, excessive bleeding, excessive fibrin deposition, a predisposing disorder (such as diabetes mellitus), wound infection, inadequate nutrients, numerous drugs, or altered collagen synthesis.

6. Dehiscence is a disruption in which the wound pulls apart at the suture line.

7. A contracture is a deformity caused by the excessive shortening of collagen in scar tissue.

GERIATRIC CONSIDERATIONS: Age-Related Factors Affecting Mechanisms of Self-Defense in the Elderly, 173
The third line of defense in the human body is adaptive (acquired) immunity, often called the immune response or immunity, and consists of lymphocytes (Figure 7-1) and serum proteins called antibodies. Once external barriers have been compromised and inflammation (innate immunity, see Chapter 6) has been activated, the adaptive immune response is called into action. Inflammation is the “first responder” that contains the initial injury and slows the spread of infection, whereas adaptive immunity slowly augments the initial defenses against infection and provides long-term security against reinfection.
Third Line of Defense: Adaptive Immunity

Inflammation and adaptive immunity differ in several key ways. First, the components of inflammation are activated immediately after tissue damage. Adaptive immunity is *inducible*; the effectors of the immune response, lymphocytes and antibodies, do not preexist but must be produced in response to infection. Thus, adaptive immunity develops more slowly than inflammation. Second, the inflammatory response is similar regardless of differences in the cause of tissue damage or whether the inflammatory site is sterile or contaminated with infectious microorganisms. The immune response is exquisitely *specific*. The lymphocytes and antibodies induced in response to infection are extremely specific to the infecting microbe. Third, the residual mediators of inflammation must be removed quickly to limit damage to surrounding healthy tissue and allow healing. The effectors of the immune response are *long-lived* and systemic, providing long-term protection against specific infections. Finally, the inflammatory response to both recurrent tissue damage and infection is identical. The immune response has *memory*. If reinfected with the same microbe, protective lymphocytes and antibody are produced immediately, thus providing permanent long-term protection against infection.

Despite the differences, the innate and adaptive immune systems are highly interactive and complementary. Many components of innate resistance are necessary for the development of the adaptive immune response. Conversely, products of the adaptive immune response activate components of innate resistance. Thus, both systems are essential for complete protection against infectious disease.

The mechanisms underlying the immune response will be discussed in this chapter. As with Chapter 6, a complete description of all the important components and processes of an effective immune response would require far more space than available. Therefore, this chapter will focus on the basic concepts and the most important, or well-studied, mediators of the immune response.

The adaptive immune response has its own vocabulary (Figure 7-2). Antigens are the molecular targets of antibodies and lymphocytes. Antigens are generally small molecules, usually within proteins, carbohydrates, or lipids, found on the surface of microbes or infected cells, although this definition will be expanded as we discuss immunologic diseases in Chapter 8. In the fetus, well before being exposed to any infectious microorganisms, lymphocytes have undergone extensive differentiation. Some lymphoid stem cells enter the thymus and differentiate into T lymphocytes (T cells, T indicates thymus derived), whereas others enter specific regions of the bone marrow and differentiate into B lymphocytes (B cells, B indicates bone marrow derived). Each type of cell develops origin-specific cell surface proteins that
identify them as T or B cells. Both B and T cells also develop cell surface antigen receptors. The receptors are remarkable because an individual lymphocyte is programmed to recognize only one specific antigen before having encountered that antigen. It is estimated that before birth each individual has produced a population of B and T lymphocytes capable of recognizing at least $10^8$ different antigens. This process is called generation of clonal diversity and refers to the process by which the extensive diversity of antigen receptors on B and T cells is established (see Figure 7-2).
FIGURE 7-2 Overview of the Immune Response. The immune response can be separated into two phases: the generation of clonal diversity and clonal selection. During the generation of clonal diversity, lymphoid stem cells from the bone marrow migrate to the central lymphoid organs (the thymus or regions of the bone marrow), where they undergo a series of cellular division and differentiation stages resulting in either immunocompetent T cells from the thymus or immunocompetent B cells from the bone marrow. These cells are still naïve in that they have never encountered foreign antigen. The immunocompetent cells enter the circulation and migrate to the secondary lymphoid organs (e.g., spleen and lymph nodes), where they establish residence in B- and T-cell–rich areas. The clonal selection phase is initiated by exposure to foreign antigen. The antigen is usually processed by antigen-presenting cells (APCs) for presentation to T-helper cells (Th cells). The intercellular cooperation among APCs, Th cells, and immunocompetent T and B cells results in a second stage of cellular proliferation and differentiation. Because antigen has “selected” those T and B cells with compatible antigen receptors, only a small population of T and B cells undergo this process at one time. The result is an active cellular immunity or humoral immunity, or both. Cellular immunity is mediated by a population of effector T cells that can kill targets (T-cytotoxic cells) or regulate the immune response (T-regulatory cells), as well as a population of memory cells (T-memory cells) that can respond more quickly to a second challenge with the same antigen. Humoral immunity is mediated by a population of soluble proteins (antibodies) produced by plasma cells and by a population of memory B cells that can produce more antibody rapidly to a second challenge with the same antigen.

Lymphocytes leave the primary lymphoid organs (bone marrow and thymus) as immunocompetent, but naïve, B and T cells. The cells are immunocompetent in that they have the capacity to respond to antigens, but they are naïve in that they have not yet encountered antigen. These cells enter the blood and lymphatic vessels and migrate to the secondary lymphoid organs (e.g., lymph nodes, spleen) of the systemic immune system (Figure 7-3). Some take up residence in B cell and T cell rich areas of those organs, and others reenter the circulation. Approximately 60% to 70% of circulating lymphocytes are immunocompetent T cells, and 10% to 20% are
immunocompetent B cells.

A second process, **clonal selection**, is initiated when an infection occurs. This process requires the cooperation among a variety of cells in the secondary lymphoid organs; antigen needs to be *processed* by phagocytic cells, primarily dendritic cells, which also express the processed antigen on their surfaces and *present* the antigen to lymphocytes. Thus begins a symphony of cellular interactions, referred to as **clonal selection**, involving several subsets of B and T cells, intercellular adhesion through antigen receptors and specific intercellular adhesion molecules, the production and response to multiple cytokines, and eventual
differentiation of immunocompetent B and T cells into highly specialized effector cells. B cells develop into plasma cells that become factories for the production of antibody. T cells develop into several subsets that can identify and kill a target cell (T-cytotoxic cells, Tc cells), regulate the immune response by helping the clonal selection process (T-helper cells, Th cells), or suppress inappropriate immune responses (T-regulatory cells, Treg cells). Both B and T cells also differentiate into very long-lived memory cells that exist for decades or, in some cases, for the life of the individual. Memory cells are rapidly activated if a second infection occurs with the same microbe.

Antibodies circulate in the blood and defend against extracellular microbes and microbial toxins. This is referred to as the humoral immune response, or humoral immunity. Effector T cells are found in the blood and tissues and defend against intracellular pathogens (e.g., viruses) and cancer cells. This is referred to as the cellular immune response, or cellular immunity (also cell-mediated immunity).

The preceding overview describes what is termed active immunity (active acquired immunity), which develops in response to antigen. In certain clinical situations, preformed antibody or lymphocytes may be administered to an individual, termed passive immunity (passive acquired immunity). Examples include individuals exposed to an infectious agent without having a preexisting vaccine-induced immunity (e.g., hepatitis A virus or rabies virus) (Table 7-1). Passive immunization with specific T cells has been used to treat several forms of cancer. Whereas active acquired immunity is long lived, passive immunity is only temporary because the donor's antibodies or T cells are eventually destroyed.

PSA, Prostate-specific antigen.
Antigens and Immunogens

We need to initially understand the molecules against which an immune response is directed. Although the terms antigen and immunogen are commonly used as synonyms, there are clinically important differences between the two. Antigen is commonly used to describe a molecule that can bind with antibodies or antigen receptors on B and T cells. A molecule that will induce an immune response is an immunogen. Thus all immunogens are antigens but not all antigens are immunogens. For instance, immunogenicity is frequently related to the size of the antigen. In general, large molecules (those greater than 10,000 daltons), such as proteins and polysaccharides, are most immunogenic. Many low-molecular-weight molecules can function as haptens; they are too small to be immunogens by themselves but become immunogenic after combining with larger molecules that function as carriers for the hapten. Poison ivy contains an oily sap called urushiol (molecular weight approximately 1500 daltons), which upon contact with the skin is chemically altered, binds to large proteins in the skin, and becomes immunogenic, resulting in a T-cell response and onset of a classic poison ivy rash. Similar conditions will be discussed in Chapter 8.

Quick Check 7-1

1. Define acquired immunity.

2. Distinguish between innate and acquired immunity.

3. Distinguish between humoral and cell-mediated immunity.

4. What are the differences among antigens, immunogens, and haptens?
Antibodies

A basic understanding of antibodies and how they react with antigen provides a foundation for more complex topics, such as the B-cell and T-cell antigen receptors, the generation of clonal diversity, and intercellular collaborations during clonal selection, which are discussed later in this chapter. The terms antibody and immunoglobulin (Ig) are frequently used interchangeably. In general, immunoglobulin is frequently used as a generic description of a general group of antibodies, whereas antibody commonly denotes one particular set of immunoglobulins known to have specificity for a particular antigen.

Classes of Immunoglobulins

There are five classes of immunoglobulins (IgG, IgA, IgM, IgE, and IgD), which are characterized by differences in structure and function (Figure 7-4). Both IgG and IgA have subclasses (Table 7-2).

sIgA, Secretory immunoglobulin A; − indicates lack of activity; + to +++ indicate relative activity or concentration.

IgG is the most abundant class of immunoglobulins, constituting 80% to 85% of the immunoglobulins in the blood and accounting for most of the protective activity against infections. During pregnancy maternal IgG is transported across the placenta and protects the newborn child during the first 6 months of life.

IgA is found in the blood and in bodily secretions as secretory IgA (subclass IgA2). Secretory IgA is a dimer consisting of two IgA2 molecules held together through a J chain and secretory piece. The secretory piece is attached to dimeric IgA during transportation through mucosal epithelial cells to protect against degradation by enzymes also found in secretions.

IgM is the largest immunoglobulin and usually exists as a pentamer (a molecule consisting of five identical smaller molecules) that is stabilized by a J chain. It is the first antibody produced during the initial, or primary, response to antigens. IgM is usually synthesized early in neonatal life, but may be increased as a response to infection in utero.

IgD is found in low concentrations in the blood. Its primary function is as an antigen receptor on the surface of early B cells.

IgE is normally at low concentrations in the circulation. It has very specialized functions as a mediator of many common allergic responses (see Chapter 8) and in the defense against parasitic infections.

### Molecular Structure

There are three parts to an antibody molecule (Figure 7-5). Two identical fragments have the ability to bind antigen and are termed antigen-binding fragments (Fab). The third fragment is termed the crystalline fragment (Fc). The Fab portions contain the recognition sites (receptors) for antigens and confer the molecule’s specificity toward a particular antigen. The Fc portion is responsible for most of the
biologic functions of antibodies.

An immunoglobulin molecule consists of four polypeptide chains: two identical light (L) chains and two identical heavy (H) chains. The class of antibody is determined by different amino acid sequences in the heavy chains. The light and heavy chains are held together by noncovalent bonds and covalent disulfide linkages. A set of disulfide bridges between the heavy chains occurs in the hinge region and, in some instances, lends a degree of flexibility at that site.

Each L and H chain is further subdivided structurally into constant (C) and variable (V) regions. The constant regions have relatively stable amino acid sequences within a particular immunoglobulin class. Conversely, among different antibodies, the sequences of the variable regions have a large number of amino acid differences and these are called complementary determining regions (CDR). They determine the specificity of an antibody for a particular antigen. The regions
between the CDR’s are called framework regions (FR) and they have more stable amino acid sequences (see Figure 7-5).

**Antigen-Antibody Binding**

Because antigens are relative small, a large molecule (e.g., protein, polysaccharide, nucleic acid) usually contains multiple and diverse antigens. The precise area of the antigen that is recognized by an antibody is called its **antigenic determinant**, or **epitope**. The matching portion on the antibody is sometimes referred to as the **antigen-binding site**, or **paratope**. The antigen fits into the antigen binding site of the antibody with the specificity of a key into a lock and is held there by noncovalent chemical interactions.

**Function of Antibodies**

The chief function of antibodies is to protect against infection. The mechanism can be either **direct**—through the action of antibody alone or **indirect**—requiring activation of other components of the innate immune response (Figure 7-6). Directly, antibodies can affect infectious agents or their toxic products by **neutralization** (inactivating or blocking the binding of antigens to receptors), **agglutination** (clumping insoluble particles that are in suspension), or **precipitation** (making a soluble antigen into an insoluble precipitate). For instance, many pathogens initiate infection by attaching to specific receptors on cells. Viruses that cause the common cold or the influenza virus must attach to specific receptors on respiratory tract epithelial cells. Some bacteria, such as *Neisseria gonorrhoeae* that causes gonorrhea, must attach to specific sites on urogenital epithelial cells. Antibodies may protect the host by covering sites on the microorganism that are needed for attachment, thereby preventing infection. Many viral infections can be prevented by vaccination with inactivated or attenuated (weakened) viruses designed to induce neutralizing antibody production at the site of the entrance of the virus into the body. Vaccination against influenza using an inhaled vaccine particularly induces protective IgA in the respiratory tract.
FIGURE 7-6  Direct and Indirect Functions of Antibody. Protective activities of antibodies can be direct (through the action of antibody alone) or indirect (requiring activation of other components of the innate immune response, usually through the Fc region). Direct means include neutralization of viruses or bacterial toxins before they bind to receptors on the surface of the host's cells. Indirect means include activation of the classical complement pathway through C1, resulting in formation of the membrane-attack complex (MAC), or increased phagocytosis of bacteria opsonized with antibody and complement components bound to appropriate surface receptors (FcR and C3bR).

Some bacteria secrete toxins that harm individuals. For instance, specific bacterial toxins cause the symptoms of tetanus or diphtheria. Most toxins are proteins that bind to surface molecules on cells and damage those cells. Protective antibodies produced against the toxin (referred to as antitoxins) can bind to the toxins, prevent their interaction with host cells, and neutralize their biologic effects (see Chapter 8).

Indirectly, through the Fc portion, antibodies activate components of innate resistance, including complement and phagocytes (Figure 7-7). Through the classical pathway, complement component C1 will be activated by binding simultaneously to the Fc regions of two adjacent antibodies bound to a microbe, resulting in activation of the entire cascade. Phagocytic cells express receptors that bind the Fc portion of antibody; thus antibody is an opsonin that facilitates phagocytosis of bacteria. IgM is the best complement-activating antibody, and IgG is the best opsonin. Some antibodies are more protective than others. It is now a
common procedure to clone the “best” antibodies (monoclonal antibodies) for use in diagnostic tests and for therapy (Box 7-1).

**Box 7-1**

**Monoclonal Antibodies**

Most humoral immune responses are polyclonal—that is, a mixture of antibodies produced from multiple B lymphocytes. Most antigenic molecules have multiple antigenic determinants, each of which induces a different group of antibodies. Thus, a polyclonal response is a mixture of antibody classes, specificities, and function, some of which are more protective than others.

Monoclonal antibody is produced in the laboratory from one B cell that has been cloned; thus the entire antibody is of the same class, specificity, and function. The advantages of monoclonal antibodies are that (1) a single antibody of known antigenic specificity is generated rather than a mixture of different antibodies; (2) monoclonal antibodies have a single, constant binding affinity; (3) monoclonal antibodies can be diluted to a constant titer (concentration in fluid) because the actual antibody concentration is known; and (4) the antibody can be easily purified. Thus, a highly concentrated antibody with optimal function has been used to develop extremely specific and sensitive laboratory tests (e.g., home and laboratory pregnancy tests) and therapies (e.g., for certain infectious diseases or several experimental therapies for cancer).

**IgE**

IgE is a special class of antibody that protects the individual from infection with large parasitic worms (helminths). However, when IgE is produced against relatively innocuous environmental antigens, it is also the primary cause of common allergies (e.g., hay fever, dust allergies, bee stings). The role of IgE in allergies is discussed in Chapter 8.

Large multicellular parasites usually invade mucosal tissues. Many antigens from the parasites induce IgE, as well as other antibody classes. IgG, IgM, and IgA bind to the surface of parasites, activate complement, generate chemotactic factors for neutrophils and macrophages, and serve as opsonins for those phagocytic cells. This response, however, does not greatly damage parasites. The only inflammatory cell that can adequately damage a parasite is the eosinophil because of the special contents of its granules, including major basic protein, eosinophil cationic protein, eosinophil peroxidase, and eosinophil neurotoxin, each of which can damage infectious worms. Thus, IgE is designed to specifically initiate an inflammatory
reaction that preferentially attracts eosinophils to the site of parasitic infection.

Mast cells in the tissues have Fc receptors that specifically and with high affinity bind IgE. IgE antibodies against antigens of the parasite are rapidly bound to the mast cell surface. Soluble parasite molecules with multiple antigenic determinants diffuse to neighboring mast cells and simultaneously bind to multiple IgE molecules. This reaction initiates a cascade of effects that can ultimately kill the parasite. The steps of the cascade are presented in Figure 7-7.

**FIGURE 7-7 IgE Function.** (1) Soluble antigens from a parasitic infection cause production of IgE antibody by B cells. (2) Secreted IgE binds to IgE-specific receptors on the mast cell. (3) Additional soluble parasite antigen cross-links the IgE on the mast cell surface, (4) leading to mast cell degranulation and release of many proinflammatory products, including eosinophil chemotactic factor of anaphylaxis (ECF-A). (5) ECF-A attracts eosinophils from the circulation. (6) The eosinophil attaches to the surface of the parasite and releases potent lysosomal enzymes that damage microorganisms.

**Secretory Immune System**

Immunocompetent lymphocytes migrate among secondary lymphoid organs and tissue as part of the systemic immune system. Another, partially independent, immune system protects the external surfaces of the body through lacrimal and salivary glands and a network of lymphoid tissues residing in the breasts, bronchi, intestines, and genitourinary tract. This system is called the secretory (mucosal)
immune system (Figure 7-8). Plasma cells in those sites secrete antibodies in bodily secretions such as tears, sweat, saliva, mucus, and breast milk to prevent pathogenic microorganism from infecting the body's surfaces and possibly penetrating to cause systemic disease.\(^5\) Alternatively, the microorganisms may reside in the membranes without causing disease, be shed, and cause infection for other individuals. Thus, an individual may become a carrier for a particular infectious organism. For instance, in the 1950s two vaccines were developed to prevent infection with poliovirus, which enters through the gastrointestinal tract. The Sabin vaccine was administered orally as an attenuated (i.e., inactivated so as to render relatively harmless) live virus. This route caused a transient, limited infection and induced effective systemic and secretory immunity that prevented both the disease and the establishment of a carrier state. The Salk vaccine, on the other hand, consisted of killed viruses administered by injection in the skin. It induced adequate systemic protection but did not generally prevent an intestinal carrier state. Thus, recipients of the Salk vaccine were protected from disease but could still shed the virus and infect others.
Secretory Immune System. A, Lymphocytes from the mucosal-associated lymphoid tissues circulate throughout the body in a pattern separate from other lymphocytes. For example, lymphocytes from the gut-associated lymphoid tissue circulate through the regional lymph nodes, the thoracic duct, and the blood and return to other mucosal-associated lymphoid tissues rather than to lymphoid tissue of the systemic immune system. B, Lymphoid tissue associated with mucous membranes is called mucosal-associated lymphoid tissue.
IgA is the dominant **secretory immunoglobulin**, although IgM and IgG also are present in secretions. The primary role of IgA is to prevent the attachment and invasion of pathogens through mucosal membranes, such as those of the gastrointestinal, pulmonary, and genitourinary tracts. Dimeric IgA antibodies containing the J chain are produced by plasma cells of the mucosa. Mucosal epithelium expresses a cell surface immunoglobulin receptor that binds and internalizes IgA. The IgA, along with the epithelial receptor (secretory piece), is secreted as secretory IgA (sIgA).

The lymphoid tissues of the secretory immune system are connected; thus many foreign antigens in a mother's gastrointestinal tract (e.g., polio virus) induce secretion of specific antibodies into the breast milk. Colostral antibodies (i.e., those found in the colostrum of breast milk) may protect the nursing newborn against infectious disease agents that enter through the gastrointestinal tract. Although colostral antibodies provide the newborn with passive immunity against gastrointestinal infections, they do not provide systemic immunity because transport across the newborn's gut into the bloodstream is discontinued after the first 24 hours of life. Maternal antibodies that pass across the placenta into the fetus before birth provide passive systemic immunity.
Immune Response: Collaboration of B Cells and T Cells

Generation of Clonal Diversity

The immune response occurs in two phases: generation of clonal diversity and clonal selection (Table 7-3 and see Figure 7-2). Clonal diversity is the production of a large population of B cells and T cells before birth that have the capacity to recognize almost any foreign antigen found in the environment. This process mostly occurs in specialized lymphoid organs (the primary [central] lymphoid organs): the bone marrow for B cells and the thymus for T cells. The result is the differentiation of lymphoid stem cells into B and T lymphocytes with the ability to react against almost any antigen that will be encountered throughout life. It is estimated that B and T cells can collectively recognize more than $10^8$ different antigenic determinants. Lymphocytes are released from these organs into the circulation as immunocompetent cells that have the capacity to react with antigens and migrate to the circulation and other (secondary) lymphoid organs in the body.

**Development of B Lymphocytes**

Lymphocytes destined to become B cells circulate through the specialized regions of the bone marrow, where they are exposed to hormones and cytokines that induce proliferation and differentiation into B cells (see Figure 7-2). Lymphoid stem cells in the bone marrow interact with stromal cells through a variety of intercellular adhesion molecules. As the stem cell begins to mature, it progressively develops a
variety of necessary surface markers important for the further differentiation and proliferation of the B cell.\textsuperscript{7} The next stage in development is formation of the B-cell receptor (BCR).

The \textbf{B-cell receptor (BCR)} is a complex of antibody bound to the cell surface and other molecules involved in intracellular signaling (Figure 7-9). Its role is to recognize an antigen and communicate that information to the cell’s nucleus. The BCRs in immunocompetent cells are membrane-associated IgM (mIgM) and IgD (mIgD) immunoglobulins that have identical specificities for antigen. The mIgM is a monomer rather than the pentamer primarily found in the blood.

![BCR complex](image)

\textbf{FIGURE 7-9} B-cell Antigen Receptor and T-cell Antigen Receptor. \textbf{A}, The antigen receptor on the surface of B cells (BCR complex) is a monomeric (single) antibody with a structure similar to that of circulating antibody, with an additional transmembrane region (TM) that anchors the molecule to the cell surface. The active BCR complex contains molecules (Igα and Igβ) that are responsible for intracellular signaling after the receptor has bound antigen. \textbf{B}, The T-cell receptor (TCR) consists of an α- and a β-chain joined by a disulfide bond. Each chain consists of a constant region (Cα and Cβ) and a variable region (Vα and Vβ). Each variable region contains CDRs and FRs in a structure similar to that of antibody. The active TCR is associated with several molecules that are responsible for intracellular signaling after antigen binding. These include the CD3, which is a complex of γ (gamma), ξ (epsilon), and δ (delta) subunits and a complex of two ζ (zeta) molecules. The ζ molecules are attached to a cytoplasmic protein kinase (ZAP70) that is critical to intracellular signaling.

As described previously, the variable regions of antibodies, as well as the BCR, contain \textbf{CDR} areas. The diversity of these CDRs is responsible for the variety of antigens that can be recognized by immunocompetent B cells.\textsuperscript{8} The enormous repertoire of specificities is made possible by rearrangement of existing DNA during B-cell development in the primary lymphoid organs, a process known as \textbf{somatic recombination}. Multiple loci in the DNA that encode for the variable regions of immunoglobulins are recombined to generate receptors that collectively
can recognize and bind to any possible antigen.\textsuperscript{8} To create the variable region of a light chain, different regions are rearranged using enzymes encoded by \textit{recombination activating genes (RAG-1, RAG-2)}. The DNA is cut and spliced (repaired) so that after this manipulation, the progeny of a single lymphocyte will synthesize immunoglobulins with identical variable regions. Those variable regions, however, are cut and spliced differently from those of another lymphocyte, making each cell unique and therefore able to react with different antigens. The gene for the H chain undergoes similar rearrangement.

Somatic rearrangement of the variable regions will frequently result in a BCR that recognizes the individual's own antigens, which may result in inadvertent attack on “self” antigens expressed on various tissue and organs causing autoimmune disease or hypersensitivities. Many of these “autoreactive” B cells are eliminated in the bone marrow. It is estimated that more than 90\% of developing B cells are induced to undergo apoptosis. This process is referred to as \textbf{central tolerance}, so that resultant immunocompetent B cells are against foreign antigens and “tolerant” to \textit{self-antigens}. The process of peripheral tolerance is discussed on p. 173.

B-cell differentiation also is characterized by the development of a variety of important surface molecules that are markers for B cells. These include CD21 (a complement receptor) and CD40 (adhesion molecule required for later interactions with T cells).

\textbf{Development of T Lymphocytes}

The process of T-cell proliferation and differentiation is similar to that for B cells (see \textbf{Figure 7-2}). The primary lymphoid organ for T-cell development is the thymus.\textsuperscript{9} Lymphoid stem cells journey through the thymus, where, under influence of thymic hormones and the cytokine IL-7, they are driven to undergo cell division and simultaneously produce receptors (\textbf{T-cell receptors [TCRs]}) against the diversity of antigens the individual will encounter throughout life. They exit the thymus through the blood vessels and lymphatics as mature (immunocompetent) T cells with antigen-specific receptors on the cell surface and establish residence in secondary lymphoid organs.

Production of the TCR proceeds in a manner very similar to that described earlier for B cells. The most common TCR resembles an antibody Fab region and consists of two protein chains, α- and β-chains, each of which has a variable region and a constant region (see \textbf{Figure 7-9}). The variable regions also undergo somatic recombination. As with the BCR, a set of intracellular signaling molecules co-assemble in the membrane with the TCR. The complex of these signaling molecules is called \textbf{CD3}.\textsuperscript{10} Thus, all immunocompetent T cells can be identified by the
presence of CD3 on the surface.

Differentiation of T cells in the thymus also results in expression in a variety of other important surface molecules. Initially, proteins called **CD4** and **CD8** are concurrently expressed on the developing cells. CD4 cells develop into T-helper cells (Th cells), whereas CD8 cells become T-cytotoxic cells (Tc cells). Approximately 60% of immunocompetent T cells in the circulation express CD4 and 40% express CD8.

Central tolerance also occurs in the thymus where more than 95% of developing T cells are deleted. Like B-cells, T-cells can also become autoreactive.

**Quick Check 7-2**

1. What are the major functions of antibodies?
2. What is the difference between the secretory and systemic immune systems?
3. What are the different types of T cells, and what function does each have?

**Clonal Selection**

Antigens initiate the second phase of the immune response, clonal selection. **Clonal selection** is the processing of antigen for a specific immune response. This process involves a complex interaction among cells in the secondary lymphoid organs (see Figure 7-2). To initiate an effective immune response, most antigens must be **processed** because they cannot react directly with most cells of the immune system and must be shown or **presented** to the immune cells in a specific manner. This is the job of **antigen-processing (antigen-presenting) cells** (usually **dendritic cells**, macrophages, or similar cells), generally referred to as **APCs**. The interaction among APCs, subpopulations of T cells that facilitate immune responses (T-helper [Th] cells), and immunocompetent B or T cells results in differentiation of B cells into active antibody-producing cells (plasma cells) and T cells into effector cells, such as T-cytotoxic cells. Both lines also develop into memory cells that respond even faster when that antigen enters the body again. Thus, activation of the immune system produces a long-lasting protection against specific antigens (see Figure 7-2). Defects in any aspect of cellular collaboration will lead to defects in cell-mediated immunity, humoral immunity, or both and, depending on the particular defect, potentially the individual's death from infection (see Chapter 8).

**Primary and Secondary Immune Responses**
The immune response to antigen has classically been divided into two phases—the primary and secondary responses—that are most easily demonstrated by measuring concentrations of circulating antibodies over time (Figure 7-10). After a single initial exposure to most antigens, there is a latent period, or lag phase, during which clonal selection occurs. After approximately 5 to 7 days, IgM antibody is detected in the circulation. This is the **primary immune response**, characterized typically by initial production of IgM followed by production of IgG against the same antigen. The quantity of IgG may be about equal to or less than the amount of IgM. The amount of antibody in a serum sample is frequently referred to as the **titer**; a higher titer indicates more antibodies. If no further exposure to the antigen occurs, the circulating antibody is catabolized (broken down) and measurable quantities fall. The individual's immune system, however, has been primed.

A second challenge by the same antigen results in the **secondary immune response**, which is characterized by the more rapid production of a larger amount of antibody than the primary response. The rapidity of the secondary immune response is the result of memory cells that require less further differentiation. IgM may be transiently produced in the secondary response, but IgG production is
increased considerably, making it the predominant antibody class. Natural infection (e.g., rubella) may result in measurable levels of protective IgG for the life of the individual. Some vaccines (e.g., polio) also may produce extremely long-lived protection, although most vaccines require boosters at specified intervals.

**Antigen Processing and Presentation**

For most antigens, the first step in clonal selection is processing and presentation by APCs. Antigens are usually expressed on large molecules found on microbes, which undergo phagocytosis and destruction by dendritic cells and macrophages. These are referred to as *exogenous antigens*. Other antigens, *endogenous antigens*, originate within a cell that has been infected by a virus or has become cancerous.

Processing results in the release of small antigenic determinants, which are presented on the surface of APCs by specialized molecules, molecules of the major histocompatibility complex (MHC). MHC molecules in humans also are called *human leukocyte antigens (HLA)* (discussed in more detail in Chapter 8) and are related to their role in transplantation. *Major histocompatibility complex (MHC)* molecules are glycoproteins found on the surface of all human cells except red blood cells. They are divided into two general classes, class I and class II, based on their molecular structure, distribution among cell populations, and function in antigen presentation. MHC class I molecules are composed of a large alpha (α) chain along with a smaller chain called β₂-microglobulin. MHC class II molecules are composed of α- and β-chains that differ from the ones used for MHC class I. The α- and β-chains of the MHC molecules are encoded from different genetic loci located as a large complex of genes on human chromosome 6 (*Figure 7-11*). MHC genes are probably the most polymorphic of any human genes; therefore, no two individuals, except identical twins, will have a complete set of identical MHC molecules.
MHC class I molecules present endogenous antigens, which are primarily recognized by T-cytotoxic (Tc) cells. Because MHC class I molecules are expressed on all cells, except red blood cells, any change in that cell caused by viral infection or malignancy may result in foreign antigens being presented. MHC class II molecules present exogenous antigens (Figure 7-12). Antigen presented by MHC class II molecules is preferentially recognized by T-helper (Th) cells. Thus, antigen presentation to Tc cells is *MHC class I restricted* and presentation to Th cells is *MHC class II restricted*. MHC class II molecules are co-expressed with MHC class I molecules on a limited number of cells that have APC function, including macrophages, dendritic cells, and B lymphocytes.
Antigen processing and presentation are required for initiation of most immune responses. Foreign antigen may be either endogenous (cytoplasmic protein) or exogenous (e.g., bacterium). Endogenous antigenic peptides are transported into the endoplasmic reticulum (ER) (1), where the MHC molecules are being assembled. In the ER, antigenic peptides bind to the α-chains of the MHC class I molecule (2), and the complex is transported to the cell surface (3). The α- and β-chains of the MHC class II molecules are also being assembled in the endoplasmic reticulum (4), but the antigen-binding site is blocked by a small molecule (invariant chain) to prevent interactions with endogenous antigenic peptides. The MHC class II–invariant chain complex is transported to phagolysosomes (5), where exogenous antigenic fragments have been produced as a result of phagocytosis (6). In the phagolysosomes, the invariant chain is digested and replaced by exogenous antigenic peptides (7), after which the MHC class II–antigen complex is inserted into the cell membrane (8).

Thus, the term antigen processing relates to the process by which large exogenous and endogenous antigens are cut up by enzymes into small antigenic fragments that are linked with the appropriate MHC molecules and inserted into the membrane of the APC. Lipid antigens are frequently presented by a molecule unrelated to the MHC, CD1, which is not discussed here.

Cellular Interactions in the Immune Response

The second step in clonal selection is a finally tuned set of intercellular collaborations that result in the production of effector cells (plasma cells, Th cells, Tc cells) and memory cells. Each collaboration requires three complementary intracellular signaling events: antigen-specific recognition through the TCR complex, activation of intercellular adhesion molecules, and the response to specific groups of cytokines. Without each signaling event, a protective immune response will not be produced.
**T-helper lymphocytes.**

Regardless of whether an antigen primarily induces a cellular or humoral immune response, APCs usually must present antigens to T-helper cells (Th cells). The APC presents antigen held by the polymorphic regions (α1 and β1) of the α- and β-chains of MHC class II molecules. The antigen also binds to the TCR on the Th cell (see Figure 7-9). The strength of the intercellular antigen binding is increased by CD4 on the Th cell, which binds to a nonpolymorphic region of the β2 region of the MHC class II molecule. The cytoplasmic portions of CD3 and CD4 interact to activate intracellular signaling pathways. A second co-stimulatory signal results from the interaction of a variety of adhesion molecules; the most critical being B7 on the APC and CD28 on the Th cell.

The third signal occurs through Th-cell cytokine receptors. In the early stages of Th-cell differentiation, IL-1 secreted by the APC provides this signal through the IL-1 receptor on the Th cell (Figure 7-13). The initial differentiation response by the Th cell includes the production of the cytokine IL-2 and up-regulation of IL-2 receptors. IL-2 is secreted and acts in an autocrine (self-stimulating) fashion to induce further maturation and proliferation of the Th cell. Without IL-2 production, the Th cell cannot efficiently mature into a functional helper cell.
FIGURE 7-13 Development of T-Cell Subsets. The most important step in clonal selection is the production of populations of T-helper (Th) cells (Th1, Th2, and Th17) and T-regulatory (Treg) cells that are necessary for the development of cellular and humoral immune responses. In this model, APCs (1) (probably multiple populations) may influence whether a precursor Th cell (Thp cell) (2) will differentiate into a Th1, Th2, Th17, or Treg cell (3). Differentiation of the Thp cell is initiated by three signaling events. The antigen signal is produced by the interaction of the T-cell receptor (TCR) and CD4 with antigen presented by MHC class II molecules. A set of co-stimulatory signals is produced from interactions between adhesion molecules (not shown). A third signal is produced by the interactions of cytokines (particularly interleukin-1 [IL-1]) with appropriate cytokine receptors (IL-1R) on the Thp cell. The Thp cell up-regulates IL-2 production and expression of the IL-2 receptor (IL-2R), which acts in an autocrine fashion to accelerate Thp cell differentiation and proliferation. Commitment to a particular phenotype results from the relative concentrations of other cytokines. IL-12 and IFN-γ produced by some populations of APCs favor differentiation into the Th1 cell phenotype; IL-4, which is produced by a variety of cells, favors differentiation into the Th2 cell phenotype; IL-6 and TGF-β (T-cell growth factor) facilitate differentiation into Th17 cells; IL-2 and TGF-β induce differentiation into Treg cells. The Th1 cell is characterized by the production of cytokines that assist in the differentiation of T-cytotoxic (Tc) cells, leading to cellular immunity, whereas the Th2 cell produces cytokines that favor B-cell differentiation and humoral immunity. Th1 and Th2 cells affect each other through the production of inhibitory cytokines: IFN-γ will inhibit development of Th2 cells, and IL-4 will inhibit the development of Th1 cells. Th17 cells produce cytokines that affect phagocytes and increase inflammation. Treg cells produce immunosuppressive cytokines that prevent the immune response from being excessive. APC, Antigen-presenting cell; IFN, interferon; MHC, major histocompatibility complex; TGF, transforming growth factor.

At this point and depending on the predominant cytokines in the immediate environment, Th cells undergo differentiation into one of several subsets: Th1, Th2, Th17, or Treg cells. These subsets have different functions: Th1 cells preferentially provide help in developing Tc cells (cell-mediated immunity), Th2 cells provide more help for developing B cells (humoral immunity), Th17 cells are lymphokine-secreting cells that activate macrophages, and Treg cells limit the
immune response (these will discussed later in this chapter). The Th subsets differ considerably in the spectrum of cytokines they produce. Additionally, Th1 and Th2 cells may suppress each other so that the immune response may favor either antibody formation, with suppression of a cell-mediated response, or the opposite. For example, antigens derived from viral or bacterial pathogens and those derived from cancer cells seem to induce a greater number of Th1 cells relative to Th2 cells, whereas antigens derived from multicellular parasites and allergens may result in production of more Th2 cells. Many antigens (e.g., tetanus vaccine), however, will produce excellent humoral and cell-mediated responses simultaneously. Th cells are necessary for development of most humoral and cellular immune responses; therefore the virus that causes acquired immune deficiency syndrome (AIDS) results in life-threatening infections because it specifically infects and destroys Th cells (see Chapter 8).

**Superantigens.**
Several pathogenic microorganisms, particularly viruses and bacteria, manipulate the normal interaction between APCs and Th cells to the detriment of the individual and the benefit of the microbe. A group of microbial molecules are called superantigens (SAGs). SAGs bind to the portion of the TCR outside of its normal antigen-specific binding site, as well as to MHC class II molecules outside of their antigen-presentation sites (Figure 7-14). Some SAGs also react with CD28 on the Th cells and provide a co-stimulatory signal. Thus, SAGs are not processed by an APC to be presented to an immune cell. This binding, which is independent of antigen recognition, provides a signal for Th-cell activation, proliferation, and cytokine production. The normal antigen-specific recognition between Th cells and APCs results in activation of relatively few cells—only those cells with specific TCRs against that antigen. SAGs activate a large population of Th cells, regardless of antigen specificity, and induce excessive production of cytokines, including IL-2, interferon gamma (IFN-γ), and tumor necrosis factor-alpha (TNF-α). The overproduction of inflammatory cytokines results in symptoms of a systemic inflammatory reaction, including fever, low blood pressure, and, potentially, fatal shock. Some examples of SAGs are the bacterial toxins produced by *Staphylococcus aureus* and *Streptococcus pyogenes* (SAGs that cause toxic shock syndrome and food poisoning).
FIGURE 7-14  Superantigens. The T-cell receptor (TCR) and major histocompatibility complex (MHC) class II molecule are normally held together by processed antigen. Superantigens, such as some bacterial exotoxins, bind directly to the variable region of the TCR β-chain and the MHC class II molecule. Each superantigen activates sets of Vβ chains independently of the antigen specificity of the TCR.

**T-cytotoxic lymphocytes.**

The differentiation of immunocompetent T cells into effector T-cytotoxic cells (Tc cells) requires similar intercellular communications as described for Th cells, with some very important differences. Rather than interacting with an APC, the immunocompetent Tc cell recognizes antigen presented by MHC class I molecules on the surface of a virus-infected cell or cancerous cell (Figure 7-15). The Tc cell expresses CD8, rather than CD4. CD8 binds to the MHC class I molecule and, as with Th cell differentiation, the proximity of the CD3 and CD8 cytoplasmic portions activates intercellular signaling pathways. Cytokine signals, especially IL-2, are produced by Th1 cells and activate cytokine receptors on the Tc cells.
**FIGURE 7-15** Tc-Cell Clonal Selection. The immunocompetent Tc cell can react with antigen but cannot yet kill target cells. During clonal selection, this cell reacts with antigen presented by MHC class I molecules on the surface of a virally infected or cancerous abnormal cell. (1) The antigen–MHC class I complex is recognized simultaneously by the T-cell receptor (TCR), which binds to antigen, and CD8, which binds to the MHC class I molecule. (2) A separate signal is provided by cytokines, particularly IL-2 from Th1 cells. (3) In response to these signals, the Tc cell develops into an effector Tc cell with the ability to kill abnormal cells.

**B-cell clonal selection.**

A further sequence of cellular interactions is required to produce an effective antibody response. The immunocompetent B cell is also an APC and expresses surface mIgM and mIgD B-cell receptors (BCRs) (Figure 7-16). Unlike the T-cell receptor that can only see processed and presented antigens, the BCR can react with soluble antigens that have not been processed. B cells also express surface CD21, which is a receptor for opsonins produced by complement activation. Antigen binding through the BCR and CD21 activates the B cell, resulting in internalization, processing, and presentation of antigen fragments by MHC class II molecules. The antigen presented on the B-cell surface is recognized by a Th2 cell through the TCR and CD4. The intercellular bridges created through antigen and other intercellular adhesion molecules induce the Th2 cell to secrete cytokines (particularly IL-4) that initiate B-cell proliferation and maturation into plasma cells.
A major component of B-cell maturation is **class switch**, the process that results in the change in antibody production from one class to another (e.g., IgM to IgG during the primary immune response). Before exposure to antigens and Th2 cells, the B cell produces IgM and IgD, which are used as cell membrane receptors. During the clonal selection process, a B cell proliferates and develops into antibody-secreting plasma cells, and each B cell has the option of becoming a secretor of IgM or changing the class of antibody to a secreted form of IgG, IgA, or IgE. Class switch occurs by another round of somatic recombination with the variable region of the antibody heavy chain being combined with a different constant region of the heavy chain. Because the variable region is conserved and the light chain remains unchanged, the antigenic specificity of the antibody also remains unchanged. The particular constant region chosen by each cell during class switch appears to be, at least partially, under the control of specific Th2 cytokines. For instance, IL-4 and IL-13 appear to preferentially stimulate switch to IgE secretion, and transforming growth factor-beta (TGF-β) and IL-5 appear to play major roles in class switch to IgA secretion. Thus, during clonal selection, a B cell may produce a population of plasma cells that are capable of producing many different classes of antibodies against the same antigen.

Although most antigens require B cells to interact with Th cells, a few antigens can bypass the need for cellular interactions and can directly stimulate B-cell maturation and proliferation. These are called **T-cell–independent antigens** (Figure 7-16).
They are mostly bacterial products that are large and are likely to have repeating identical antigenic determinants that bind and cross-link several BCRs. The accumulated intracellular signal is adequate to induce differentiation into a plasma cell but is not adequate to induce a change in the class of antibody that will be produced. Therefore, T-cell–independent antigens usually induce relatively pure IgM primary and secondary immune responses.

**FIGURE 7-17** Activation of a B Cell by a T-Cell–Independent Antigen. Molecules containing repeating identical antigenic determinants may interact simultaneously with several receptors on the surface of the B cell and induce the proliferation and production of immunoglobulins. Because Th2 cells do not participate, class switch does not occur and the resultant antibody response is IgM.

**Memory cells.**

During the clonal selection process, both B cells and T cells differentiate and proliferate into an extremely large population of long-lived memory cells. Memory cells remain inactive until subsequent exposure to the same antigen. Upon reexposure, these memory cells do not require much further differentiation and will therefore rapidly become new plasma cells or effector T cells without the cellular interactions described previously.
Cell-Mediated Immunity

The rather straightforward function of antibodies has been discussed earlier in this chapter. The function of effector T cells is more complex and utilizes the principles of intercellular recognition necessary for clonal selection.

T-Lymphocyte Function

The clonal selection process produces several subsets of effector T cells. Th cells and T memory cells have already been discussed. Other effector T cells include T-cytotoxic (Tc) cells that attack and destroy cells expressing antigens from intracellular (endogenous) origins, T-regulatory cells (Treg) that limit (suppress) the immune response, and T-lymphokine producing cells that secrete cytokines that activate other cells.

T-Cytotoxic Lymphocytes

T-cytotoxic (Tc) cells are responsible for the cell-mediated destruction of tumor cells or cells infected with viruses. In a fashion similar to intercellular recognition during the clonal selection process, the Tc cell must directly adhere to the target cell through antigen presented by MHC class I molecules and CD8 (Figure 7-18). Because of the broad cellular distribution of MHC class I molecules, Tc cells can recognize antigens on the surface of almost any type of cell that has been infected by a virus or has become cancerous. Unlike clonal selection, the roles of co-stimulatory signals through adhesion molecules and cytokines are of less importance here. Attachment to a target cell activates multiple killing mechanisms through which the Tc cell induces the target cell to undergo apoptosis.
Various other cells kill targets in a fashion similar to Tc lymphocytes. Prominent among these cells are natural killer cells. **Natural killer (NK) cells** are a special group of lymphoid cells that are similar to T cells but lack antigen-specific receptors. Instead, they express a variety of cell surface activation receptors (similar to pattern recognition receptors, see [Chapter 6](#)) that identify protein changes on the surface of cells infected with viruses or that have become cancerous. After attachment, the NK cell kills its target in a manner similar to that of Tc cells. NK cells also have receptors for MHC class I. However, NK cells lack CD8; therefore binding to MHC class I molecules results in inactivation of the NK cell. Thus, NK cells complement the effects of Tc cells. In some instances, a virus-infected or
cancerous cell will “protect” itself by down-regulating MHC class I molecule expression. Without surface MHC class I molecules a cell becomes resistant to Tc-cell recognition and killing. NK cells primarily kill target cells that have suppressed the expression of MHC class I.

NK cells, as well as some macrophages, can specifically kill targets through use of antibodies. NK cells express Fc receptors for IgG. If antigens on the infected or cancerous cell bind IgG, the NK cell can attach through Fc receptors and activate its normal killing mechanisms. This is referred to as antibody-dependent cellular cytotoxicity (ADCC).

**Lymphokine-Secreting T Cells**

Two subsets of Th cells amplify inflammation. Th1 cells, in addition to assisting Tc-cell clonal selection, secrete cytokines that activate M1 macrophages to increase phagocytic and microbial killing functions (described in *Chapter 6*). The most important cytokine for macrophage activation is interferon-γ (IFN-γ). Th2 cells, in addition to assisting B-cell clonal selection, secrete cytokines (e.g., IL-4, IL-13) that activate M2 macrophages for healing and repair of damaged tissue (described in *Chapter 6*). Th17 cells secrete a set of cytokines (e.g., IL-17, IL-22, chemokines) that recruit phagocytic cells to a site of inflammation. Th17-cell cytokines also may activate cells, particularly epithelial cells, to produce antimicrobial proteins in defense against certain bacterial and fungal pathogens.

**T-Regulatory Lymphocytes**

T-regulatory (Treg) cells are a diverse group of T cells that control the immune response, usually suppressing the response and maintaining tolerance against self-antigens. This process occurs in the secondary lymphoid organs and other tissues, known as peripheral tolerance, in contrast to the process of central tolerance described earlier. This population of Treg cells that differentiate from the Th-cell population expresses CD4 and binds to antigens presented by MHC class II molecules. Unlike other Th cells, however, Treg cells express consistently high levels of CD25 (the IL-2 receptor). Differentiation from the Th precursor cell is controlled, primarily by TGF-β and IL-2. Treg cells produce very high levels of immunosuppressive cytokines TGF-β and IL-10, which generally decrease Th1 and Th2 activity by suppressing antigen recognition and Th-cell proliferation.
1. What are antigen-presenting cells?

2. Define BCR and TCR.

3. What is the role of T-helper cells?

4. Why are cytokines important to the immune response?

5. What is the difference between central tolerance and peripheral tolerance?

Age-related mechanisms of self-defense in the newborn child and in the elderly are listed in the *Pediatric Considerations* and *Geriatric Considerations* boxes.

**Pediatric Considerations**

**Age-Related Factors Affecting Mechanisms of Self-Defense in the Newborn Child**

Normal human newborns are immunologically immature; they have deficient antibody production, phagocytic activity, and complement activity, especially components of alternative pathways (e.g., factor B).

The newborn cannot produce all classes of antibody; IgM is produced by the newborn (develops in the last trimester) to in utero infections (e.g., cytomegalovirus, rubella virus, and *Toxoplasma gondii*); only limited amounts of IgA are produced in the newborn; IgG production begins after birth and rises steadily throughout the first year of life.

Maternal antibodies provide protection within the newborn's circulation (see figure below).

Deficits in specific maternal transplacental antibody may lead to a tendency to develop severe, overwhelming sepsis and meningitis in the newborn.
Antibody Levels in Umbilical Cord Blood and in Neonatal Circulation. Early in gestation, maternal IgG begins active transport across the placenta and enters the fetal circulation. At birth, the fetal circulation may contain nearly adult levels of IgG, which is almost exclusively from the maternal source. The fetal immune system has the capacity to produce IgM and small amounts of IgA before birth (not shown). After delivery, maternal IgG is rapidly destroyed and neonatal IgG production increases.
**Geriatric Considerations**

**Age-Related Factors Affecting Mechanisms of Self-Defense in the Elderly**

Immune function decreases with age; diminished T-cell function and reduced antibody responses to antigenic challenge occur with age.

The thymus reaches maximum size at sexual maturity and then undergoes involution until it is a vestigial remnant by middle age; by 45 to 50 years of age, the thymus is only 15% of its maximum size.

With age there is a decrease in thymic hormone production and the organ's ability to mediate T-cell differentiation.
Did You Understand?

Third Line of Defense: Adaptive Immunity

1. Adaptive immunity is a state of protection, primarily against infectious agents, that differs from inflammation by being slower to develop, being more specific, and having memory that makes it much longer lived.

2. The adaptive immune response is most often initiated by cells of the innate system. These cells process and present portions of invading pathogens (i.e., antigens) to lymphocytes in peripheral lymphoid tissue.

3. The adaptive immune response is mediated by two different types of lymphocytes—B lymphocytes and T lymphocytes. Each has distinct functions. B cells are responsible for humoral immunity that is mediated by circulating antibodies (immunoglobulins), whereas T cells are responsible for cell-mediated immunity, in which they kill targets directly or stimulate the activity of other leukocytes.

4. Adaptive immunity can be either active or passive depending on whether immune response components originated in the host or came from a donor.

Antigens and Immunogens

1. Antigens are molecules that bind and react with components of the immune response, such as antibodies and receptors on B and T cells. Most antigens can induce an immune response, and these antigens are called immunogens.

2. All immunogens are antigens but not all antigens are immunogens.

3. Some pathogens are successful because they mimic “self” antigens but avoid inducing an immune response.

4. Large molecules, such as proteins, polysaccharides, and nucleic acids, are most immunogenic. Thus molecular size is an important factor for antigen immunogenicity.

5. Haptens are antigens too small to be immunogens by themselves but become immunogenic after combining with larger molecules.

6. The antigenic determinant, or epitope, is the precise chemical structure with
which an antibody or B-cell/T-cell receptor reacts.

7. Self-antigens are antigens on an individual's own cells. The individual's immune system does not normally recognize self-antigens as immunogenic, a condition known as tolerance.

8. The response to antigen can be divided into two phases: the primary and secondary responses. The primary response of humoral immunity is usually dominated by IgM, with lesser amounts of IgG. The secondary immune response has a more rapid production of a larger amount of antibodies, predominantly IgG.

**Antibodies**

1. The humoral immune response consists of molecules (antibodies) produced by B cells. B cells are lymphocytes.

2. Antibodies are plasma glycoproteins that can be classified by chemical structure and biologic activity as IgG, IgM, IgA, IgE, or IgD.

3. A typical antibody molecule is constructed of two identical heavy chains and two identical light chains (either κ or λ) and has two Fab portions that bind antigen and an Fc portion that interacts with complement or receptors on cells.

4. The protective effects of antibodies may be *direct* through the action of antibody alone or *indirect* requiring activation of other components of the innate immune response.

5. IgE is a special class of antibody produced against environmental antigens that are the primary cause of common allergies. It also protects the individual from infection by large parasitic worms (helminthes).

6. The secretory immune system protects the external surfaces of the body through secretion of antibodies in bodily secretions, such as tears, sweat, saliva, mucus, and breast milk. IgA is the dominant secretory immunoglobulin.

**Immune Response: Collaboration of B Cells and T Cells**

1. The generation of clonal diversity results in production of B and T lymphocytes
with receptors against millions of antigens that possibly will be encountered in an individual's lifetime occurs in the fetus in the primary lymphoid organs: the thymus for T cells and portions of the bone marrow for B cells.

2. The generation of clonal diversity is the differentiation of lymphoid stem cells into B and T lymphocytes. Lymphoid stem cells interact with stromal cells through a variety of adhesion factors. As the stem cell matures it develops a variety of surface markers or receptors, one of the earliest is IL-7 receptor. IL-7, produced by stromal cells is critical for driving differentiation and proliferation of the B cell.

3. The next stage in development is formation of the B-cell receptor (BCR). The role of the BCR is to recognize antigen and communicate that information to the cell's nucleus.

4. The variable regions of antibodies, as well as the BCR, contain CDR areas. The diversity of these CDRs is responsible for the variety of antigens recognized by immunocompetent B cells. The enormous repertoire of antibody specificities is made possible by rearrangement of existing DNA during B-cell development in the primary lymphoid organs, a process called somatic recombination.

5. Somatic rearrangement of the antibody variable regions will frequently result in a BCR that recognizes the individual's own antigens, which may result in attack on “self” antigens expressed on various tissue and organs. Many of these “autoreactive” B cells are eliminated in the bone marrow. Most of the developing B cells undergo apoptosis. This entire process is referred to as central tolerance.

6. The process of T-cell proliferation and differentiation is similar to that for B cells. The primary lymphoid organ for T-cell development is the thymus. Lymphoid stem cells travel through the thymus, where thymic hormones and the cytokine IL-7 promote lymphoid stem cell division and the production of receptors. They exit the thymus as mature immunocompetent T cells with antigen-specific receptors on the cell surface.

7. T cell receptor, or TCR, proceeds in a manner similar to BCR. Initially proteins called CD4 and CD8 are expressed on the developing cells. Eventually CD4 cells develop into T-helper cells (Th cells) and CD8 cells become T-cytotoxic cells. Other mature T cells include T-regulatory cells (Treg) and memory cells.

8. The generation of clonal diversity concludes when immunocompetent T and B cells migrate from the primary lymphoid organs into the circulation and secondary
lymphoid organs to await antigen.

9. The induction of an immune response, or clonal selection, begins when antigen enters the individual's body.

10. Most antigens must first interact with antigen-presenting cells (APCs) (e.g., macrophages). Dendritic cells present in the skin, mucosa, and lymphoid tissues also present antigen.

11. Antigen is processed in the APCs and presented on the cell surface by molecules of the MHC. The particular MHC molecule (class I or class II) that presents antigen determines which cell will respond to that antigen. Th cells require that the antigen be presented in a complex with MHC class II molecules. Tc cells require that the antigen be presented by MHC class I molecules.

12. The T cell sees the presented antigen through the T-cell receptor (TCR) and accessory molecules: CD4 or CD8. CD4 is found on Th cells and reacts specifically with MHC class II. CD8 is found on Tc cells and reacts specifically with MHC class I.

13. Th cells consist of Th1 cells, which help Tc cells respond to antigen; Th2 cells, which help B cells develop into plasma cells; and Th17 cells, which help activate macrophages.

14. Tc cells bind to and kill cellular targets such as cells infected with viruses or cancer cells.

15. The natural killer (NK) cell has some characteristics of the Tc cells and is important for killing target cells in which viral infection or malignancy has resulted in the loss of cellular MHC molecules.

**Pediatric Considerations: Age-Related Factors Affecting Mechanisms of Self-Defense in the Newborn Child**

1. Neonates often have transiently depressed inflammatory function, particularly neutrophil chemotaxis and alternative complement pathway activity.

2. The T-cell–independent immune response is adequate in the fetus and neonate, but
the T-cell–dependent immune response develops slowly during the first 6 months of life.

3. Maternal IgG antibodies are transported across the placenta into the fetal blood and protect the neonate for the first 6 months, after which they are replaced by the child's own antibodies.

**Geriatric Considerations: Age-Related Factors Affecting Mechanisms of Self-Defense in the Elderly**

1. Elderly persons are at risk for impaired wound healing, usually because of chronic illnesses.

2. T-cell function and antibody production are somewhat deficient in elderly persons. Elderly individuals also tend to have increased levels of circulating autoantibodies (antibodies against self-antigens).

Antigenic Targets of Hypersensitivity Reactions,
The defensive system protecting the body from infection is a finely tuned network, but it is not perfect. Sometimes infectious agents can inhibit or escape defense mechanisms or the system may break down, leading to inadequate protection or inappropriate activation. An inadequate response (commonly called an immune deficiency) may range from relatively mild defects to life-threatening severity. Inappropriate responses (hypersensitivity reactions) may be (1) exaggerated against noninfectious environmental substances (allergy); (2) misdirected against the body's own cells (autoimmunity); or (3) directed against beneficial foreign tissues, such as transfusions or transplants (alloimmunity). Several of these inappropriate responses can be serious or life-threatening. This chapter provides an overview of conditions under which our protective systems have failed.
Infection

Modern health care has shown great progress in preventing and treating infectious diseases. In the United States, heart disease and malignancies greatly surpass infectious disease as major causes of death. However, endemic diseases, such as chronic hepatitis, human immunodeficiency virus (HIV), other sexually transmitted infections, and foodborne infections, remain major challenges.\(^1\) Most deaths related to infections occur in individuals whose protective systems are compromised (children, elderly, and those with chronic disease). Influenza/pneumonia (eighth leading cause of death) and sepsis (eleventh leading cause) accounted for more than 89,000 deaths (3.5% of the total number of deaths) in 2011.\(^2\) Other infections resulted in an additional 27,000 deaths.

Infectious disease remains a significant threat to life in many parts of the world, including India, Africa, and Southeast Asia.\(^3\) The advent of sanitary living conditions, clean water, uncontaminated food, vaccinations, and antimicrobial medications has improved the health of many; but inefficient healthcare systems, endemic poverty, political unrest, and other factors have slowed progress in some regions. As a result of these initiatives, smallpox has been eradicated from the globe (the last reported case was in 1975 in Somalia). Worldwide, polio has declined by more than 99% and eradicated from the Western hemisphere. Measles was decreased by 78% and was nearly eliminated in the Western hemisphere. Although vaccines and antimicrobials have diminished the frequency of some infectious diseases, the emergence of new diseases, such as West Nile virus, severe acute respiratory syndrome (SARS), Middle East respiratory syndrome coronavirus (MERS-CoV), and Hantavirus, and the uncontrolled spread of diseases, such as Ebola virus infection, into new regions of Africa, as well as the continued development of many multiple drug–resistant microorganisms, are examples of the current intense challenges in the struggle to prevent and control infectious disease. Some tropical diseases are emerging for the first time in the United States, possibly a result of global warming.

Microorganisms and Humans: A Dynamic Relationship

The increase in antibiotic resistance, in particular, places more importance on maintenance of an intact inflammatory and immune system. Individuals with immune deficiencies become easily infected with opportunistic microorganisms—those that normally would not cause disease but seize the opportunity provided by the person's decreased immune or inflammatory responses.
Unlike opportunistic infections, true pathogens have devised means to circumvent the normal controls provided by the innate and adaptive system. Several factors influence the capacity of a pathogen to cause disease.

- **Communicability**: Ability to spread from one individual to others (e.g., measles and pertussis spread very easily; human immunodeficiency virus [HIV] is of lower communicability)
- **Infectivity**: Ability of the pathogen to invade and multiply in the host (e.g., herpes simplex virus can survive for long periods in a latent stage)
- **Virulence**: Capacity of a pathogen to cause severe disease (e.g., measles virus is of low virulence; rabies and Ebola viruses are highly virulent)
- **Pathogenicity**: Ability of an agent to produce disease—success depends on communicability, infectivity, extent of tissue damage, and virulence (e.g., HIV can kill T lymphocytes)
- **Portal of entry**: Route by which a pathogenic microorganism infects the host (e.g., direct contact, inhalation, ingestion, or bites of an animal or insect)
- **Toxigenicity**: Ability to produce soluble toxins or endotoxins, factors that greatly influence the pathogen's degree of virulence

Infectivity is facilitated by the ability of pathogens to attach to cell surfaces, release enzymes that dissolve protective barriers, multiply rapidly, escape the action of phagocytes, or resist the effect of low pH. After penetrating protective barriers (invasion), pathogens then multiply and spread through the lymph and blood to tissues and organs, where they continue multiplying and cause disease. In humans the route of entrance of many pathogenic microorganisms also becomes the site of shedding of new infectious agents to other individuals, completing a cycle of infection.

Infectious disease can be caused by microorganisms that range in size from 20 nanometers (nm) (poliovirus) to 10 meters (m) (tapeworm). Classes of pathogenic microorganisms and their characteristics are summarized in Table 8-1. Some mechanisms of tissue damage caused by microorganisms are summarized in Table 8-2. The multiple layers of defense against infection are described in Chapters 6 and 7. Table 8-3 contains examples of microorganisms that defeat our protective systems.

### Bacterial Disease

Bacteria are prokaryocytes (lacking a discrete nucleus) and are relatively small. They can be aerobic or anaerobic and motile or immotile. Spherical bacteria are called cocci, rodlike forms are called bacilli, and spiral forms are termed *spirochetes*. Gram stain differentiates the microorganisms as gram-positive or gram-negative bacteria. Examples of human diseases caused by specific bacteria are listed in Table 8-4. The general structure of bacteria is reviewed in Figure 8-1.

</table>
Bacterial survival and growth depend on the effectiveness of the body's defense mechanisms and on the bacterium's ability to resist these defenses. A vast amount of
information has been published about bacterial pathogenesis. The main aspects of how bacteria cause disease may be illustrated in how one particular microorganism, *Staphylococcus aureus*, has adapted to become a life-threatening pathogen. *Staphylococcus aureus* has become a major cause of hospital-acquired (nosocomial) infections and is now spreading throughout the community. This microorganism is a common commensal inhabitant of normal skin and nasal passages (estimates depict that from 30% to 80% of individuals may be nasal carriers) and can be transmitted by direct skin-to-skin contact or by contact with shared items or surfaces that have become contaminated by another person (e.g., towels, used bandages).  

Although a relatively benign commensal microorganism under normal conditions, *S. aureus* is well equipped to act as a life-threatening pathogen when the opportunity arises; thus it is an opportunistic microorganism. Skin infections may occur at sites of trauma, such as cuts and abrasions, and at areas of the body covered by hair (e.g., back of neck, groin, buttock, armpit, beard area of men). Most infections are relatively mild and localized, appearing as red and swollen pustules on the skin, containing pus or other drainage. They can develop into abscesses, boils, carbuncles, cellulitis, or furunculosis. Invasive disease may originate from wound infections (e.g., trauma, surgical wounds, indwelling medical devices, prosthetic joints) and lead to fatal septicemia and abscesses in internal organs (e.g., lungs, kidney, bones, skeletal muscle, meninges, or heart) (Figure 8-2).
Microscopically, staphylococci are gram-positive cocci that generally grow in grapelike clusters. However, this microorganism possesses a myriad of potential virulence factors that determine the severity, location, and clinical features of infection. It should be noted that individual strains of this opportunistic pathogen utilize only some of the entire array of virulence factors.

Microorganisms frequently exist as part of complex multicellular masses called biofilms. Biofilms consist of mixed species of microorganisms, including bacteria, fungi, and viruses. Growth of bacteria in biofilms offers survival advantage by protection from the host's responses and exposure to antibiotics. These structures are associated with otitis media; urinary tract infections secondary to indwelling catheters; foot ulcers in diabetic persons; infected burn wounds; vaginitis;
osteomyelitis; pneumonia secondary to cystic fibrosis; and diseases of the oral cavity related to dental plaque, such as dental caries and periodontitis. *S. aureus* biofilms are associated with persistent nasopharyngeal colonization and colonization of implanted devices.\(^5\)

A variety of surface proteins mediate adherence among microorganisms in biofilms and to connective tissue (laminin, fibrin, fibronectin) and endothelium. Attachment to collagen occurs in strains causing osteomyelitis and septic arthritis. The capsular polysaccharide mediates attachment to prosthetic devices and also protects against phagocytosis. One surface protein, protein A, binds IgG by the Fc portion so that the Fab regions are facing outward.

Thus, the bacteria appear coated with a self-protein, and, with the Fc bound directly to protein A, the IgG cannot activate complement or act as an opsonin.\(^6\) A coagulase that induces fibrin clotting on the bacterial surface also masks bacterial antigens under a surface of self-proteins. Staphylococcal protein A and also a protein called staphylococcal binder of immunoglobulin are secreted and bind and neutralize IgG. *Staphylococcus* produces proteins that inhibit complement activity, including activation of C3 and C5, preventing production of C3b, C3a, and C5a.\(^7\)

Some strains of *S. aureus* are programmed to avoid innate immunity. They can produce inhibitors of antimicrobial peptides and avoid recognition by Toll-like receptors.\(^8\) Even when engulfed by a phagocyte, *S. aureus* may resist intracellular oxidative killing by inactivating hydrogen peroxide and other reactive oxygen species. They also resist lysozyme by changing the chemistry of the cell wall.\(^9\)

Many bacteria use toxins as virulence factors, including exotoxins and endotoxins. Exotoxins are secreted molecules and are immunogenic eliciting production of antibodies known as antitoxins (important for vaccine development, see page 187). The most poisonous yet discovered is botulinum neurotoxin produced by *Clostridium botulinum*; less than 1 ng/kg is toxic to humans. Strains of *S. aureus* are capable of producing a wide array of secreted toxic molecules or exotoxins. These include those that damage the cell membrane (α-toxin, which forms pores in membranes; hemolysin, which destroys erythrocytes; β-toxin, which is a sphingomyelinase; δ-toxin, a detergent-like toxin; and leukocidin, which lyzes phagocytes). Other toxins include coagulase, which causes blood clots; staphylokinase, which breaks down clots; exfoliative toxins, which cause separation of the epidermis resulting in scalded skin syndrome; lipase, which degrades lipids on the skin surface and facilitates abscess formation; enterotoxins, which cause food poisoning; and superantigens (discussed in Chapter 7).\(^10\) Each infectious strain of *S. aureus* may produce a few of these toxins so that strains differ in their capacities to cause particular diseases; thus, different strains may cause purulent dermal infections, food poisoning, or toxic shock syndrome.
Antibiotic resistance has become a major problem with *S. aureus*. For several decades pathogenic strains have commonly produced **β-lactamase**, an enzyme that destroys penicillin. More recently, staphylococci have developed resistance to broad-spectrum antibiotics, including methicillin-like antibiotics (methicillin-resistant *Staphylococcus aureus* [MRSA]), which were widely used to treat penicillin-resistant microorganisms.

It is clear that *S. aureus* succeeds as an opportunistic pathogen because of a wide array of virulence factors that neutralize important components of the innate and adaptive immune systems, destroy tissue, and resist much of our repertoire of antibiotics. The major remaining option is the development of an effective vaccine, a task that is sometimes difficult. As mentioned in the beginning of this section, *S. aureus* is only one of many bacteria that have developed similar characteristics.

Gram-negative microbes produce an **endotoxin (lipopolysaccharide [LPS])** that is a structural portion of the cell wall and is released during growth, lysis, or destruction of the bacteria or during treatment with antibiotics. Therefore, antibiotics cannot prevent the toxic effects of the endotoxin. Bacteria that produce endotoxins are called pyrogenic bacteria because they activate the inflammatory process and produce fever. The innermost part of the lipopolysaccharide, lipid A, consists of polysaccharide and fatty acids and is responsible for the substance's toxic effects.

**Bacteremia** occurs when bacteria are present in the blood. Gram-negative sepsis (sepsis or septicemia) occurs when bacteria are growing in the blood and release large amounts of endotoxin, which can cause **endotoxic shock** with up to 50% mortality. Released endotoxin, as well as other bacterial products, reacts with pattern recognition receptors (PRRs) and induces the overproduction of proinflammatory cytokines, particularly tumor necrosis factor-alpha (TNF-α), interleukin-1 (IL-1), and interleukin-6 (IL-6), which may secondarily be immunosuppressive. Endotoxin also is a potent activator of the complement and clotting systems, leading to a degree of capillary permeability sufficient to permit escape of large volumes of plasma into surrounding tissue, contributing to hypotension and, in severe cases, cardiovascular shock (see Chapter 24). Activation of the coagulation cascade leads to the syndrome of disseminated (or diffuse) intravascular coagulation (see Chapter 21).

**Viral Disease**

Viral diseases are the most common afflictions of humans and range from the common cold, caused by many viruses, and the “cold sore” of herpes simplex virus to cancers and acquired immunodeficiency syndrome (AIDS). Examples of human
diseases caused by specific viruses are listed in Table 8-5. Viruses are very simple microorganisms consisting of nucleic acid protected from the environment by a layer or layers of proteins (capsid). The viral genome can be double-stranded DNA (dsDNA), single-stranded DNA (ssDNA), double-stranded RNA (dsRNA), or single-stranded RNA (ssRNA). A select group of viruses (e.g., human immunodeficiency virus [HIV], herpesviruses, influenza virus) bud from the surface of an infected cell, retaining a portion of the cell's plasma membrane (envelope) as added protection. Viral replication depends totally on their ability to infect a permissive host cell—a cell that cannot resist viral invasion and replication. Thus, viruses are obligatory intracellular microbes. Transmission is usually from one infected individual to an uninfected individual by aerosols of respiratory tract fluids, contact with infected blood, sexual contact, or transmission from an animal reservoir (zoonotic infection) usually through a vector, such as mosquitoes.¹⁴
To understand the basic concepts of viral pathogenicity, it may be best to look closely at a single virus. Influenza is a ssRNA virus with a segmented genome (eight pieces of ssRNA). It is transmitted through aerosols or body fluids and is highly infectious. Symptoms begin 1 to 4 days after infection and may include chills, fever, sore throat, muscle aches, severe headaches, coughing, weakness, generalized discomfort, nausea, and vomiting and may lead to pneumonia. It can be fatal, particularly in young children and older adults. The normal rate of infectivity is about 5% to 15%, with a mortality of about 0.1%, and in most cases recovery occurs
in 1 to 2 weeks. Yearly seasonal influenza outbreaks result in about 250,000 to 500,000 deaths worldwide.

The life cycle of every virus is completely intracellular and involves several steps, the first being *attachment* to a receptor on the target cell (Figure 8-3). The influenza virion expresses two surface proteins that are essential to virulence. The hemagglutinin (HA) protein is a glycoprotein that is necessary for entrance into cells by binding to glycan receptors on the surface of respiratory tract epithelium. The viral surface neuraminidase (NA) is an enzyme that is necessary for release of new virions from infected cells by cleaving cellular sialic acids (a common component of mammalian cell membranes). The specificity of this virus-receptor interaction (*tropism*) dictates the range of host cells that a particular virus will infect and, therefore, the clinical symptoms that reflect the alteration of the function of the infected cells. Other viruses also use specific receptors; for example, HIV attaches to CD4 on T-helper cells, Epstein-Barr virus (EBV, a cause of mononucleosis and Burkitt lymphoma) attaches to complement receptor 2 (CR2) on B lymphocytes, and Rhinovirus (a group of viruses that cause the common cold) attaches to intracellular adhesion molecule-1 (ICAM-1) on respiratory tract epithelium.
Attachment is followed by penetration (entrance into the cell by endocytosis or membrane fusion), uncoating (release of viral nucleic acid from the viral capsid by viral or host enzymes), replication (synthesis of mRNA and viral proteins), assembly (formation of new virions), and release (exit from the cell by lysis or budding). The influenza virus enters the respiratory tract epithelial cells by endocytosis. Low pH leads to intermembrane fusion between the endosome and viral envelop and uncoating. The viral ssRNA is transported to the nucleus where transcription and replication occur using the viral RNA-dependent RNA polymerase. Viral proteins assemble in the cytoplasm to form the matrix around the viral genome, and the virion buds from the cell surface. Infected cells usually die as a direct effect of the virus. The severity of clinical symptoms is usually secondary to the level of cytokines produced by the infected cells or in response to death of the cells.

The effects of virus on the infected cell vary greatly. Some viruses, such as herpesviruses, will initiate a latency phase during which the host cell is transformed (i.e., herpes simplex viruses 1 and 2 establish latency in neurons). During this phase, the viral DNA may be integrated into the DNA of the host cell and become a permanent passenger in that cell and its progeny. In response to stimuli, such as stress, hormonal changes, or disease, the virus may exit latency and enter a
productive cycle. Herpesviruses 1 and 2 are released from the neurons and infect skin epithelium, where lesions in the skin are a result of the immune response against the infected epithelium.

Cytopathic effects caused by other viruses include the following:

1. Cessation of DNA, RNA, and protein synthesis (e.g., herpesvirus)

2. Disruption of lysosomal membranes, resulting in release of digestive lysosomal enzymes that can kill the cell (e.g., herpesvirus)

3. Fusion of host cells, producing multinucleated giant cells (e.g., respiratory syncytial virus)

4. Alteration of the antigenic properties, or identity, of the infected cell, causing the individual's immune system to attack the cell as if it were foreign (e.g., hepatitis B virus)

5. Transformation of host cells into cancerous cells, resulting in uninhibited and unregulated growth (e.g., human papillomavirus)

6. Promotion of secondary bacterial infection in tissues damaged by viruses

The principal method by which influenza virus eludes the immune system is by changing viral surface antigens, a process known as **antigenic variation**. Antibodies against the HA and NA antigens are responsible for protection against influenza infection. Infections are seasonal and protection gained from the previous year's infection does not totally protect against influenza in the following year because the HA and NA antigens undergo yearly change. Usually antigenic variation is relatively minor (**antigenic drift**) and results from mutations. Individuals frequently have partial protection resulting from the previous year's infection, which lessens the clinical effects of the disease. Two groups of influenza virus, influenza A and influenza B, infect humans and the yearly vaccine against influenza is a trivalent mixture of inactivated proteins from two influenza A subtypes and one influenza B subtype. Influenza B almost exclusively infects humans and mutates at a much lower rate than influenza A. Influenza A has antigenically distinct subtypes based on HA (17 forms) and NA (10 forms) antigens. Currently, subtypes H1N1, H1N2, and H3N2 are the primary causes of influenza worldwide.

Influenza A periodically undergoes major antigenic changes (**antigenic shifts**) ([Figure 8-4](#)). Influenza A can infect birds and mammals and shifts occur in animals cointected by a human and an avian strain of influenza. The genome is segmented
and the segments can undergo recombination, during which the human virus obtains a new HA or NA antigen. Without a shift occurring, clinical influenza is usually considered epidemic (the number of new infections exceeds the number usually observed at other times of the year). When major antigenic changes occur, previous protection may not exist, resulting in a major pandemic (an epidemic that spreads over a large area, such as a continent or worldwide) and much more severe disease.

A major worry regards zoonotic influenza during which a lethal influenza virus that infects birds or other animals suddenly develops the capacity to infect humans. These infections are monitored closely by agencies, such as the Centers for Disease Control and Prevention (CDC) in Atlanta. The CDC is currently monitoring human
cases of several zoonotic influenza outbreaks, including swine influenza virus (H1N1), a pathogenic H5N1 avian influenza virus, and a new strain of avian influenza (H7N9) that recently appeared.

Viral pathogens bypass many defense mechanisms by hiding within cells and away from normal inflammatory or immune responses. Some viruses spread from cell-to-cell through the bloodstream (e.g., influenza, rubella) and are highly sensitive to neutralizing antibodies that block viral spread and eventually cure the infection; therefore the disease is described as self-limiting. Other viruses (e.g., measles, herpes) are inaccessible to antibodies after initial infection because they remain inside infected cells, spreading by direct cell-to-cell contact. Most viruses have developed additional defense mechanisms. For instance, influenza virus produces NS1 protein (viral non-structural protein-1) that blocks the antiviral effects of type I interferon.

**Fungal Disease**

Fungi are relatively large eukaryotic microorganisms with thick walls that have two basic structures: single-celled yeasts (spheres) or multicellular molds (filaments or hyphae) (Figure 8-5). Some fungi can exist in either form and are called **dimorphic fungi**. The cell walls of fungi are rigid and multilayered and composed of polysaccharides different from the peptidoglycans of bacteria. The lack of peptidoglycans allows fungi to resist the action of bacterial cell wall inhibitors such as penicillin and cephalosporin. Molds are aerobic, and yeasts are facultative anaerobes, which adapt to, but do not require, anaerobic conditions. They usually reproduce by simple division or budding.
Diseases caused by fungi are called mycoses. Mycoses can be superficial, deep, or opportunistic. Superficial mycoses occur on or near skin or mucous membranes and usually produce mild and superficial disease. Fungi that invade the skin, hair, or nails are known as dermatophytes. The diseases they produce are called tineas (ringworm), for example, tinea capitis (scalp), tinea pedis (feet), and tinea cruris (groin). Chapter 41 discusses the various skin disorders caused by fungi.

Pathologic fungi cause disease by adapting to the host environment. Fungi that colonize the skin can digest keratin. Other fungi can grow with wide temperature variations in lower oxygen environments. Still other fungi have the capacity to suppress host immune defenses. Phagocytes and T lymphocytes are important in controlling fungi. Low white blood cell counts promote fungal infection and infection control is particularly important for individuals who are immunosuppressed. Common pathologic fungi are summarized in Table 8-6.

*Candida albicans* is the most common cause of fungal infections in humans. It is an opportunistic yeast that is a commensal inhabitant in the normal microbiome of many healthy individuals, residing in the skin, gastrointestinal tract, mouth (30% to 55% of healthy individuals), and vagina (20% of healthy women). *Candida albicans* is normally under the control of local defense mechanisms, including members of the bacterial microbiome that produce antifungal agents. In healthy individuals antibiotic therapy can diminish the microbiome (e.g., diminished levels of *Lactobacillus* in the gastrointestinal or vaginal microbiome). *Candida* overgrowth may occur, resulting in localized infection such as vaginitis or oropharyngeal infection (thrust).

In immunocompromised individuals, particularly those with diminished levels of neutrophils (neutropenia), disseminated infection may occur. *Candida* is the most common fungal infection in people with cancer (particularly acute leukemia and other hematologic cancers), transplantation (bone marrow and solid organ), and HIV/AIDS. Invasive candidiasis also may be secondary to indwelling catheters, intravenous lines, or peritoneal dialysis, which provides direct entrance into the bloodstream.

Disseminated candidiasis may involve deep infections of several internal organs, including abscesses in the kidney, brain, liver, and heart, and is characterized by
persistent or recurrent fever, gram-negative shock-like symptoms (hypotension, tachycardia), and disseminated intravascular coagulation (DIC). The death rates of septic or disseminated candidiasis are in the range of 30% to 40%.

**Parasitic Disease**

*Parasitic microorganisms* establish a relationship in which the parasite benefits at the expense of the other species. Parasites range from a unicellular protozoan to large worms. Parasitic worms (helminths) include intestinal and tissue nematodes (e.g., hookworm, roundworm), flukes (e.g., liver fluke, lung fluke), and tapeworms. A protozoan is a eukaryotic, unicellular microorganism with a nucleus and cytoplasm. Pathogenic protozoa include malaria (*Plasmodium*), amoebae (e.g., *Entamoeba histolytica*, which causes amoebic dysentery), and flagellates (e.g., *Giardia lamblia*, which causes diarrhea; *Trypanosoma*, which causes sleeping sickness). Although less common in the United States, parasites and protozoa are common causes of infections worldwide, with a significant effect on the mortality and morbidity of individuals in developing countries. Important parasites of humans are listed in Table 8-7.

*Most common in the United States.

Malaria is one of the most common infections worldwide. In 2012, the World Health Organization (WHO) estimated that there were 207 million cases of malaria
with an estimated 627,000 deaths; 90% were in Africa where 82% of the deaths were children younger than age 5 years. Malaria is caused by *Plasmodium falciparum*, a protozoan ( unicellular) parasite.

Many protozoan parasites are transmitted through vectors or ingested. Vectors include the tsetse fly (*Trypanosoma cruzi*, which causes Chagas disease in South America; *Trypanosoma brucei*, which causes sleeping sickness in Africa) and sand fleas (leishmaniasis). Water and food can be contaminated with protozoal parasites (e.g., *E. histolytica, G. lamblia*). Transmission of *Plasmodium* is through the bite of an infected female *Anopheles* mosquito, where the parasite grows in the salivary gland.

The initial attachment to cells depends on the presence of the microorganism in the bloodstream or gastrointestinal tract. Microorganisms in the bloodstream have surface proteins that allow them to attach to various receptors to infect macrophages, red blood cells, or organ cells such as the liver. For example, multiplication of *Plasmodium* occurs in erythrocytes and results in the release of additional parasites that infect other erythrocytes. Periodic (48 to 72 hours) lysis of the erythrocytes results in anemia and induction of cytokines (e.g., TNF-α, IFN-γ, IL-1) that provoke fever, chills, sweating, headache, muscle pains, and vomiting. Severe symptoms include anemia, pulmonary edema, and other complications causing death. Neurologic complications may result from infected red blood cells adhering to endothelium in capillaries of the brain.

**Countermeasures Against Infectious Microorganisms**

The body's innate and adaptive responses against microorganisms are numerous and involve an interaction between the immune and inflammatory systems. Pathogenic microorganisms, however, have developed means of circumventing the individual's protective defenses. Therefore prophylactic or interventive procedures have been developed either to prevent the pathogen from initiating disease (vaccines, public health measures) or to destroy the pathogen once the disease process has started (antimicrobials). Most vaccine development has focused on preventing the most severe and common infections (Table 8-8). With the initial success of antibiotic therapy, there was no perceived need for vaccination against many common and non–life-threatening infections. The increasing problem of antibiotic-resistant pathogens, however, has forced a reappraisal of that strategy, and a greater emphasis now is being placed on the development of new vaccines.

### Infection Control Measures

Although effective means of safeguarding populations from exposure to infectious disease are well-known, lack of implementation or breakdowns in application of these initiatives has led to the reemergence of some infectious diseases, particularly in less developed countries. The following are some examples of environmental infection control measures:

1. Sanitary disposal of sewage, garbage, and animal waste
2. Provision of water treatment and prevention of water contamination
3. Maintenance of sanitation practices for the transport, preparation, and serving of food
4. Control of insect vectors by draining standing water and implementation of mosquito eradication programs
5. Support of research to develop safe agents for insecticide-resistant insect vectors

### Antimicrobials

Since initiation of the widespread use of penicillin during World War II, antibiotics have significantly prevented the spread of infections. Antibiotics are natural products of fungi, bacteria, and related microorganisms that affect the growth of
other microorganisms. Some antibacterial antibiotics are bactericidal (kill the microorganism), whereas others are bacteriostatic (inhibit growth until the microorganism is destroyed by the individual's own protective mechanisms). The mechanisms of action of most antibiotics are (1) inhibition of the function or production of the cell wall/membrane, (2) prevention of protein synthesis, (3) blockage of DNA replication, or (4) interference with folic acid metabolism (Table 8-9). Because viruses use the enzymes of the host's cells, there has been far less success in developing antiviral antibiotics.

Immediately after antibiotics became widely used, antibiotic-resistant microorganisms were observed. By 1944 an adequate supply of penicillin allowed its widespread use to treat infections. In 1946 a hospital in Britain reported that 14% of all Staphylococcus aureus infections were penicillin resistant, producing β-lactamase, an enzyme that destroys penicillin. The same hospital reported an increase to 59% by 1950 and to greater than 89% in the 1990s.

More than 2 million individuals develop antibiotic-resistant infections yearly, resulting in more than 23,000 deaths. Antibiotic resistance to a single antibiotic has rapidly progressed to multiple-antibiotic resistance. The CDC released a lengthy document on Antibiotic Resistance Threats in the United States, 2013, in which 18 pathogens were sorted into “Urgent Threats,” “Serious Threats,” and “Concerning Threats.” The most urgent threats are Clostridium difficile (C. difficile), carbapenem (an “antibiotic of last resort” against penicillin-resistant organisms) resistant Enterobacteriaceae species (i.e., Klebsiella and E. coli), and drug-resistant Neisseria gonorrhoeae (N. gonorrhoeae).

Many other infections considered routine and easily treatable are now resistant to almost all currently available antibiotics, including methicillin-resistant Staphylococcus aureus [MRSA] and Streptococcus pneumoniae, which causes
pneumonia, meningitis, and acute otitis media (middle ear infection), which were once routinely susceptible to penicillin. Additionally, there are major increases in resistant *Salmonella typhi* (typhoid fever), *Shigella* (bloody diarrhea), *Acinetobacter* (pneumonia), *Campylobacter* (bloody diarrhea), *Enterococcus* (sepsis, wound infection, urinary tract infection), *Pseudomonas aeruginosa* (burn infection, sepsis), and *Mycobacterium tuberculosis* (tuberculosis).\(^{20}\) Antibiotic-resistant fungi (e.g., fluconazole-resistant *Candida albicans*) have evolved and malarial parasites have recently developed broad drug resistance, including to chloroquine—the previous mainstay of the preventive and therapeutic arsenal of antimalarial drugs.

Antibiotic resistance is usually a result of *genetic mutations* that can be transmitted directly to neighboring microorganisms by plasmid exchange or incorporation of free DNA. Some microorganisms can *inactivate antibiotics*, penicillin resistance being the classic example. Other forms of resistance result from *modification of the target molecule*. Azidothymidine (AZT) is a family of antivirals that suppresses the enzymatic activity of reverse transcriptase, a viral-specific enzyme responsible for the replication of viral RNA and production of a DNA copy. HIV frequently mutates and produces an AZT-resistant reverse transcriptase. Multidrug transporters in the microorganism's membrane mediate a third mechanism of resistance. These transporters affect the rate of intracellular accumulation of the antimicrobial by *preventing entrance* or, more commonly, by *increasing active efflux of the antibiotic*. Antibiotic-resistant strains of *M. tuberculosis* are protected from aminoglycosides and tetracycline by a multidrug pump that increases efflux.

Why have multiple antibiotic–resistant microorganisms appeared? Lack of compliance in completing the therapeutic regimen with antibiotics allows the selective resurgence of microorganisms that are more relatively resistant to the antibiotic. Overuse of antibiotics can lead to the destruction of the normal microbiome, allowing the selective overgrowth of antibiotic-resistant strains or pathogens that had previously been controlled. There also is concern that overuse of antibiotics to promote growth in cattle results in ingestion of antibiotic-containing meat.\(^{21}\)

**Active Immunization**

Recovery from an infection generally results in the strongest resistance to a future infection with the same microbe. **Vaccines** are biologic preparations of antigens that when administered stimulate production of protective antibodies or cellular immunity against a specific pathogen without causing potentially life-threatening disease. The purpose of **vaccination** is to induce long-lasting protective immune
responses under safe conditions. The primary immune response from vaccination is generally short lived; therefore booster injections are used to push the immune response through multiple secondary responses that result in large numbers of memory cells and sustained protective levels of antibody or T cells, or both.

Mass vaccination programs have been tremendously successful and have led to major changes in the health of the world's population. In the early 1950s an estimated 50 million cases of smallpox occurred each year, with about 15 million deaths. The World Health Organization (WHO) conducted an aggressive immunization campaign from 1967 to 1977 that resulted in the global eradication of smallpox by 1979. Many vaccines are used in the United States and the Centers for Disease Control and Prevention (CDC) provides updated vaccine schedules at their website: www.cdc.gov/vaccines/recs/schedules/default.htm.

Development of a successful vaccine is costly and depends on several factors. These include identification of the protective immune response and the appropriate antigen to induce that response. For instance, individuals with ongoing HIV infection produce a great deal of antibody against several HIV antigens. But, for development of a successful vaccine, we must first understand which antibody, if any, will protect against an initial infection.

Once a good candidate antigen is identified, it must be developed into an effective, cost-efficient, stable, and safe vaccine. Most vaccines against viral infection (measles, mumps, rubella, varicella [chickenpox]) contain live viruses that are weakened (attenuated virus) so they continue to express appropriate antigens but establish only a limited and easily controlled infection. Limited replication of the virus appears to afford better long-term protection than using viral antigen. Current exceptions are the hepatitis B vaccine, which uses a recombinant viral protein, and the hepatitis A vaccine, which is an inactivated (killed) virus and normally should not cause an infection.

Even attenuated viruses can establish life-threatening infections in individuals whose immune systems are deficient or suppressed. The risk of infection by the vaccine strain of virus is extremely small, but it may affect the choice of recommended vaccines. For instance, the Sabin polio vaccine was an attenuated virus that was administered orally. It provided systemic protection and induced a secretory immune response to prevent growth of the poliovirus in the intestinal tract. Being a live virus, the vaccine could cause polio in some children who had unsuspected immune deficiencies (about 1 case in 2.4 million doses). The Salk vaccine was a completely inactivated virus administered by injection. It induced protective systemic immunity but did not provide adequate secretory immunity. Therefore even if the individual was protected from systemic infection by poliovirus, the virus could establish a limited infection in the individual's intestinal
mucosa, be shed, and infect others. When polio was epidemic, the oral vaccine was preferred. However, the live attenuated vaccine itself caused about eight cases of paralytic polio per year in the United States in individuals with inadequate immune systems. As a result, the current recommendation of the CDC is vaccination with the killed virus.

Some common bacterial vaccines are killed microorganisms or extracts of bacterial antigens. The vaccine against pneumococcal pneumonia consists of a mixture of capsular polysaccharides from 23 strains of *Streptococcus pneumoniae*. Of the more than 90 known strains of this microorganism, these 23 cause the most severe illnesses. However, the capsular vaccine is not very immunogenic in young children. A *conjugated* vaccine is available that contains capsular polysaccharides from 13 strains conjugated to carrier proteins in order to increase immunogenicity. A similar vaccine is available for *Haemophilus influenzae* type b (Hib).

Some bacterial pathogens are not invasive, but colonize mucosal membranes or wounds and release potent exotoxins that act locally or systemically. Vaccination against systemic exotoxins (e.g., diphtheria, tetanus, pertussis) has been achieved using toxoids—purified exotoxins that have been chemically detoxified without loss of immunogenicity. Pertussis (whooping cough) vaccine has been changed from a killed whole-cell vaccine to cellular extract (acellular) vaccine that contains the pertussis toxoid and additional bacterial antigens. This change has dramatically reduced adverse side effects (fever, local inflammatory reactions, and others) of vaccination.

With so many recommended vaccines, there has been an effort to combine vaccines in order to minimize the number of required injections. One of the first licensed vaccine mixtures was DPT, which now usually contains diphtheria (D) and tetanus (T) toxoids and acellular pertussis vaccine (aP). More recent mixtures include DTaP with inactivated poliovirus, either with Hib conjugate to tetanus toxoid or with hepatitis B antigen.

Common problems confronting vaccination programs include access to the programs in less developed countries or lack of compliance of the susceptible population even when vaccination programs are available. A certain percentage of the population will be genetically unresponsive or less responsive to a particular vaccine and therefore will not produce a protective immune response. As many as 10% of the population may not respond adequately to the recommended series of injections. With most vaccines, the percentage of unresponsive individuals is low, and they will benefit from successful immunization of the rest of the population. Depending on the microorganism, a certain percentage of the population (usually about 85%) should be immunized in order to achieve protection of the total population. This is referred to as *herd immunity*. If this level of immunization is not
achieved, outbreaks of infection can occur. More recently resistance to immunization with measles has increased, and in early 2008 the number of measles cases in the United States increased by about fourfold. In several European countries antivaccine groups have disrupted immunization programs. As a result the incidence of pertussis (whooping cough) increased by 10 to 100 times in those countries compared with neighboring countries that maintained a high incidence of immunization. Immunizations should be complete before children start school.

The reluctance to vaccinate has generally been based on potential vaccine dangers. As with any medicine, complications can arise. In the case of vaccines, these include pain and redness at the injection site, fever, allergic reactions to vaccine ingredients, infection associated with attenuated viruses in immune-deficient individuals, and others. More severe dangers do exist, although they are extremely rare. More commonly the reluctance to vaccination is based on inadequate information. A common fear related to the presence of the preservative thimerosal in vaccines. Thimerosal is a mercury-containing compound that had been used as a preservative since the 1930s. Although no cases of mercury toxicity have been reported secondary to vaccination, thimerosal was removed from all vaccines in 2001, with the exception of some inactivated influenza vaccines. In 2003 groups in northern Nigeria claimed that the oral vaccine was unsafe and were tainted with antifertility drugs (estradiol), HIV, and cancer-causing agents. The reasoning appeared to be secondary to mounting distrust of Western nations because of conflicts in the Middle East. The effect was suspension of polio immunization for almost 1 year in two Nigerian states and reduction of immunization in three other states. The incidence of polio rose dramatically, and more than 27,000 cases of paralysis resulted. The goal of the WHO is to eradicate polio worldwide by 2022. As of November 2014, the total global number of wild polio (naturally occurring) cases was 291; the highest number of cases were in Pakistan (246).

**Passive Immunotherapy**

Passive immunotherapy is a form of countermeasure against pathogens in which preformed antibodies are given to the individual. Passive immunotherapy with human immunoglobulin has been approved for several infections, including hepatitis A and hepatitis B. Treatment of potential rabies infection after a bite combines passive and active immunization. The rabies virus proliferates very slowly. Individuals who have been bitten receive a onetime injection with human rabies immunoglobulin, or, more recently, with monoclonal antibody to slow further viral proliferation, followed by multiple injections with a killed viral vaccine to induce greater protective immunity. More specific therapy with
monoclonal antibodies is being evaluated for other infectious diseases. A monoclonal antibody against respiratory syncytial virus has been approved for therapy, and recently an experimental monoclonal antibody preparation seems to have neutralized the Ebola virus.

In the past, vaccines and therapeutic antibodies were developed only for the most deadly pathogens. With the increase in antibiotic-resistant microorganisms, the development and widespread use of new vaccines and antibodies against these microorganisms must be considered.\(^\text{28}\)

**Quick Check 8-1**

1. How do antigenic changes in viral pathogens promote disease?
2. What are three mechanisms pathogens use to block the immune system?
3. What is the difference between an endotoxin and an exotoxin?
4. How do bacteria develop antibiotic resistance?
Deficiencies in Immunity

An immune deficiency is the failure of the immune or inflammatory response to function normally, resulting in increased susceptibility to infections. Primary (congenital) immune deficiency is caused by a genetic defect, whereas secondary (acquired) immune deficiency is caused by another condition, such as cancer, infection, or normal physiologic changes, such as aging. Acquired forms of immune deficiency are far more common than the congenital forms.

Initial Clinical Presentation

The clinical hallmark of immune deficiency is a tendency to develop unusual or recurrent, severe infections. The most severe primary immune deficiencies develop in young children, 2 years old and younger. Preschool and school-age children normally may have 6 to 12 infections per year, and adults may have 2 to 4 infections per year. Most of these are not severe and are limited to viral infections of the upper respiratory tract, recurrent streptococcal pharyngitis, or mild otitis media (middle ear infections).

Potential immune deficiencies should be considered if the individual has experienced severe, documented bouts of pneumonia, otitis media, sinusitis (sinus infection), bronchitis, septicemia (blood infection), or meningitis or infections with rare opportunistic microorganisms (e.g., Pneumocystis carinii). Infections are generally recurrent with only short intervals of relative health, and multiple simultaneous infections are common. Individuals with immune deficiencies often have eight or more purulent ear infections, two or more serious sinus infections, and two or more pneumonias, recurrent abscesses, or persistent fungal infections (particularly thrush) within a year. Invasive fungal infections are rare in healthy individuals and strongly indicate a defective immune system. Recurrent internal infections, such as meningitis, osteomyelitis, or sepsis, are common. Prolonged antibiotic use is commonly ineffective by oral or injected routes and may necessitate intravenous administration. Children frequently present with failure to thrive because of chronic diarrhea and other chronic symptoms. A familial history of immune deficiency may be found in some types of primary deficiency.

Routine care of individuals with immune deficiencies must be tempered with the knowledge that the immune system may be totally ineffective. It is unsafe to administer conventional immunizing agents or blood products to many of these individuals because of the risk of causing an uncontrolled infection. Infection is a particular problem when attenuated vaccines that contain live but weakened microorganisms are used (e.g., live polio vaccine; vaccines against measles,
mumps, and rubella).

The type of recurrent infections may indicate the type of immune defect. Deficiencies in T-cell immune responses are associated with recurrent infections caused by certain viruses (e.g., varicella herpes, cytomegalovirus), fungi, and yeasts (e.g., *Candida, Histoplasma*), or atypical microorganisms (e.g., *P. carinii*). B-cell deficiencies and phagocyte deficiencies, however, are suggested if the individual has documented, recurrent infections with microorganisms that require opsonization (e.g., encapsulated bacteria) or with viruses against which humoral immunity is normally effective (e.g., rubella). Some complement deficiencies resemble defects in antibody or phagocyte function, but others are associated with disseminated infections with bacteria of the genus *Neisseria* (*Neisseria meningitides* and *Neisseria gonorrhoeae*).

**Primary (Congenital) Immune Deficiencies**

Most primary immune deficiencies are the result of *single gene defects* (Table 8-10). Generally, the mutations are sporadic and not inherited: a family history exists in only about 25% of individuals. The sporadic mutations occur before birth, but the onset of symptoms may be early or later, depending on the particular syndrome. In some instances, symptoms of immune deficiency appear within the first 2 years of life. Other immune deficiencies are progressive, with the onset of symptoms appearing in the second or third decade of life.

</tbody>
</table>

Individually, primary immune deficiencies are rare. For instance, only 30 to 50 new cases of severe combined immunodeficiency (SCID) are diagnosed in the United States yearly. However, more than 250 different deficiencies have been identified, and the number is growing rapidly. Together, primary immune deficiencies are more common than cystic fibrosis, hemophilia, childhood leukemia, or many other well-known diseases. Many are subtle with minor deficiencies, but several result from major defects and lead to recurrent life-threatening infections. The distribution between genders is about even, although some specific diseases have a male or female predominance. The three most commonly diagnosed deficiencies are common variable immune deficiency (34% of individuals with primary immune deficiencies), selective immunoglobulin A (IgA) deficiency (24%), and IgG subclass deficiency (17%).

Primary immune deficiencies have recently been reclassified into nine groups,
based on the principal component of the immune or inflammatory systems that is defective.\textsuperscript{31} The major groups include combined with or without nonimmune defects (both B and T lymphocytes are deficient, although this group contains some diseases previously classified as T-cell defects), predominantly antibody deficiencies, immune dysregulation (defects in control of lymphocyte proliferation, T-regulatory cells defects), phagocytic defects (inadequate numbers or function), defects in innate immunity, and complement defects. To provide a better understanding of the diversity and severity of primary immune deficiencies, a few select examples will be discussed.

\textbf{Combined Deficiencies}

\textbf{Combined deficiencies} include the most life-threatening disorders and result from defects that directly affect the development of both T and B lymphocytes. However, the severity depends upon the degree to which B and T cells are affected.\textsuperscript{32} The most severe disorders are called \textit{severe combined immunodeficiencies (SCIDs)}. Most individuals with SCIDs have few detectable lymphocytes in the circulation and secondary lymphoid organs (spleen, lymph nodes). The thymus usually is underdeveloped because of the absence of T cells. Immunoglobulin levels, especially IgM and IgA, are absent or greatly reduced. Several forms of SCID are caused by autosomal recessive enzymatic defects that result in the accumulation of toxic metabolites, and rapidly dividing cells, such as lymphocytes, are especially sensitive. For instance, deficiency of \textit{adenosine deaminase (ADA deficiency)} results in the accumulation of toxic purines. \textbf{X-linked SCID} results from a common defect in most of the important interleukin (IL) receptors needed for lymphocyte maturation (e.g., IL-2, IL-4, IL-7, and others).

Even if nearly adequate numbers of B and T cells are produced, their cooperation may be defective. The \textit{bare lymphocyte syndrome} is an immune deficiency characterized by an inability of lymphocytes and macrophages to produce major histocompatibility complex (MHC) class I or class II molecules. Without MHC molecules, antigen presentation and intercellular cooperation cannot occur effectively. Children with this deficiency develop serious, life-threatening infections and usually die before the age of 5 years.

Some combined immune deficiencies result in depressed development of a small portion of the immune system. For instance, an individual can be unable to produce a certain class of antibody, as in \textbf{Wiskott-Aldrich syndrome (WAS, an X-linked recessive disorder)}, where IgM antibody production is greatly depressed. Antibody responses against antigens that elicit primarily an IgM response, such as polysaccharide antigens from bacterial cell walls (e.g., \textit{P. aeruginosa}, \textit{S.})
pneumoniae, Haemophilus influenzae, and other microorganisms with polysaccharide outer capsules), are deficient.

Many combined immune deficiencies also are associated with other characteristic defects, some of which appear to be unrelated to the immune system yet may be life-threatening by themselves. These associated symptoms can be useful diagnostically and can clarify the pathophysiology of the disease. WAS results from a mutation in the WAS gene that affects the actin cytoskeleton, which is important for platelet function. Thus, WAS has an associated major defect in platelet function and is classified as a combined deficiency with nonimmune defects. Clinical manifestations include bleeding secondary to thrombocytopenia (low platelet counts), eczema, and recurrent infections (e.g., otitis media, pneumonia, herpes simplex, cytomegalovirus).

DiGeorge syndrome (congenital thymic aplasia or hypoplasia and diminished parathyroid gland development) is caused by the lack or partial lack of the thymus, resulting in greatly decreased T-cell numbers and function. Defective development of the third and fourth pharyngeal pouches during embryonic development results in the thymic defects and the lack of the parathyroid gland (causing an inability to regulate calcium concentration). Low blood calcium levels cause the development of tetany or involuntary rigid muscular contraction. DiGeorge syndrome is frequently associated with abnormal development of facial features that are controlled by the same embryonic pouches; these include low-set ears, fish-shaped mouth, and other altered features (Figure 8-6). Other examples of combined immune deficiencies include defects in CD3 resulting in the loss of T-cell receptor intracellular signaling, defective somatic gene rearrangement of variable region genes or constant region genes, IL-2 receptor defects, and defects in DNA repair.
Predominantly Antibody Deficiencies

**Predominantly antibody deficiencies** result from defects in B-cell maturation or function and are the most common of immune deficiencies. T-cell immune responses are not affected in pure B-lymphocyte deficiencies. The results are lower levels of circulating immunoglobulins (hypogammaglobulinemia) or occasionally totally or nearly absent immunoglobulins (agammaglobulinemia).

Some defects may involve a particular class of antibody, such as **selective IgA deficiency**, in which only IgA is suppressed. This occurs in 1 in 700 to 1 in 400 individuals and may result from a failure to class-switch to IgA and mature into IgA-producing plasma cells. Many individuals are asymptomatic, although others have a history of recurring sinus, pulmonary, and gastrointestinal infections. Individuals with IgA deficiency often have chronic intestinal candidiasis (infection with *C. albicans*). Complications of IgA deficiency include severe allergic disease and autoimmune diseases. Secretory IgA normally may prevent the uptake of allergens from the environment; therefore IgA deficiency may lead to a more intense challenge to the immune system by environmental antigens.

**Bruton agammaglobulinemia** is caused by blocked development of mature B cells in the bone marrow. There are few or no circulating B cells, although T-cell number and function are normal, resulting in repeated bacterial infections, such as otitis media, streptococcal sore throat, and conjunctivitis, and more serious conditions, such as septicemia.
Other predominantly antibody deficiencies include severe reduction in particular classes or subclasses of antibody; defects in B-cell surface receptors, such as CD21 and CD40; and defects in class-switch, which may result in a hyper-IgM syndrome.

**Phagocyte Defects**

Phagocyte defects range from inadequate numbers of phagocytes (e.g., severe congenital neutropenia) to defects in phagocyte function that can result in recurrent infections with the same group of microorganisms (encapsulated bacteria) associated with antibody, and complement deficiencies. Chronic granulomatous disease (CGD) is a severe defect in the myeloperoxidase–hydrogen peroxide system—a major means of bacterial destruction using the enzyme myeloperoxidase, halides (e.g., chloride ion), and hydrogen peroxide (H₂O₂). As a result of phagocytosis, neutrophils and other phagocytes switch much of their glucose metabolism to the hexose-monophosphate shunt. A byproduct of this pathway is the conversion of molecular oxygen by nicotinamide adenine dinucleotide phosphate (NADPH) oxidase into highly reactive oxygen derivatives, including hydrogen peroxide. Mutations in NADPH oxidase result in deficient production of hydrogen peroxide and other oxygen products needed for phagocytic killing. Thus, affected individuals have adequate myeloperoxidase and halide but lack the necessary hydrogen peroxide. This results in recurrent severe pneumonias; tumor-like granulomata in lungs, skin, and bones; and other infections with some opportunistic microorganisms, such as *Staphylococcus aureus*, *Serratia marcescens*, and *Aspergillus* species. Other phagocytic deficiencies include defects in various leukocyte adhesion molecules, defects in the phagocytosis process or bacterial killing, and defects in cytokine receptors.

**Defects in Innate Immunity**

Some immune deficiencies are characterized by a defect in the capacity to produce an immune response against a particular antigen. In chronic mucocutaneous candidiasis, interaction between the Th17 lymphocytes and macrophages is ineffective related to a specific infectious agent, *C. albicans*. Thus the macrophage cannot be activated and these individuals usually have mild to extremely severe recurrent *Candida* infections involving the mucous membranes and skin. Other defects in innate immunity include defects in Toll-like receptors and natural killer cells.

**Complement Deficiencies**

Many complement deficiencies have been described. C3 deficiency is the most
severe defect because of its central role in the complement cascade. Loss of C3b and C3a production and the inability to activate C5 result in recurrent life-threatening infections with encapsulated bacteria (e.g., *Haemophilus influenzae* and *Streptococcus pneumoniae*) at an early age. Deficiencies of any of the terminal components of the complement cascade (C5, C6, C7, C8, or C9 deficiencies) are associated with increased infections with only one group of bacteria—those of the genus *Neisseria* (*Neisseria meningitides* or *N. gonorrhoeae*). *Neisseria* bacteria usually cause localized infections (meningitis or gonorrhea), but terminal pathway defects result in an 8000-fold increased risk for systemic infections with atypical strains of these microorganisms.

**Mannose-binding lectin (MBL) deficiency** is the primary defect of the lectin pathway of complement activation. This defect, as well as defects in the alternative pathway, results in increased risk of infection with microorganisms that have polysaccharide capsules rich in mannose, particularly the yeast *Saccharomyces cerevisiae* and encapsulated bacteria such as *N. meningitidis* and *S. pneumoniae*. Other complement deficiencies include defects in components C1, C4, C2, C5, C1 inhibitor, factor B, factor D, properdin, complement control factors, MASP, or complement receptors.

**Secondary (Acquired) Immune Deficiencies**

Secondary, or acquired, immune deficiencies are far more common than primary deficiencies. These deficiencies are complications of other physiologic or pathophysiologic conditions. Some conditions that are known to be associated with acquired deficiencies are summarized in **Box 8-1**.

**Box 8-1**

**Some Conditions Known to Be Associated with Acquired Immunodeficiencies**

**Normal Physiologic Conditions**

Pregnancy

Infancy

Aging
Psychologic Stress

Emotional trauma

Eating disorders

Dietary Insufficiencies

Malnutrition caused by insufficient intake of large categories of nutrients, such as protein or calories

Insufficient intake of specific nutrients, such as vitamins, iron, or zinc

Infections

Congenital infections, such as rubella, cytomegalovirus, hepatitis B

Acquired infections, such as AIDS

Malignancies

Malignancies of lymphoid tissues, such as Hodgkin disease, acute or chronic leukemia, or myeloma

Malignancies of nonlymphoid tissues, such as sarcomas and carcinomas

Physical Trauma

Burns

Medical Treatments

Stress caused by surgery

Anesthesia

Immunosuppressive treatment with corticosteroids or antilymphocyte antibodies

Splenectomy

Cancer treatment with cytotoxic drugs or ionizing radiation
Other Diseases or Genetic Syndromes

Diabetes
Alcoholic cirrhosis
Sickle cell disease
Systemic lupus erythematosus (SLE)
Chromosome abnormalities, such as trisomy 21

Although secondary deficiencies are common, many are not clinically relevant. In many cases, the degree of the immune deficiency is relatively minor and without any apparent increased susceptibility to infection. Alternatively, the immune system may be substantially suppressed, but only for a short duration, thus minimizing the incidence of clinically relevant infections. Some secondary immune deficiencies (e.g., AIDS or immunosuppression by cancer), however, are extremely severe and may result in recurrent life-threatening infections.

Evaluation and Care of Those with Immune Deficiency

A review of clinical characteristics can help select the appropriate tests. A basic screening test is a complete blood count (CBC) with a differential. The CBC provides information on the numbers of red blood cells, white blood cells, and platelets, and the differential indicates the quantities of lymphocytes, granulocytes, and monocytes in the blood. Quantitative determination of immunoglobulins (IgG, IgM, IgA) is a screening test for antibody production, and an assay for total complement (total hemolytic complement, CH₅₀) is useful if a complement defect is suspected. Further testing is described in Table 8-11.

Replacement Therapies for Immune Deficiencies

Many immune deficiencies can be successfully treated by replacing the missing component of the immune system. Individuals with B-cell deficiencies that cause hypogammaglobulinemia or agammaglobulinemia usually are treated by administration of intravenous immune globulin (IVIg), antibody-rich fractions prepared from plasma pooled from large numbers of donors. Administration of IVIg replaces the individual's antibodies temporarily; these antibodies have a half-life of 3 to 4 weeks. Thus individuals must be treated repeatedly to maintain a protective level of antibodies in the blood.

Defects in lymphoid cell development in the primary lymphoid organs (e.g., SCID, Wiskott-Aldrich syndrome) can sometimes be treated by replacement of stem cells through transplantation of bone marrow, umbilical cord cells, or other cell populations that are rich in stem cells. Thymic defects (e.g., DiGeorge syndrome, chronic mucocutaneous candidiasis) may be treated by transplantation of fetal thymus tissue or thymic epithelial cells (the cells that produce thymic hormones). However, in most cases improvement is only temporary.

Enzymatic defects that cause SCID (e.g., adenosine deaminase deficiency) have been treated successfully with transfusions of glycerol frozen-packed erythrocytes.
The donor erythrocytes contain the needed enzyme and can, at least temporarily, provide sufficient enzyme for normal lymphocyte function.

Bone marrow transplants containing hematopoietic stem cells are routinely used to treat SCID. However, as discussed later in this chapter, the donor and recipient should be matched as closely as possible for HLA antigens. Individuals with SCID are at risk for **graft-versus-host disease (GVHD)**. This occurs if T cells in a transplanted graft (e.g., transfused blood, bone marrow transplants) are mature and therefore capable of cell-mediated immunity against the recipient's HLA. The primary targets for GVHD are the skin (e.g., rash, loss or increase of pigment, thickening of skin), liver (e.g., damage to bile duct, hepatomegaly), mouth (e.g., dry mouth, ulcers, infections), eyes (e.g., burning, irritation, dryness), and gastrointestinal tract (e.g., severe diarrhea), and the disease may lead to death from infections. The risk of GVHD can be diminished by removing mature T cells from tissue used to treat individuals with immune deficiencies.36

Injection of **mesenchymal stem cells (MSCs)** may be useful in these individuals. Stem cells are relatively undifferentiated cells and can be obtained from a variety of sources (e.g., embryos, bone marrow, adult tissues). MSCs are present in all adult tissues. These particular stem cells undergo differentiation into other cell types and, more importantly, have potent immunosuppressive properties.37 Several clinical trials have demonstrated complete suppression of GVHD in a large number of recipients of MSCs.38

The first successful therapeutic replacement of defective genes was performed in two girls with SCID caused by an ADA deficiency.39 The normal gene for ADA was cloned and inserted into a retroviral vector.40 The gene for ADA replaced some retroviral genes, resulting in a virus that carried the normal human gene but did not cause disease. The virus was used to infect bone marrow stem cells from these children. The retrovirus inserted the normal ADA gene into the individuals' genetic material. The genetically altered stem cells were infused into the children, resulting in reconstitution of their immune systems. Gene therapy trials have verified immune reconstitution in individuals with ADA deficiency, X-linked SCID, CGD, and WAS.41 However, the treatment trials have not been without some major complications, such as leukemia, that raise questions concerning the use of retroviral vectors for the insertion of new genes.

**Acquired Immunodeficiency Syndrome (AIDS)**

Acquired immunodeficiency syndrome is a secondary immune deficiency that develops in response to viral infection. The **human immunodeficiency virus (HIV)** infects and destroys the CD4-positive (CD4+) Th cells, which are necessary for the
development of both plasma cells and cytotoxic T cells. Therefore HIV suppresses the immune response against itself and secondarily creates a generalized immune deficiency by suppressing the development of immune responses against other pathogens and opportunistic microorganisms, leading to the development of **acquired immunodeficiency syndrome (AIDS)**.

Despite major efforts by healthcare agencies around the world, the number of cases and deaths from HIV infection and AIDS (HIV/AIDS) remains a major health concern. The WHO estimated that at the end of 2013, 35.3 million people were living with HIV/AIDS worldwide and more than 2.5 million were newly infected. Approximately 3 million deaths occur each year from AIDS. Since 1980 it is estimated that more than 36 million individuals have died from AIDS worldwide. The majority of cases are in sub-Saharan Africa where about 1 in 20 adults is living with HIV, but the epidemic is worldwide and the number of new cases is increasing rapidly, particularly in Asia.

In the United States the spread of HIV/AIDS remains somewhat stable. The CDC estimated in 2013 (the most recent data) that approximately 47,352 people were newly infected with HIV. Although new infections remain at about 50,000 per year, both encouraging and discouraging trends were apparent. Although new HIV infections in black women decreased by 12% between 2008 and 2010, new infections in young gay and bisexual men increased by 21%. Men who had sex with men accounted for 78% of new HIV infections in 2010. Heterosexual transmission accounted for about 25% of new HIV infections. with two thirds of those cases occurring in women, with the highest number among black women. Deaths related to HIV/AIDS were 13,712 in 2012, and appear to be decreasing. The cumulative number of HIV/AIDS-related deaths in the United States is in excess of 658,507, and more than 1,201,100 persons age 13 years and older are currently living with HIV/AIDS.

Before the implementation of massive public health campaigns and the use of antiviral drugs in the United States, the progression from HIV infection to AIDS and death was unrelenting. In 1995 AIDS became the number one killer of individuals between the ages of 25 and 44 years and remains the eighth most common cause of death in that age group. With the advent of effective therapy to stabilize progression of the disease in the mid-1990s, HIV infection has become a chronic disease in the United States, with many fewer deaths.

**Epidemiology of AIDS**

HIV is a blood-borne pathogen with the typical routes of transmission: blood or blood products, intravenous drug abuse, both heterosexual and homosexual activity,
and maternal-child transmission before or during birth. Although the disease first gained attention in the United States related to sexual transmission between males, the most common route worldwide is through heterosexual activity (see Health Alert: Risk of HIV Transmission Associated with Sexual Practices). Worldwide, women constitute more than half of those living with HIV/AIDS. In the United States, as in the rest of the world, the predominant means of transmission to women is through heterosexual contact. Hundreds of thousands of cases of HIV/AIDS have been reported in children who contracted the virus from their mothers across the placenta, through contact with infected blood during delivery, or through the milk during breast-feeding.

**Health Alert**

Risk of HIV Transmission Associated with Sexual Practices

High Risk (in descending order of risk)

Receptive anal intercourse with ejaculation (no condom)

Receptive vaginal intercourse with ejaculation (no condom)

Insertive anal intercourse (no condom)

Insertive vaginal intercourse (no condom)

Receptive anal intercourse with withdrawal before ejaculation

Insertive anal intercourse with withdrawal before ejaculation

Receptive vaginal intercourse (with spermicidal foam but no condom)

Insertive vaginal intercourse (with spermicidal foam but no
Receptive anal or vaginal intercourse (with a condom)

Insertive anal or vaginal intercourse (with a condom)

Some Risk (in descending order of risk)

Oral sex with men with ejaculation

Oral sex with women

Oral sex with men with preejaculation fluid (precum)

Oral sex with men, no ejaculation or precum

Oral sex with men (with a condom)

Some Risk (depending on situation, intactness of mucous membranes, etc.)

Mutual masturbation with external or internal touching

Sharing sex toys

Anal or vaginal fisting

No Risk

Masturbating with another person without touching one another
Hugging/massage/dry kissing

Frottage (rubbing genitals while remaining clothed)

Masturbating alone

Abstinence

Unresolved Issues

The role of precum in transmission

The protection offered by covering female genitals with a dental dam during oral sex on the women

The risk of transmission from wet kissing

Pathogenesis of AIDS

HIV is a member of a family of viruses called retroviruses, which carry genetic information in the form of RNA rather than DNA (Figure 8-7). Retroviruses use a viral enzyme, reverse transcriptase, to convert RNA into double-stranded DNA. Using a second viral enzyme, HIV integrase, the new DNA is inserted into the infected cell's genetic material, where it may remain dormant. If the cell is activated, translation of the viral information may be initiated, resulting in the formation of new virions, lysis and death of the infected cell, and shedding of infectious HIV particles. During that process, HIV protease is essential in processing proteins needed from the viral internal structure (capsid). If, however, the cell remains relatively dormant, the viral genetic material may remain latent for years and is probably present for the life of the individual.
The primary surface receptor on HIV is the envelope protein gp120, which binds to the molecule CD4 on the surface of Th cells. Several other necessary coreceptors, particularly the chemokine receptor CCR5, have been identified on target
cells. Thus the major immunologic finding in AIDS is the striking decrease in the number of CD4+ Th cells (Figure 8-8).
Clinical Manifestations of AIDS

Depletion of CD4+ cells has a profound effect on the immune system, causing a severely diminished response to a wide array of infectious pathogens and cancers (Box 8-2). At the time of diagnosis, the individual may present with one of several different conditions: serologically negative (no detectable antibody), serologically positive (positive for antibody against HIV proteins) but asymptomatic, early stages of HIV disease, or AIDS (Figure 8-9).

Box 8-2

AIDS-Defining Opportunistic Infections and
Neoplasms Found in Individuals with HIV Infection

Infections

Protozoal and Helminthic Infections

Cryptosporidiosis or isosporiasis (enteritis)

Pneumocystosis (pneumonia or disseminated infection)

Toxoplasmosis (pneumonia or CNS infection)

Fungal Infections

Candidiasis (esophageal, tracheal, or pulmonary)

Coccidioidomycosis (disseminated)

Cryptococcosis (CNS infection)

Histoplasmosis (disseminated)

Bacterial Infections

Mycobacteriosis (“atypical,” e.g., *Mycobacterium avium-intracellulare*, disseminated or extrapulmonary)

*M. tuberculosis*, disseminated or extrapulmonary)

Nocardiosis (pneumonia, meningitis, disseminated)

Salmonella infections (septicemia, recurrent)

Viral Infections

Cytomegalovirus (pulmonary, intestinal, retinitis, or CNS)

Herpes simplex virus (localized or disseminated)

Progressive multifocal leukoencephalopathy
Varicella-zoster virus (localized or disseminated)

Neoplasms

Invasive cancer of the uterine cervix
Kaposi sarcoma
Non-Hodgkin lymphomas (Burkitt, immunoblastic)
Primary lymphoma of brain

CNS, Central nervous system.

**FIGURE 8-9** Typical Progression from HIV Infection to AIDS in Untreated Persons. A, Clinical progression begins within weeks after infection; the person may experience symptoms of acute HIV syndrome. During this early period, the virus progressively infects T cells and other cells and spreads to the lymphoid organs, with a sharp decrease in the number of circulating CD4+ T cells. During a period of clinical latency, the virus replicates and T-cell destruction continues, although the person is generally asymptomatic. The individual may develop HIV-related disease (constitutional symptoms)—a variety of symptoms of acute viral infection that do not involve opportunistic infections or malignancies. When the number of CD4+ cells is critically suppressed, the individual becomes susceptible to a variety of opportunistic infections and cancers with a diagnosis of AIDS. The length of time for progression from HIV infection to AIDS may vary considerably from person to person. B, Laboratory tests are changing throughout infection. Antibody and Tc cell (cytotoxic T lymphocytes [CTLs]) levels change during the progression to AIDS. During the initial phase antibodies against HIV-1 are not yet detectable (window period), but viral products, including proteins and RNA, and infectious virus may be detectable in the blood a few weeks after infection. Most antibodies against HIV are not detectable in the early phase. During the latent phase of infection antibody levels against p24 and other viral proteins, as well as HIV-specific CTLs, increase, and then remain constant until the development of AIDS. (A redrawn from Fauci AS, Lane HC: Human immunodeficiency virus disease: AIDS and related conditions. In Fauci AS et al, editors: Harrison’s principles of internal medicine, ed 14, New York, 1997, McGrawHill; B from Kumar V et al: Robbins and Cotran pathologic basis of disease, ed 9, Philadelphia, 2015, Saunders.)

The presence of circulating antibody against the HIV protein p24 followed by
more complex tests for antibodies against additional HIV proteins (e.g., Western blot analysis) or for HIV DNA (e.g., polymerase chain reaction) indicates infection by the virus, although many of these individuals are asymptomatic. Antibody appears rather rapidly after infection through blood products, usually within 4 to 7 weeks, although some individuals have been seronegative for longer periods. The period between infection and the appearance of antibody is referred to as the window period. Although a person does not have antibody against HIV, he or she may have virus growing, have virus in the blood and body fluids, and be infectious to others.

Those with the early stages of HIV disease (early-stage disease) usually initially present with relatively mild and nonspecific symptoms resembling influenza, such as headaches, fever, or fatigue. These symptoms disappear after 1 to 6 weeks, and although individuals appear to be in clinical latency the virus is actively proliferating in lymph nodes.

The currently accepted definition of AIDS relies on both laboratory tests and clinical symptoms. If the individual is positive for antibodies against HIV, the diagnosis of AIDS is made in association with various clinical symptoms (Figure 8-10; also see Box 8-2). The symptoms include atypical or opportunistic infections and cancers, as well as indications of debilitating chronic disease (e.g., wasting syndrome, recurrent fevers). Most commonly, new cases of AIDS are diagnosed initially by decreased CD4+ T cell numbers. Individuals who are not HIV infected typically have 800 to 1000 CD4+ cells per cubic millimeter of blood, with a range from 600/mm³ to 1200/mm³. A diagnosis of AIDS can be made if the CD4+ T cell numbers decrease to less than 200/mm³. Without treatment, the average time from infection to development of AIDS is just over 10 years. Some estimates are that approximately 99% of untreated HIV-infected individuals would eventually progress to AIDS.
TREATMENT AND PREVENTION OF AIDS

Approved AIDS medications are classified by mechanism of action: nucleoside and non-nucleoside inhibitors of reverse transcriptase (reverse transcriptase inhibitors), inhibitors of the viral protease (HIV protease inhibitors), inhibitors of the viral integrase (HIV integrase inhibitors), inhibitors of viral entrance into the target cell (HIV fusion inhibitors), and a CCR5 antagonist (inhibitor of viral
attachment) (see Figure 8-8). The current regimen for treatment of HIV infection is a combination of drugs, termed **antiretroviral therapy (ART)**. ART protocols require a combination of synergist drugs from different classes and specific regimens (e.g., timing of drug administration, doses, drug combinations) are adapted based on age of the individual, secondary clinical symptoms (renal or hepatic insufficiency), CD4+ T cell levels, viral load, specific coinfections, pre-existing cardiac risk factors, past history of treatment failure, suspected drug resistance, and other parameters.⁴⁴,⁴⁵ The clinical benefits of ART are profound. Death from AIDS-related diseases has been reduced significantly since the introduction of ART. However, resistant variants to these drugs have been identified. Drug therapy for AIDS is not curative because HIV incorporates into the genetic material of the host, particularly CD4+ T memory cells, and may never be removed by antimicrobial therapy.⁴⁶ Therefore drug administration to control the virus may have to continue for the lifetime of the individual. Additionally, HIV may persist in regions where the antiviral drugs are not as effective, such as the CNS.

The chronic nature of HIV/AIDS resulting from successful ART has led to additional concerns. Long-term toxicity of ART drugs has resulted in increased risk for cardiovascular disease, metabolic disorders, and organ failure. Treated individuals frequently fail to reconstitute their immune system and develop chronic immune activation characterized by activation of monocytes and T cells, production of pro-inflammatory cytokines (e.g., interferon-γ [IFN-γ], interleukin-6 [IL-6]), and depletion of Th17 cells.⁴⁷ Chronic immune activation tends to exacerbate clinical disease in adults and neonates.⁴⁸

Vaccine development should be the most effective means of preventing HIV infection and may be useful in treating preexisting infection. Most of the common viral vaccines (e.g., rubella, mumps, influenza) induce protective antibodies that block the initial infection. Only one vaccine (rabies) is used after the infection has occurred. The rabies vaccine is successful because the rabies virus proliferates and spreads very slowly. However, the ability of an HIV vaccine to either successfully prevent or treat HIV infection is questionable for several reasons.⁴⁹ First, the AIDS virus is genetically and antigenically variable, like the influenza virus, so that a vaccine created against one variant may not provide protection against another variant. Second, although individuals with HIV/AIDS have high levels of circulating antibodies against the virus, these antibodies do not appear to be protective. Therefore even if a circulating antibody response can be induced by vaccination, that response might not be effective. A vaccine may have to induce both circulating and secretory (to prevent initial infection of the mucosal T cell) antibody and Tc cells.
Pediatric AIDS and Central Nervous System Involvement

HIV can be transmitted from mother to child during pregnancy, at the time of delivery, or through breast-feeding, although the risk of mother-to-child transmission has dropped precipitously since the use of anti-retroviral drugs in pregnant women. The clinical diagnosis of HIV infection in young children born of HIV-infected mothers is very often a difficult task because the presence of maternal antibodies may result in a misleading false-positive test for antibodies against HIV for as long as 18 months after birth. Testing for antibody against HIV can be performed recurrently from birth until 18 months; if the test results become negative and remain so after 12 months, the child can be considered uninfected.

The 2008 revised surveillance case definition for HIV infection in children younger than 18 months, which remains in effect today, recommends testing for HIV or viral components in two separate specimens, not including cord blood. These include detection of HIV nucleic acid or p24 antigen, or direct isolation of HIV in viral cultures.

HIV infection of babies is generally more aggressive than in adults; on average an untreated child will die by his or her second birthday. Neurologic involvement occurs more commonly in children than in adults and results from CNS involvement, rather than effects on peripheral portions of the nervous system. HIV encephalopathy occurs with varying degrees of severity and is a clinical component in the diagnosis of AIDS in children. Most HIV-infected newborns appear normal, but may progressively develop signs of CNS involvement. These usually appear as failure to attain, or loss of, developmental milestones or loss of intellectual ability, verified by standard developmental scale or neuropsychologic tests; acquired symmetric motor deficits, seen in children older than age 1 month; impaired brain growth or acquired microcephaly, demonstrated by head circumference measurements; or brain atrophy, demonstrated by computed tomography (CT) or magnetic resonance imaging (MRI) with serial imaging and required in children younger than 2 years of age.

It may be difficult to completely differentiate the effect of HIV infection on the CNS from other risk factors, including prenatal drug exposure, prematurity, chronic illness, and a chaotic social atmosphere. The pathogenesis of HIV encephalopathy in children is poorly understood, but the presence of inflammatory mediators may be a contributing factor.

Because HIV infection in infants progresses very rapidly, treatment must begin at the diagnosis of infection. In older children the criteria for treatment are similar to those used in adults. A growing number of investigational protocols are available for treatment of children with HIV. In general, treatment is focused on the
preservation and maintenance of the immune system, aggressive response to opportunistic infections, support and relief of symptomatic occurrences, and administration of ART.

Quick Check 8-2

1. Why is the development of recurrent or unusual infections the clinical hallmark of immunodeficiency?

2. Compare and contrast the most common infections in individuals with defects in cell-mediated immune response and those with defects in humoral immune response.

3. What are the new treatments for HIV?
Hypersensitivity: Allergy, Autoimmunity, and Alloimmunity

Allergy, autoimmunity, and alloimmunity are classified as hypersensitivity reactions. **Hypersensitivity** is an altered immunologic response to an antigen that results in disease or damage to the individual. Allergy, autoimmunity, and alloimmunity (also termed *isoimmunity*) can be most easily understood in relationship to the source of the antigen against which the hypersensitivity response is directed (Table 8-12). **Allergy** refers to a hypersensitivity to environmental antigens. These can include medicines, natural products (e.g., pollens, bee stings), infectious agents, and any other antigen that is not naturally found in the individual.

**Autoimmunity** is a disturbance in the immunologic tolerance of self-antigens. The immune system normally does not strongly recognize the individual's own antigens. Healthy individuals of all ages, but particularly the elderly, may produce low quantities of antibodies against their own antigens (*autoantibodies*) without developing overt autoimmune disease. Therefore the presence of low quantities of autoantibodies does not necessarily indicate a disease state. Autoimmune diseases occur when the immune system reacts against self-antigens to such a degree that autoantibodies or autoreactive T cells damage the individual's tissues. Many clinical disorders are associated with autoimmunity and are generally referred to as **autoimmune diseases** (Table 8-13). Autoimmune diseases are more prevalent in women and the overall prevalence is rising.51

**Alloimmune diseases** occur when the immune system of one individual produces an immunologic reaction against tissues of another individual. **Alloimmunity** can be observed during immunologic reactions against transfusions, transplanted tissue, or the fetus during pregnancy.

The mechanism that initiates the onset of hypersensitivity, whether allergy, autoimmunity, or alloimmunity, is not completely understood. It is generally accepted that genetic, infectious, and possibly environmental factors contribute to the development of hypersensitivity reactions.

**Mechanisms of Hypersensitivity**

Hypersensitivity reactions can be characterized also by the particular immune mechanism that results in the disease (Table 8-14). These mechanisms are apparent
in most hypersensitivity reactions and have been divided into four distinct types: *type I* (IgE-mediated reactions), *type II* (tissue-specific reactions), *type III* (immune complex–mediated reactions), and *type IV* (cell-mediated reactions). This classification is artificial and seldom is a particular disease associated with only a single mechanism. The four mechanisms are interrelated, and in most hypersensitivity reactions several mechanisms can be functioning simultaneously or sequentially.

As with all immune responses, hypersensitivity reactions require sensitization against a particular antigen that results in a primary immune response. Disease symptoms appear after an adequate secondary immune response occurs. Hypersensitivity reactions are immediate or delayed, depending on the time required to elicit clinical symptoms after reexposure to the antigen. Reactions that occur within minutes to a few hours after exposure to antigen are termed **immediate hypersensitivity reactions**. **Delayed hypersensitivity reactions** may take several hours to appear and are at maximal severity days after reexposure to the antigen. Generally, immediate reactions are caused by antibody, whereas delayed reactions are caused by cells (e.g., T cells, NK cells, macrophages).

The most rapid and severe immediate hypersensitivity reaction is **anaphylaxis**. Anaphylaxis occurs within minutes of reexposure to the antigen and can be either systemic (generalized) or cutaneous (localized). Symptoms of systemic anaphylaxis include pruritus, erythema, vomiting, abdominal cramps, diarrhea, and breathing difficulties, and the most severe reactions may include contraction of bronchial smooth muscle, edema of the throat, and decreased blood pressure that can lead to shock and death. Examples of systemic anaphylaxis are allergic reactions to bee stings (see p. 206), peanuts, shellfish, or eggs. Cutaneous anaphylaxis results in local symptoms, such as pain, swelling, and redness, which occur at the site of exposure to an antigen (e.g., a painful local reaction to an injected vaccine or drug).
Type I: IgE-Mediated Hypersensitivity Reactions

Type I hypersensitivity reactions are mediated by antigen-specific IgE and the products of tissue mast cells (Figure 8-11). Most common allergic reactions are type I reactions. In addition, most type I reactions occur against environmental antigens and are therefore allergic. Because of this strong association, many healthcare professionals use the term allergy to indicate only IgE-mediated reactions. However, IgE can contribute to some autoimmune and alloimmune diseases, and many common allergies (e.g., poison ivy) are not mediated by IgE.
FIGURE 8-11 Mechanism of Type I, IgE-Mediated Reactions. First exposure to an allergen leads to antigen processing and presentation of antigen by an antigen-presenting cell (APC) to B lymphocytes, which is under the direction of T-helper 2 (Th2) cells. Th2 cells produce specific cytokines (e.g., IL-4, IL-13, and others) that favor maturation of the B lymphocytes into plasma cells that secrete IgE. The IgE is adsorbed to the surface of the mast cell by binding with IgE-specific Fc receptors. When an adequate amount of IgE is bound the mast cell is sensitized. During a reexposure, the allergen cross-links the surface-bound IgE and causes degranulation of the mast cell. Contents of the mast cell granules, primarily histamine, induce local edema, smooth muscle contraction, mucous secretion, and other characteristics of an acute inflammatory reaction. (See Chapter 6 for more details on the role of mast cells in inflammation.)

IgE has a relatively short life span in the blood because it rapidly binds to Fc receptors on mast cells. Unlike Fc receptors on phagocytes, which bind IgG that has previously reacted with antigen, the Fc receptors on mast cells specifically bind IgE that has not previously interacted with antigen. After a large amount of IgE has bound to the mast cells, an individual is considered sensitized. Further exposure of a sensitized individual to the allergen results in degranulation of the mast cell and the release of mast cell products (see Chapter 6).
Mechanisms of IgE-mediated hypersensitivity.

The most potent mediator of IgE-mediated hypersensitivity is histamine, which affects several key target cells. Acting through H1 receptors, histamine contracts bronchial smooth muscles (bronchial constriction), increases vascular permeability (edema), and causes vasodilation (increased blood flow) (see Chapter 6). The interaction of histamine with H2 receptors results in increased gastric acid secretion. Blocking histamine receptors with antihistamines can control some type I responses.

Clinical manifestations of IgE-mediated hypersensitivity.

The clinical manifestations of type I reactions are attributable mostly to the biologic effects of histamine. The tissues most commonly affected by type I responses contain large numbers of mast cells and are sensitive to the effects of histamine released from them. These tissues are found in the gastrointestinal tract, the skin, and the respiratory tract (Figure 8-12 and Table 8-15).
FIGURE 8-12 Type I Hypersensitivity Reactions. Manifestations of allergic reactions as a result of type I hypersensitivity include pruritus, angioedema (swelling caused by exudation), edema of the larynx, urticaria (hives), bronchospasm (constriction of airways in the lungs), hypotension (low blood pressure), and dysrhythmias (irregular heartbeat) because of anaphylactic shock, and gastrointestinal cramping caused by inflammation of the gastrointestinal mucosa. Photographic inserts show a diffuse allergic-like eye and skin reaction on an individual. The skin lesions have raised edges and develop within minutes or hours, with resolution occurring after about 12 hours. (Inserts from Male D et al: Immunology, ed 8, St Louis, 2013, Mosby)

*An order of fungi that grows best at high temperatures (between 45° and 80° C [113° and 176° F]).

Gastrointestinal allergy is caused by allergens that enter through the mouth—usually foods or medicines. Symptoms include vomiting, diarrhea, or abdominal pain. Foods most often implicated in gastrointestinal allergies are milk, chocolate, citrus fruits, eggs, wheat, nuts, peanut butter, and fish.\(^5^4\) The most common food allergy in adults is a reaction to shellfish, which may initiate an anaphylactic response and death.\(^5^5\) When food is the source of an allergen, the active immunogen may be an unidentifiable product of how the food is processed during manufacture or broken down by digestive enzymes.\(^5^6\) Sometimes the allergen is a drug, an additive, or a preservative in the food. For example, cows treated for mastitis with penicillin yield milk containing trace amounts of this antibiotic. Thus hypersensitivity apparently caused by milk proteins may instead be the result of an allergy to penicillin.

**Urticaria**, or hives, is a dermal (skin) manifestation of allergic reactions (see Figure 8-12). The underlying mechanism is the localized release of histamine and increased vascular permeability, resulting in limited areas of edema. Urticaria is characterized by white fluid-filled blisters (wheals) surrounded by areas of redness (flares). This **wheal and flare reaction** is usually accompanied by pruritus. Not all urticarial symptoms are caused by immunologic reactions. Some, termed **nonimmunologic urticaria**, result from exposure to cold temperatures, emotional stress, medications, systemic diseases, or malignancies (e.g., lymphomas).

Effects of allergens on the mucosa of the eyes, nose, and respiratory tract include conjunctivitis (inflammation of the membranes lining the eyelids) (see Figure 8-12), rhinitis (inflammation of the mucous membranes of the nose), and asthma
(constriction of the bronchi). Symptoms are caused by vasodilation, hypersecretion of mucus, edema, and swelling of the respiratory mucosa. Because the mucous membranes lining the respiratory tract are continuous, they are all adversely affected. The degree to which each is affected determines the symptoms of the disease; most anaphylactic reactions are type I hypersensitivities.

The central problem in allergic diseases of the lung is obstruction of the large and small airways (bronchi) of the lower respiratory tract by bronchospasm (constriction of smooth muscle in airway walls), edema, and thick secretions. This leads to ventilatory insufficiency, wheezing, and difficult or labored breathing (see Chapter 27).

Certain individuals are genetically predisposed to develop allergies and are called atopic. In families in which one parent has an allergy, allergies develop in about 40% of the offspring. If both parents have allergies, the incidence may be as high as 80%. Atopic individuals tend to produce higher quantities of IgE and have more Fc receptors for IgE on their mast cells. The airways and the skin of atopic individuals have increased responsiveness to a wide variety of both specific and nonspecific stimuli.

**Evaluation and treatment of IgE hypersensitivity.**

Allergic reactions can be life-threatening; therefore it is essential that severely allergic individuals be informed of the specific allergen against which they are sensitized and instructed to avoid contact with that material. Several tests are available to evaluate allergic individuals. These include food challenges, skin tests with allergens, and laboratory tests for total IgE and allergen-specific IgE.

**Type II: Tissue-Specific Hypersensitivity Reactions**

Type II hypersensitivities are generally reactions against a specific cell or tissue. Cells express a variety of antigens on their surfaces, some of which are called tissue-specific antigens because they are expressed on the plasma membranes of only certain cells. Platelets, for example, have groups of antigens that are found on no other cells of the body. The symptoms of many type II diseases are determined by which tissue or organ expresses the particular antigen. Environmental antigens (e.g., drugs or their metabolites) may bind to the plasma membranes of specific cells (especially erythrocytes and platelets) and function as targets of type II reactions. The five general mechanisms by which type II hypersensitivity reactions can affect cells are shown in Figure 8-13. Each mechanism begins with antibody binding to tissue-specific antigens or antigens that have attached to particular tissues.
FIGURE 8-13  Mechanisms of Type II, Tissue-Specific Reactions. Antigens on the target cell bind with antibody and are destroyed or prevented from functioning by one of the following mechanisms: (A) complement-mediated lysis (an erythrocyte target is illustrated here); (B) clearance (phagocytosis) by macrophages in the tissue; (C) neutrophil-mediated immune destruction; (D) antibody-dependent cell-mediated cytotoxicity (ADCC) (apoptosis of target cells is induced by natural killer [NK] cells by two mechanisms: by the release of granzymes and perforin, which is a molecule that creates pores in the plasma membrane, and enzymes [granzymes] that enter the target through the perforin pores; by the interactions of Fas ligand [FasL; a molecule similar to TNF-α] on the surface of NK cells with Fas [the receptor for FasL] on the surface of target cells); or (E) modulation or blocking of the normal function of receptors by
This example of mechanism (E) depicts myasthenia gravis in which acetylcholine receptor antibodies block acetylcholine from attaching to its receptors on the motor end plates of skeletal muscle, thereby impairing neuromuscular transmission and causing muscle weakness. C1, Complement component C1; C3b, complement fragment produced from C3, which acts as an opsonin; C5a, complement fragment produced from C5, which acts as a chemotactic factor for neutrophils; Fcγ receptor, cellular receptor for the Fc portion of IgG; FcR, Fc receptor.

The cell may be destroyed by antibody and complement (see Figure 8-13, A). The antibody (IgM or IgG) reacts with an antigen on the surface of the cell, causing activation of the complement cascade through the classical pathway. Formation of the membrane attack complex (C5-9) damages the membrane and may result in lysis of the cell. For example, erythrocytes are destroyed by complement-mediated lysis in individuals with autoimmune hemolytic anemia (see Chapters 21 and 22) or as a result of an alloimmune reaction to mismatched transfused blood cells.

Antibody may cause cell destruction through phagocytosis by macrophages (see Figure 8-13, B). The antibody may additionally activate complement, resulting in the deposition of C3b on the cell surface. Receptors on the macrophage recognize and bind opsonins (e.g., antibody or C3b) and increase phagocytosis of the target cell. For example, antibodies against platelet-specific antigens or against red blood cell antigens of the Rh system cause their removal by phagocytosis in the spleen.

Tissue damage may be caused by toxic products produced by neutrophils (see Figure 8-13, C). Soluble antigens such as medications, molecules released from infectious agents, or molecules released from an individual's own cells may enter the circulation. In some instances, the antigens are deposited on the surface of tissues, where they bind antibody. The antibody may activate complement, resulting in the release of C3a and C5a, which are chemotactic for neutrophils, and the deposition of complement component C3b. Neutrophils are attracted, bind to the tissues through receptors for the Fc portion of antibody (Fc receptor) or for C3b, and release their granules onto the healthy tissue. The components of neutrophil granules, as well as the toxic oxygen products produced by these cells, will damage the tissue.

Antibody-dependent cell-mediated cytotoxicity (ADCC) involves natural killer (NK) cells (see Figure 8-13, D). Antibody on the target cell is recognized by Fc receptors on the NK cells, which release toxic substances that destroy the target cell.

The last mechanism does not destroy the target cell but rather causes the cell to malfunction (see Figure 8-13, E). The antibody is usually directed against antigenic determinants associated with specific cell surface receptors. The antibody changes the function of the receptor by preventing interactions with their normal ligands, replacing the ligand and inappropriately stimulating the receptor, or destroying the receptor. For example, in the hyperthyroidism (excessive thyroid activity) of Graves disease, autoantibody binds to and activates receptors for thyroid-stimulating
hormone (TSH) (a pituitary hormone that controls the production of the hormone thyroxine by the thyroid). In this way, the antibody stimulates the thyroid cells to produce thyroxine. Under normal conditions, the increasing levels of thyroxine in the blood would signal the pituitary to decrease TSH production, which would result in less stimulation of the TSH receptor in the thyroid and a concomitant decrease in thyroxine production. Increasing amounts of thyroxine in the blood have no effect on anti-TSH receptor antibodies, which continue to stimulate despite decreasing amounts of TSH (see Chapter 19).

**Type III: Immune Complex–Mediated Hypersensitivity Reactions**

**Mechanisms of type III hypersensitivity.**

Most type III hypersensitivity diseases reactions are caused by antigen-antibody (immune) complexes that are formed in the circulation and deposited later in vessel walls or other tissues (Figure 8-14). The primary difference between type II and type III mechanisms is that in type II hypersensitivity antibody binds to antigen on the cell surface, whereas in type III antibody binds to soluble antigen that was released into the blood or body fluids, and the complex is then deposited in the tissues. Type III reactions are not organ specific, and symptoms are mostly unrelated to the particular antigenic target of the antibody. The harmful effects of immune complex deposition are caused by complement activation, particularly through the generation of chemotactic factors for neutrophils. The neutrophils bind to antibody and C3b contained in the complexes and attempt to ingest the immune complexes. They are often unsuccessful because the complexes are bound to large areas of tissue. During the attempted phagocytosis, large quantities of lysosomal enzymes are released into the inflammatory site instead of into phagolysosomes. The attraction of neutrophils and the subsequent release of lysosomal enzymes cause most of the resulting tissue damage.
Immune complex disease.

Two prototypic models of type III hypersensitivity help explain the variety of diseases in this category. Serum sickness is a model of systemic type III hypersensitivities, and the Arthus reaction is a model of localized or cutaneous reactions.

Serum sickness—type reactions are caused by the formation of immune complexes in the blood and their subsequent generalized deposition in target tissues. Typically affected tissues are the blood vessels, joints, and kidneys. Symptoms include fever, enlarged lymph nodes, rash, and pain at sites of inflammation. Serum sickness was initially described as a complication of therapeutic administration of horse serum that contained antibody against tetanus toxin. Foreign serum is not administered to individuals today, although serum sickness reactions can be caused by the repeated intravenous administration of other antigens, such as drugs, and the characteristics of serum sickness are observed in systemic type III autoimmune diseases.

A form of serum sickness is Raynaud phenomenon, a condition caused by the
temperature-dependent deposition of immune complexes in the capillary beds of the peripheral circulation. Certain immune complexes precipitate at temperatures below normal body temperature, particularly in the tips of the fingers, toes, and nose, and are called cryoglobulins. The precipitates block the circulation and cause localized pallor and numbness, followed by cyanosis (a bluish tinge resulting from oxygen deprivation) and eventually gangrene if the circulation is not restored.

An Arthus reaction is caused by repeated local exposure to an antigen that reacts with preformed antibody and forms immune complexes in the walls of the local blood vessels. Symptoms of an Arthus reaction begin within 1 hour of exposure and peak 6 to 12 hours later. The lesions are characterized by a typical inflammatory reaction, with increased vascular permeability, an accumulation of neutrophils, edema, hemorrhage, clotting, and tissue damage.

Arthus reactions may be observed after injection, ingestion, or inhalation of allergens. Skin reactions can follow subcutaneous or intradermal inoculation with drugs, fungal extracts, or antigens used in skin tests. Gastrointestinal reactions, such as gluten-sensitive enteropathy (celiac disease), follow ingestion of antigen, usually gluten from wheat products (see Chapter 37). Allergic alveolitis (farmer lung, pigeon breeder disease) is an Arthus-like acute hemorrhagic inflammation of the air sacs (alveoli) of the lungs resulting from inhalation of fungal antigens, usually particles from moldy hay or pigeon feces (see Chapter 27).

**Type IV: Cell-Mediated Hypersensitivity Reactions**

Whereas types I, II, and III hypersensitivity reactions are mediated by antibody, type IV hypersensitivity reactions are mediated by T lymphocytes and do not involve antibody (Figure 8-15). Type IV mechanisms occur through either cytotoxic T lymphocytes (Tc cells) or lymphokine-producing Th1 and Th17 cells. Tc cells attack and destroy cellular targets directly. Th1 and Th17 cells produce cytokines that recruit and activate phagocytic cells, especially macrophages. Destruction of the tissue is usually caused by direct killing by Tc cells or the release of soluble factors, such as lysosomal enzymes and toxic reactive oxygen species, from activated macrophages.
Clinical examples of type IV hypersensitivity reactions include graft rejection, the skin test for tuberculosis, and allergic reactions resulting from contact with such substances as poison ivy and metals. A type IV component also may be present in many autoimmune diseases. For example, T cells against type II collagen (a protein present in joint tissues) contribute to the destruction of joints in rheumatoid arthritis; T cells against a thyroid cell–surface antigen contribute to the destruction of the thyroid in autoimmune thyroiditis (Hashimoto disease); and T cells against an antigen on the surface of pancreatic beta cells (the cell that normally produces insulin) are responsible for beta-cell destruction in insulin-dependent (type 1) diabetes mellitus.

In 1891 Ehrlich was the first to thoroughly describe a type IV hypersensitivity reaction in the skin, leading to the development of a diagnostic skin test for tuberculosis. The reaction follows an intradermal injection of tuberculin antigen into a suitably sensitized individual and is called a **delayed hypersensitivity skin test** because of its slow onset—24 to 72 hours to reach maximal intensity. The reaction site is infiltrated with T lymphocytes and macrophages, resulting in a clear
hard center (induration) and a reddish surrounding area (erythema).

Allergic type IV reactions are elicited by some environmental antigens that are haptens (Chapter 7) and become immunogenic after binding to larger (carrier) proteins in the individual. In allergic contact dermatitis, the carrier protein is in the skin. The best-known example is poison ivy (Figure 8-16). The antigen is a plant catechol, urushiol, which reacts with normal skin proteins and evokes a cell-mediated immune response. Skin reactions to industrial chemicals, cosmetics, detergents, clothing, food, metals, and topical medicines (such as penicillin) are elicited by the same mechanism. Contact dermatitis consists of lesions only at the site of contact with the allergen, such as a metal allergy to jewelry.

Quick Check 8-3

1. Distinguish among the four types of hypersensitivity mechanisms.

2. What is the mechanism of anaphylaxis?

3. What are some clinical examples of type IV hypersensitivity?
**Antigenic Targets of Hypersensitivity Reactions**

**Allergy**

**Allergens.**

Allergies are the most common hypersensitivity reactions. The majority of allergies
are type I reactions that lead to annoying symptoms, including rhinitis, sneezing, and other relatively mild reactions. In some individuals, however, these reactions can be excessive and life-threatening (anaphylaxis). Antigens that cause allergic responses are called **allergens**. It is not known why some antigens are allergens and others are not. Typical allergens include pollens (e.g., ragweed), molds and fungi (e.g., *Penicillium chrysogenum*), foods (e.g., milk, eggs, fish), animals (e.g., cat dander, dog dander), cigarette smoke, and components of house dust (e.g., fecal pellets of house mites). Often the allergen is contained within a particle that is too large to be phagocytosed or is surrounded by a protective nonallergenic coat. The actual allergen is released after enzymatic breakdown (e.g., by lysozyme in secretions) of the larger particle.

**Allergic disease: bee sting allergy.**

Bee venoms contain a mixture of enzymes and other proteins that may serve as allergens and cause a type I hypersensitivity reaction. About 1% of children may have an anaphylactic reaction to bee venom. Within minutes they may develop excessive swelling (edema) at the bee sting site, followed by generalized hives, pruritus, and swelling in areas distal from the sting (e.g., eyes, lips), and other systemic symptoms including flushing, sweating, dizziness, and headache. The most severe symptoms may include gastrointestinal (e.g., stomach cramps, vomiting), respiratory (e.g., tightness in the throat, wheezing, difficulty breathing), and vascular (e.g., low blood pressure, shock) reactions. Severe respiratory tract and vascular reactions may lead to death.

For an individual with known bee sting hypersensitivity, lifestyle changes include avoidance of stinging or biting insects. If a child has experienced a previous anaphylactic reaction, the chance of having another is about 60%. The primary life-threatening symptoms result from contraction of respiratory tract smooth muscle. Autonomic nervous system mediators, such as epinephrine, bind to specific receptors on smooth muscle and reverse the effects of histamine, resulting in muscle relaxation. Thus most individuals with bee sting allergies carry self-injectable epinephrine. The administration of antihistamines has little effect because histamine has already bound H1 receptors and initiated severe bronchial smooth muscle contraction.

Clinical **desensitization** to allergens can be achieved in some individuals. Minute quantities of the allergen are injected in increasing doses over a prolonged period. The procedure may reduce the severity of the allergic reaction in the treated individual. However, this form of therapy may trigger systemic anaphylaxis, which can be severe and life-threatening. This approach works best for routine respiratory
tract allergens and biting insect allergies (80% to 90% rate of desensitization over 5 years of treatment). Food allergies have been very difficult to suppress, but some promising trials are underway to evaluate desensitization by oral or sublingual administration of increasing amounts of allergen.

**Autoimmunity**

Autoimmune diseases originate from an initiating event in a genetic predisposed individual. Current models of factors related to autoimmune diseases include genetic factors, environmental factors, and random or stochastic changes. Some autoimmune diseases can be familial and attributed to the presence of a very small number of susceptibility genes; affected family members may not all develop the same disease, but have different disorders characterized by a variety of hypersensitivity reactions, including autoimmune and allergic. For instance, the HLA antigen B27 (HLA is discussed further under transplant rejection, p. 209) is a risk factor for developing ankylosing spondylitis (AS), an autoimmune inflammatory disease of the spine; 95% of individuals diagnosed with AS express HLA-B27 whereas only 4% to 8% of the general population expresses this antigen. Although most autoimmune diseases appear as isolated events without a positive family history, susceptibility for developing such diseases appears to be linked to a combination of multiple genes.

**Breakdown of tolerance.**

An individual is usually tolerant to his or her own antigens. Tolerance is a state of immunologic control so that the individual does not make a detrimental immune response against his or her own cells and tissues. Autoimmune disease results from a breakdown of this tolerance.

The initiating event that breaks tolerance is unclear for most autoimmune diseases. It is also unclear as to the bodily site initially involved to cause autoimmunity. Potential infectious initiators of autoimmune disease are being investigated, but only one example is known: acute rheumatic fever. In a small number of individuals with group A streptococcal sore throats, the M proteins in the bacterial capsule mimic (antigenic mimicry) normal heart antigens and induce antibodies that also react with proteins in the heart valve, damaging the valve. Thus acute rheumatic fever is a type II autoimmune hypersensitivity. Additionally, some streptococcal skin or throat infections release bacterial antigens into the blood that form circulating immune complexes. The complexes may deposit in the kidneys and initiate an immune complex–mediated glomerulonephritis (inflammation of the kidney). Thus streptococcal antigens (an environmental antigen) may also cause a
type III allergic hypersensitivity (poststreptococcal glomerulonephritis).

**Autoimmune disease: systemic lupus erythematosus.**

Systemic lupus erythematosus (SLE) is the most common, complex, and serious of the autoimmune disorders. SLE is characterized by the production of a large variety of antibodies (autoantibodies) against self-antigens, including nucleic acids, erythrocytes, coagulation proteins, phospholipids, lymphocytes, platelets, and many other self-components. The most characteristic autoantibodies are against nucleic acids (e.g., single-stranded DNA, double-stranded DNA), histones, ribonucleoproteins, and other nuclear materials. Approximately 98% of persons with SLE have detectable antibodies against nuclear antigens. The blood normally contains many of these products of cellular turnover and breakdown so that autoantibodies react with the circulating antigen and form circulating immune complexes. The deposition of circulating DNA/anti-DNA complexes in the kidneys can cause severe kidney inflammation. Similar reactions can occur in the brain, heart, spleen, lung, gastrointestinal tract, peritoneum, and skin. Thus some of the symptoms of SLE result from a type III hypersensitivity reaction. Other symptoms, such as destruction of red blood cells (anemia), lymphocytes (lymphopenia), and other cells, may be type II hypersensitivity reactions.

SLE, like most autoimmune diseases, occurs more often in women (approximately a 9 : 1 predominance of females), especially in the 20- to 40-year-old age group. Blacks are affected more often than whites (about an eightfold increased risk). A genetic predisposition for the disease has been implicated on the basis of increased incidence in twins and the existence of autoimmune disease in the families of individuals with SLE.

As with many autoimmune diseases, clinical manifestations of SLE may wax and wane; the individual may go through periods of remission and be relatively disease free until the onset of a flare (exacerbated disease activity). Symptoms include arthralgias or arthritis (90% of individuals), vasculitis and rash (70% to 80% of individuals), renal disease (40% to 50% of individuals), hematologic abnormalities (50% of individuals, with anemia being the most common complication), and cardiovascular diseases (30% to 50% of individuals) (see discoid lupus erythematosus in Chapter 41). Because the signs and symptoms affect almost every body system and tend to vacillate, SLE is extremely difficult to diagnose. This has led to the development of a list of 11 common clinical findings, which has been modified slightly to increase sensitivity of the diagnosis. The serial or simultaneous presence of at least four of these findings indicates that the individual has SLE. The findings are as follows:
1. Facial rash confined to the cheeks (malar rash)

2. Discoid rash (raised patches, scaling)

3. Photosensitivity (development of skin rash as a result of exposure to sunlight)

4. Oral or nasopharyngeal ulcers

5. Nonerosive arthritis of at least two peripheral joints

6. Serositis (inflammation of membranes of lung [pleurisy] or heart [pericarditis])

7. Renal disorder (persistent proteinuria of >0.5 g/day or >3 on dipstick, or cellular casts)

8. Neurologic disorders (seizures or psychosis in the absence of known causes)

9. Hematologic disorders (hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia)

10. Immunologic disorders (anti–double-stranded DNA (dsDNA), anti–Smith [Sm] antigen, false-positive serologic test for syphilis, or antiphospholipid antibodies [anticardiolipin antibody or lupus anticoagulant])

11. Presence of antinuclear antibody (ANA)

Laboratory diagnosis is usually based on a positive ANA screening test; about 98% of individuals with SLE are positive, but a substantial number of false-positives occur in healthy individuals and those with other diseases. Because SLE is a progressive and slowly developing disease, some laboratory tests, including the ANA, may be positive years before the onset of clinical symptoms. Detection of a positive ANA is usually followed by one or more specific tests (e.g., antibodies against Sm, dsDNA) that are complicated by low sensitivity (only a portion of individuals with SLE will be positive, although the number of false-positives is low).

There is no cure for SLE or most other autoimmune diseases. Fatalities resulting from SLE are usually related to infection, organ failure, or cardiovascular disease. The goals of treatment are to control symptoms and prevent further damage by suppressing the autoimmune response. Nonsteroidal anti-inflammatory drugs, such as aspirin, ibuprofen, or naproxen, reduce inflammation and relieve pain. Corticosteroids are often prescribed for more serious active disease.
Immunosuppressive drugs (e.g., methotrexate, azathioprine, or cyclophosphamide) are used to treat severe symptoms involving internal organs. Antimalarial medications (e.g., hydroxychloroquine) are preferred treatments for individuals with stable disease. Ultraviolet light may initiate flares and protection from sun exposure is helpful. Prolonged use of certain drugs can cause transient SLE-like symptoms, and the medication history is important for differential diagnosis.

**Alloimmunity**

**Alloantigens.**

Genetic diversity is the norm in humans. Diversity also is observed among self-antigens, so that two individuals may have different antigens on their tissues and, therefore, make an immune response against each other's tissues. Some self-antigens, such as the ABO blood group, have limited diversity with very few different antigens being expressed in the population, whereas others, such as the HLA system, have tremendous diversity.

**Alloimmune disease: transfusion reactions.**

Red blood cells (erythrocytes) express several important surface antigens, which are known collectively as the **blood group antigens** and can be targets of alloimmune reactions. More than 80 different red cell antigens are grouped into several dozen blood group systems. The most important of these, because they provoke the strongest humoral alloimmune response, are the ABO and Rh systems.

The **ABO blood group** consists of two major carbohydrate antigens, labeled A and B (Figure 8-17), that are expressed on virtually all cells. These are codominant so that both A and B can be simultaneously expressed, resulting in an individual having any one of four different blood types. The erythrocytes of blood type A express the type A carbohydrate antigen, those with blood type B express the B antigen, those with blood type AB express both A and B antigens on the same cell, and those of blood type O express neither the A nor the B antigen. A person with type A blood also has circulating antibodies to the B carbohydrate antigen. If this person receives blood from a type AB or B individual, a severe transfusion reaction occurs, and the transfused erythrocytes are destroyed by agglutination or complement-mediated lysis. Similarly, a type B individual (whose blood contains anti-A antibodies) cannot receive blood from a type A or AB donor. Type O individuals, who have neither antigen but have both anti-A and anti-B antibodies, cannot accept blood from any of the other three types. These naturally occurring antibodies, called **isohemagglutinins**, are IgM immunoglobulins and are induced
early in life against similar antigens expressed on naturally occurring bacteria in the intestinal tract.

Because individuals with type O blood lack both types of antigens, they are considered **universal donors**, meaning that anyone can accept their red blood cells. Similarly, type AB individuals are considered **universal recipients** because they lack both anti-A and anti-B antibodies and can be transfused with any ABO blood type. Harmful transfusion reactions can be prevented only by complete and careful ABO matching between donor and recipient.

The **Rh blood group** is a group of antigens expressed only on red blood cells. This is the most diverse group of red cell antigens, consisting of at least 45 separate antigens, although only 1 is considered of major importance: the D antigen. Individuals who express the D antigen on their red cells are Rh-positive, whereas
individuals who do not express the D antigen are Rh-negative. When discussing the gene for the Rh antigen, the letter d is used to indicate lack of D. Rh-positive individuals can have either a DD or Dd genotype, whereas Rh-negative individuals have the dd genotype. About 85% of North Americans are Rh-positive. Rh-negative individuals can make an IgG antibody to the D antigen (anti-D) if exposed to Rh-positive erythrocytes.

A disease called hemolytic disease of the newborn was most commonly caused by IgG anti-D alloantibody produced by Rh-negative mothers against erythrocytes of their Rh-positive fetuses (see Chapter 22). The mother's antibody crossed the placenta and destroyed the red blood cells of the fetus. The occurrence of this particular form of the disease has decreased dramatically because of the use of prophylactic anti-D immunoglobulin (i.e., RhoGAM). By mechanisms that are still not completely understood, administration of anti-D antibody within a few days of exposure to RhD-positive erythrocytes completely prevents sensitization against the D antigen. Because hemolytic disease of the newborn related to the D antigen has been controlled, alloantibodies against the other Rh antigens have become more important. In general, these alloantibodies are associated with a less severe hemolytic disease.

**Alloimmune disease: transplant rejection.**

Molecules of the major histocompatibility complex (MHC) were discussed in Chapter 7 as antigen-presenting molecules. MHC molecules are also a major target of transplant rejection. As a result of studies of transplantation, the human MHC molecules are also referred to as human leukocyte antigens (HLAs) and the different MHC genetic loci are commonly called HLA-A, HLA-B, HLA-C, HLA-DR, HLA-DQ, and HLA-DP (Figure 8-18). Additional genes for complement components (e.g., C4, factor B) are also contained in the MHC region and are referred to as class III loci. The class I (HLA-A, -B, and -C) and class II MHC loci (HLA-DR, -DQ, and -DP) are the most genetically diverse (polymorphic) of any human genetic loci. Within the human population, the number of possible different alleles (i.e., forms of the gene) expressed by each locus is astounding. For example, more than 300 different HLA-A molecules are expressed in the population. These numbers are based on the polymorphism of observed DNA sequences and may not reflect differences in function.
FIGURE 8-18 Human Leukocyte Antigens (HLAs). The major histocompatibility complex (MHC) is located on the short arm of chromosome 6 and contains genes that code for class I antigens, class II antigens, and class III proteins (i.e., complement proteins and cytokines). (From Peakman M, Vergani D: Basic and clinical immunology, ed 2, London, 2009, Churchill Livingstone.)

Clearly, not every allele is expressed in the same individual. Humans have two copies of each MHC locus (one inherited from each parent) that are codominant so that molecules encoded by each parent's genes are expressed on the surface of every cell, except erythrocytes. Within an individual, each locus will express only one allele. For instance, each person will have at most two different HLA-A proteins (one from each parent). However, with the tremendous number of possible alleles that can be expressed throughout the population, it is likely that any two unrelated individuals will have different MHC antigens.

The diversity of MHC molecules becomes clinically relevant during organ transplantation. The recipient of a transplant can mount an immune response against the foreign HLA antigens on the donor tissue, resulting in rejection. To minimize the chance of tissue rejection, the donor and recipient are often tissue-typed beforehand to identify differences in HLA antigens. Because of the large number of different alleles, it is highly unlikely that a perfect match can be found between someone who needs a transplant and a potential donor from the general population. The more similar two individuals are in their HLA tissue type, the more likely a transplant from one to the other will be successful. Clearly, the most successful transplants would be between identical twins because they are identical genetically.

The specific combination of alleles at the six major HLA loci on one chromosome (A, B, C, DR, DQ, and DP) is termed a haplotype. Each individual has two HLA haplotypes, one from the paternal chromosome 6 and another from the maternal chromosome (Figure 8-19). Each parent passes on one set of HLA antigens to each of his or her offspring, meaning that children usually share half their HLA antigens with each parent. Odds dictate that children will share one haplotype with half their siblings and either no haplotypes or both haplotypes with a quarter of their siblings. Thus the chance of finding a match among siblings is much higher (25%) than the general population.
Transplant rejection may be classified as hyperacute, acute, or chronic, depending on the amount of time that elapses between transplantation and rejection. 

**Hyperacute rejection** is immediate and rare. When the circulation is reestablished to the grafted area, the graft may immediately turn white (the so-called *white graft*) instead of a normal pink color. Hyperacute rejection usually occurs because of preexisting antibody (type II reaction) to HLA antigens on the vascular endothelial cells in the grafted tissue.

**Acute rejection** is a cell-mediated immune response that occurs within days to months after transplantation. This type of rejection occurs when the recipient develops an immune response against unmatched HLA antigens after transplantation. A biopsy of the rejected organ usually shows an infiltration of lymphocytes and macrophages characteristic of a type IV reaction.

**Chronic rejection** may occur after a period of months or years of normal function. It is characterized by slow, progressive organ failure. Chronic rejection usually results from a weak cell-mediated (type IV) reaction against minor histocompatibility antigens on the grafted tissue. However, antibodies against HLA and other antigens also may cause chronic rejection through activation of complement or antibody-dependent cellular cytotoxicity (ADCC) with NK cells.
1. Why do certain drugs become immunogenic to the host?

2. Why is SLE considered an autoimmune disease?

3. Define the different types of graft rejection.
Did You Understand?

**Infection**

1. Infectious disease is a significant cause of morbidity and mortality in the United States and worldwide.

2. Pathogens have unique characteristics that influence their ability to cause disease.

3. Bacteria injure cells by producing exotoxins or endotoxins. Exotoxins are enzymes that can damage the plasma membranes of host cells or can inactivate enzymes critical to protein synthesis, and endotoxins activate the inflammatory response and produce fever.

4. Septicemia is the proliferation of bacteria in the blood. Endotoxins released by blood-borne bacteria cause the release of vasoactive enzymes that increase the permeability of blood vessels. Leakage from vessels causes hypotension that can result in septic shock.

5. Viruses enter host cells and use the metabolic processes of host cells to proliferate and cause disease.

6. Viruses that have invaded host cells may decrease protein synthesis, disrupt lysosomal membranes, form inclusion bodies where synthesis of viral nucleic acids is occurring, fuse with host cells to produce giant cells, alter antigenic properties of the host cell, transform host cells into cancerous cells, and promote bacterial infection.

7. Diseases caused by fungi are called mycoses, and they occur in two forms: yeasts (spheres) and molds (filaments or hyphae).

8. Dermatophytes are fungi that infect skin, hair, and nails with diseases such as ringworm and athlete's foot.

9. Fungi release toxins and enzymes that are damaging to tissue. *Candida albicans* is the most common cause of fungal infections in humans.

10. Parasitic microorganisms range from unicellular protozoa to large worms. Although less common in the United States, parasites and protozoa are common causes of infection worldwide.
11. Parasitic and protozoal infections are rarely transmitted from human to human. Infection mainly spreads through vectors (e.g., by mosquito bites) or through contaminated water or food (i.e., malaria, Chagas disease, sleeping sickness, and leishmaniasis).

12. Infection control measures include implementation of clean food and water, management of sewage and waste, control of insects that transmit disease, vaccination, appropriate use of antimicrobials, and passive immunotherapy.

**Deficiencies in Immunity**

1. Immunodeficiency is the failure of mechanisms of self-defense to function in their normal capacity.

2. Immunodeficiencies are either congenital (primary) or acquired (secondary). Congenital immunodeficiencies are caused by genetic defects that disrupt lymphocyte development, whereas acquired immunodeficiencies are secondary to disease or other physiologic alterations.

3. The clinical hallmark of immunodeficiency is a propensity to unusual or recurrent severe infections. The type of infection usually reflects the immune system defect.

4. The most common infections in individuals with defects of cell-mediated immune response are fungal and viral, whereas infections in individuals with defects of the humoral immune response or complement function are primarily bacterial.

5. Severe combined immunodeficiency (SCID) is a total lack of T-cell function and a severe (either partial or total) lack of B-cell function.

6. Wiskott-Aldrich syndrome is caused by decreased production of IgM antibody.

7. DiGeorge syndrome (congenital thymic aplasia or hypoplasia) is characterized by complete or partial lack of the thymus (resulting in depressed T-cell immunity), frequently associated with diminished or absent parathyroid gland activity (resulting in hypocalcemia) and cardiac anomalies.

8. Antibody deficiencies result from defects in B-cell maturation or function and range from a complete lack of the human bursal equivalent, the lymphoid organs required for B-cell maturation (as in Bruton agammaglobulinemia), to deficiencies
in a single class of immunoglobulins (e.g., selective IgA deficiency).

9. Phagocyte defects include inadequate numbers or alteration in function, such as inadequate adhesion to bacteria or ineffective killing.

10. Complement and mannose-binding lectin deficiencies also are rare causes of increased risk for infection.

11. Acquired immunodeficiencies are caused by superimposed conditions, such as malnutrition, medical therapies, physical or psychologic trauma, or infections.

12. Immunodeficiency syndromes usually are treated by replacement therapy. Deficient antibody production is treated by replacement of missing immunoglobulins with commercial gamma-globulin preparations. Lymphocyte deficiencies are treated by the replacement of host lymphocytes with transplants of bone marrow, fetal liver, or fetal thymus from a donor. There are ongoing trials for gene therapy.

13. AIDS is an acquired dysfunction of the immune system caused by a retrovirus (HIV) that infects and destroys CD4+ lymphocytes (T-helper cells).

Hypersensitivity: Allergy, Autoimmunity, and Alloimmunity

1. Hypersensitivity is an immune response misdirected against the host's own tissues (autoimmunity) or directed against beneficial foreign tissues, such as transfusions or transplants (alloimmunity); or it can be exaggerated responses against environmental antigens (allergy).

2. Mechanisms of hypersensitivity are classified as type I (IgE-mediated) reactions, type II (tissue-specific) reactions, type III (immune complex–mediated) reactions, and type IV (cell-mediated) reactions.

3. Hypersensitivity reactions can be immediate (developing within seconds or hours) or delayed (developing within hours or days).

4. Anaphylaxis, the most rapid immediate hypersensitivity reaction, is an explosive reaction that occurs within minutes of reexposure to the antigen and can lead to cardiovascular shock.
5. Type I (IgE-mediated) reactions occur after antigen reacts with IgE on mast cells, leading to mast cell degranulation and the release of histamine and other inflammatory substances.

6. Type II (tissue-specific) reactions are caused by four possible mechanisms: complement-mediated lysis, opsonization and phagocytosis, antibody-dependent cell-mediated cytotoxicity, and modulation of cellular function.

7. Type III (immune complex–mediated) reactions are caused by the formation of immune complexes that are deposited in target tissues, where they activate the complement cascade, generating chemotactic fragments that attract neutrophils into the inflammatory site.

8. Immune complex disease can be a systemic reaction, such as serum sickness (e.g., Raynaud phenomenon), or localized, such as the Arthus reaction.

9. Type IV (cell-mediated) reactions are caused by specifically sensitized T cells, which either kill target cells directly or release lymphokines that activate other cells, such as macrophages.

10. Allergens are antigens that cause allergic responses, usually a type I hypersensitivity response.

11. Autoimmune disease is loss of tolerance to self-antigens. There can be a genetic predisposition and the diseases can be a type II or type III hypersensitivity reaction.

12. Alloimmunity is the immune system's reaction against antigens on the tissues of other members of the same species.

13. Alloimmune disorders include transient neonatal disease, in which the maternal immune system becomes sensitized against antigens expressed by the fetus; and transplant rejection and transfusion reactions, in which the immune system of the recipient of an organ transplant or blood transfusion reacts against foreign antigens on the donor's cells.

Stress is broadly defined as a perceived or anticipated threat that disrupts a person's well-being or homeostasis. Stress involves a complex interaction between the body and brain in the face of random and constant external and internal challenges called stressors.\textsuperscript{1,2} A stressor may stem from psychologic/emotional (fear, social rejection), physical (dramatic temperature changes, abuse), or physiologic (infection, inflammation) stimuli that trigger the stress response. Many physical and physiologic stressors also are discussed in various chapters. This chapter highlights the effects of psychologic and emotional stressors on modulating the onset of human diseases.

Exposure to acute stress activates defensive neural, autonomic, and immune systems to facilitate adaptation and survival.\textsuperscript{3-5} However, unremitting or toxic stress induces adverse effects by promoting pathophysiology in the very systems that function to meet the challenges of acute stress. For example, whereas acute stress enhances the immune system to protect the individual, adverse situations that cannot be resolved and are accompanied by prolonged activation of the body's stress systems may lead to immunosuppression that impairs the body's ability to fight diseases.\textsuperscript{6}

Although modern society offers many positive opportunities, events perceived as especially stressful and uncontrollable, such as loss of a family member, loss of a job, cancer diagnosis, physical abuse, social neglect, or financial hardships, may induce unhealthy coping strategies (e.g., smoking, drinking alcohol, drug abuse) and poor decisions, such as foregoing sleep, eating high calorie comfort foods, and withdrawing from physical activity. Continued engagement in these behavioral activities is linked to a number of serious illnesses, such as hypertension, depression, diabetes, and obesity (Figure 9-1).\textsuperscript{4,7,8} Thus, information should be made widely available to inform people of the positive benefits of coping behavior (e.g., mindfulness, yoga, exercise) or to seek social support from others and healthcare professionals to maintain a healthy behavioral and physiologic profile.
Physiologic and Behavioral Stress Responses. Stress processes arise from bidirectional communication patterns between the brain and other physiologic systems (autonomic, immune, neural, and endocrine). Importantly, these bidirectional mechanisms are protective, promoting short-term adaptation (allostasis). Chronic stress mechanisms, however, can lead to long-term dysregulation and promote behavioral responses and physiologic responses that lead to stress-induced disorders/diseases (allostatic load), compromising health. (From McEwen BS: Eur J Pharmacol 583(2-3):174-185, 2008.)
Historical Background and General Concepts

Walter B. Cannon used the term stress in both a physiologic and a psychologic sense as early as 1914, and coined the term “fight-or-flight response” to describe the body's preparation to deal with threat.\(^9\) He applied the engineering concepts of stress and strain in a physiologic context and believed that emotional stimuli also were capable of causing stress. The physiologic reactions to stress included increased heart rate and blood supply of oxygen and glucose to muscles and the brain, elevated respiration, dilation of pupils, and inhibition of gastric secretions.

In 1946, Hans Selye further popularized and advanced the concept of stress in terms of a chemical or physical change (i.e., physiologic stress, in response either to the external environment or within the body itself). His work showed that **physiologic stress** involved: (1) enlargement of the adrenal gland, (2) decreased lymphocyte levels in the blood from damage to lymphatic structures of the immune system, and (3) development of bleeding ulcers in the stomach and duodenal lining. Selye concluded physiologic stress will impair the ability of the organism to resist future stressors and represented the hallmark pattern of a nonspecific stress response that was labeled the **general adaptation syndrome (GAS)**.\(^{10}\)

The GAS involved three successive stages: the alarm, the resistance or adaptation, and the exhaustion stages. The **alarm stage** is the emergency reaction that prepares the body to fight or flee from threat. This stage involves the secretion of hormones and catecholamines to support physiologic/metabolic activity (Figures 9-2 and 9-3) and boosts the immune system to thwart infection and disease. The ensuing **resistance or adaptation stage** requires continued mobilization of the body's resources to cope and overcome a sustained challenge. The **exhaustion stage** (currently described as allostatic overload; discussed later) occurs when the body's physiologic and immune systems no longer effectively cope with the stressor and marks the onset of diseases (**diseases of adaptation**). That is, when stress continues unabated and adaptation is not successful, body organs that are weak, such as the heart and kidney, may no longer function and lead to death.
The alarm reaction includes increased secretion of glucocorticoids (cortisol) by the adrenal cortex and increased secretion of epinephrine and small amounts of norepinephrine from the adrenal medulla. The response to the release of cortisol and sympathetic nerve activation is summarized in Figure 9-3. ACTH, Adrenocorticotropic hormone. (Adapted from Thibodeau GA, Patton KT: Anatomy & physiology, ed 9, St Louis, 2016, Mosby.)
Although the GAS is considered a cornerstone of stress research, the concept that stress is entirely the result of a physical disturbance is an oversimplification. In the mid-1950s, studies emerged demonstrating that psychologic stressors were highly effective in activating adrenal hormone secretion. For example, stress hormone levels increased when monkeys were reexposed to a clicking sound previously paired with electric shock.\textsuperscript{11} Similarly, stress hormone secretion in humans increased when exposed to psychologic stressors,\textsuperscript{12} such as a stressful interview.\textsuperscript{13} According to Mason a number of psychologic factors, such as degree of comfort, unpleasantness, or suddenness of an unanticipated stimulus, could modulate the magnitude of the stress response.\textsuperscript{14} 

Research from the 1970s has demonstrated a remarkable sensitivity of the central nervous system and endocrine system to emotional, psychologic, and social influences. Psychologic stressors can elicit a reactive or anticipatory stress response. For example, an examination with no physical stressor may elicit a reactive response involving physiologic changes, such as increased heart rate and dry mouth. Anticipatory responses occur when physiologic responses develop in anticipation of psychologic stress or threat. Anticipatory responses can be generated
by the fear of a potential encounter with a dangerous, unconditioned stimulus (such as a predator) or in conditioned situations when a person learns that a specific event was associated with an aversive situation. Anticipation of reexposure to these unwanted events produces a physiologic stress response. For example, a child with a history of parental abuse may experience a physiologic stress response in anticipation of further abuse when that parent enters the room. Another well-known example of a conditioned emotional response is the development of posttraumatic stress disorder (PSTD) in some military veterans and survivors of natural disasters.

**Psychoneuroimmunology (PNI)** is the study of how consciousness (*psycho*), mediated by the CNS (*neuro*), interacts with the immune system (*immunology*) to defend the body against infection. Psychoneuroimmunology assumes that immune-mediated diseases result from complex interrelationships among psychosocial, emotional, genetic, neurologic, endocrine, immunologic, and behavioral factors. The immune system is integrated with other physiologic processes and sensitive to changes in CNS and endocrine functioning linked to psychologic states. Stressors include a broad range of physical and emotional sources—for example, infection, noise, decreased oxygen supply, pain, malnutrition, heat, cold, trauma, prolonged exertion, radiation, responses to life events (including anxiety, depression, anger, fear, loss, and excitement), obesity, advanced age, drugs, disease, surgery, and medical treatment.

The study of PNI has generated broad scientific debate, especially with respect to the causal role of personality and emotional factors in cancer mortality and morbidity. For example, mouse models suggest a strong link between stress and breast cancer progression, but this effect is not consistently found in humans. What is becoming increasingly clear is that secretion of stress hormones influences many metabolic systems and physiologic events in both adults and children. Furthermore, studies now point to a strong association between modulation of the immune system by psychosocial stressors and health outcomes. With increased understanding of the relationship between stress and human diseases, new strategies are emerging to treat stress-related disorders.

**Stress Overview: Allostasis, Multiple Mediators, and Systems**

Increased knowledge of the link between stress and disease is supported by the concept of **allostasis**, introduced by Sterling and Eyer, and refers to “stability through change.” This concept differs from the “fixed homeostasis model” in which physiologic regulation revolves around an unchanging set point. For example, after exposure to a challenging stressor, heightened physiologic secretion of stress
hormones (e.g., cortisol) must return to basal levels. By contrast, allostasis involves a dynamic strategy with the brain continuously monitoring many parameters to anticipate what is required from the neuroendocrine and autonomic systems to meet the challenges of future events.\textsuperscript{3,27,28} Hence, return to initial basal hormone levels may not be the most adaptive strategy to cope with anticipated stress encounters. However, when chronic activation of regulatory systems taxes the body and brain, diseases and disorders may emerge. \textit{Allostatic overload} is the term used to describe overactivation of adaptive regulatory physiologic systems that may lead to clinical pathophysiology and increase susceptibility of disease.

Research suggests that allostasis and allostatic overload are highly individualized; that is, an event or situation that is considered normal in one person may be stressful to another.\textsuperscript{29,30} In people experiencing allostatic overload, this load exacts a “wear and tear” toll on our bodies. Because the brain is a key player in perceiving stress, it is influential in determining when we have reached allostatic overload. Thus, psychologic stress is increasingly recognized both as a precipitating factor for some diseases as well as a contributor that worsens symptoms and negative outcomes in anxiety, chronic pain and fatigue syndromes, ulcers, asthma, obesity, metabolic syndrome, essential hypertension, and type 2 diabetes. In addition, stress disrupts the biologic process of sleep and growth and reproductive functions.\textsuperscript{24,31-34} Some of these disorders are the leading causes of death in the United States (Table 9-1).

In response to acute and chronic stress, brain regions, including the hippocampus, amygdala, and prefrontal cortex, may respond by undergoing structural remodeling
that alters behavioral and physiologic responses to increase the risk of developing cognitive impairments and depression.\textsuperscript{1,28} Key physiologic systems involved in allostatic overload include exaggerated secretion of cortisol, catecholamines of the sympathetic nervous system, and proinflammatory cytokines, as well as a decline in parasympathetic activity. A prevalent example is sleep deprivation from being “stressed out.” Sleep deprivation and disturbances, such as sleep apnea, short sleep duration, and insomnia, have significant associations with allostatic load, leading to damaging effects including elevated evening cortisol concentration; elevated insulin and blood glucose levels; increased blood pressure; reduced parasympathetic activity; increased levels of proinflammatory cytokines; and increased secretion of the hormone ghrelin (primarily by cells of the stomach and pancreas), which increases appetite.\textsuperscript{35,36} Overall, the dynamic and damaging effects of allostatic overload can induce sleep deprivation, which then facilitates increased caloric intake, depressed mood, cognitive deficits, and a host of other unhealthy responses.

\textbf{Quick Check 9-1}

1. How is stress related to unhealthy coping behaviors?

2. Briefly describe the three stages of the general adaptation syndrome.

3. Define allostatic load and allostatic overload.
The Stress Response

Because evidence points to the important role that stress plays in many disease processes, research has begun to focus on physiologic mechanisms underlying mind-body interactions in order to understand and prevent stress-related diseases. Using a multidisciplinary approach involving molecular biology, immunology, neurology, endocrinology, and behavioral science, researchers are investigating how stressful life events occurring over a prolonged period of time impair immune functions. Knowledge emerging from the various disciplines offers a holistic and complex model of the biochemical relationships among the central nervous system (CNS), autonomic nervous system (ANS), endocrine system, and immune system.

Regulation of the Hypothalamic-Pituitary-Adrenal System

A key stress hormone relationship is the regulation of the hypothalamic-pituitary-adrenal (HPA) system (Figure 9-4). In sequence, the perception of stress activates the hypothalamus to secrete corticotropin-releasing hormone (CRH), which binds to specific receptors on anterior pituitary cells that, in turn, produce adrenocorticotrophic hormone (ACTH). ACTH is then transported through the blood to the adrenal glands located on the top of the kidneys. After binding to specific receptors on the cortex of the adrenal glands, glucocorticoid hormones (primarily cortisol) are released.
Physiologic Effects of Cortisol

During stress, the secretion of gluocorticoid hormones, primarily cortisol (cortisol is known outside the body as hydrocortisone), reaches all tissues, including the brain, easily penetrates cell membranes, and reacts with numerous
intracellular glucocorticoid receptors (see Figure 9-3). Because they spare almost no tissue or organ and influence a large proportion of the human genome, glucocorticoids exert significant diverse biologic actions.\textsuperscript{24} They regulate many functions of the CNS, including arousal, cognition, mood, sleep, metabolism, maintenance of cardiovascular tone, the immune and inflammatory reaction, and growth and reproduction.

Cortisol mobilizes substances needed for cellular metabolism and stimulates gluconeogenesis or the formation of glucose from non-carbohydrate sources, such as amino acids or free fatty acids in the liver. In addition, cortisol enhances the elevation of blood glucose levels that is promoted by other hormones, such as epinephrine, glucagon, and growth hormone. Cortisol also inhibits the uptake and oxidation of glucose by many body cells. Overall, cortisol's actions on carbohydrate metabolism result in increased blood glucose levels, thereby energizing the body to combat the stressor. The effects of cortisol are summarized in Table 9-2.
### TABLE 9-2  
Physiologic Effects of Cortisol

<table>
<thead>
<tr>
<th>Functions Affected</th>
<th>Physiologic Effects</th>
</tr>
</thead>
<tbody>
<tr>
<td>Carbohydrate and lipid metabolism</td>
<td>Diminishes peripheral uptake and utilization of glucose; promotes gluconeogenesis in liver metabolism cells; enhances gluconeogenic response to other hormones; promotes lipolysis in adipose tissue</td>
</tr>
<tr>
<td>Protein metabolism</td>
<td>Increases protein synthesis in liver and decreases protein synthesis (including immunoglobulin synthesis) in muscle, lymphoid tissue, adipose tissue, skin, and bone; increases plasma level of amino acids; stimulates deamination in liver</td>
</tr>
<tr>
<td>Anti-inflammatory effects (systemic effects)</td>
<td>High levels of cortisol used in drug therapy suppress inflammatory response and inhibit proinflammatory activity of many growth factors and cytokines; however, over time some individuals may develop tolerance to glucocorticoids, causing an increased susceptibility to both inflammatory and autoimmune diseases</td>
</tr>
<tr>
<td>Proinflammatory effects (possible local effects)</td>
<td>Cortisol levels released during stress response may increase proinflammatory effects</td>
</tr>
<tr>
<td>Lipid metabolism</td>
<td>Lipolysis in extremities and lipogenesis in face and trunk</td>
</tr>
<tr>
<td>Immune effects</td>
<td>Treatment levels of glucocorticoids are immunosuppressive; thus they are valuable agents used in numerous diseases/conditions; T-cell or innate immune system is particularly affected by these larger doses of glucocorticoids, with suppression of Th1 function or innate immunity; stress can cause a different pattern of immune response; these nontherapeutic levels can suppress innate (Th1) and increase adaptive (Th2) immunity—the so-called Th2 shift; several factors influence this complex physiology and include long-term adaptations, reproductive hormones (i.e., overall, androgens suppress and estrogens stimulate immune responses), defects of the hypothalamic-pituitary-adrenal axis, histamine-generated responses, and acute versus chronic stress; thus stress seems to cause a Th2 shift systemically, whereas locally, under certain conditions, it can induce proinflammatory activities and by these mechanisms may influence onset or course of infections, autoimmune/inflammatory, allergic, and neoplastic diseases</td>
</tr>

<td>Possible synergism with estrogen in pregnancy?</td>
<td>May suppress maternal immune system to prevent rejection of fetus</td>
</tr>
</tbody>
</table>

Cortisol also affects protein metabolism. It has an anabolic effect by increasing the rate of protein synthesis and ribonucleic acid (RNA) in the liver. This is countered by its catabolic effect on protein stores in other tissues. Protein catabolism acts to increase levels of circulating amino acids; therefore chronic exposure to excess cortisol can severely deplete protein stores in muscle, bone, connective tissue, and skin.

Another important adaptive function of cortisol is to enhance immunity during acute stress. Cortisol exerts beneficial effects by inhibiting initial inflammatory effects, for example, vasodilation and increased capillary permeability. Cortisol also promotes resolution and repair. These actions are mainly accomplished by facilitating the effects of glucocorticoid receptor (GR), namely, the transcription of genetic material (through DNA binding) within leukocytes.

### Pathophysiologic Effects of Cortisol
Chronic dysregulation of the HPA axis, especially abnormal elevated levels of cortisol, has been linked to a wide variety of disorders, including obesity, sleep deprivation, lipid abnormalities, hypertension, diabetes, atherosclerosis, and loss of bone density. In the brain, chronic glucocorticoid secretion may reduce hippocampal volume, enlarge the ventricles, and modulate reversible cortical atrophy. These CNS changes may contribute to cognitive impairments and emotional disorders.

In the periphery, heightened stress-induced cortisol levels promote gastric secretion in the stomach and intestines, potentially causing gastric ulcers, which may account for the gastrointestinal ulceration observed by Selye. Furthermore, glucocorticoids contribute to the development of metabolic syndrome and the pathogenesis of obesity (see Health Alert: Glucocorticoids, Insulin, Inflammation, and Obesity) by directly causing insulin resistance and influencing genetic variations that predispose to obesity.

### Health Alert

**Glucocorticoids, Insulin, Inflammation, and Obesity**

The signs and symptoms of Cushing syndrome (e.g., excess glucocorticoids [GCs]) include truncal obesity, relatively thin extremities, a “moon face,” and a “buffalo neck” hump.” In such individuals the possibility of associated hypertension is high as well as increased risk of infection and metabolic syndrome or frank type 2 diabetes. In addition, the likelihood of an elevated ratio of intraabdominal subcutaneous fat mass to nonabdominal fat mass is high because the glucocorticoids mediate the redistribution of stored calories into the abdominal region. The specific increase in abdominal fat stores is a consequence of elevated levels of glucocorticoids combined with increased insulin action. However, the increased levels of glucocorticoids need not be present in the circulation; instead, they can be generated locally in fat by conversion of inactive cortisone to active cortisol through the action of the isoenzyme 11β-hydroxysteroid dehydrogenase (11β-HSD) type 1. This conversion is referred to as “pre-receptor” metabolism of cortisol. The active steroid is secreted directly to the liver through the portal vein. In vitro insulin synthesis and secretion from the pancreas are inhibited by the glucocorticoids. However, increasing levels of glucocorticoids in vivo are associated with increasing insulin secretion, possibly because of an anti-insulin effect on the liver, which appears to be vulnerable to the negative effects of glucocorticoids on insulin action. Hepatic insulin resistance is strongly associated
Recent data reveal that the plasma concentration of inflammatory mediators, such as tumor necrosis factor-alpha (TNF-α) and interleukin-6 (IL-6), is increased in the insulin-resistant states of obesity and type 2 diabetes. Two mechanisms might be involved in the pathogenesis of inflammation: (1) glucose and macronutrient intake (i.e., which can be mediated through chronic stress) causes oxidative stress; and (2) the increased concentrations of TNF-α and IL-6 associated with obesity and type 2 diabetes might interfere with insulin signal transduction. This interference might promote inflammation. Chronic overnutrition (obesity) might thus be a proinflammatory state with oxidative stress.

The impact of cortisol on fetal development and subsequent risk for future disease also has been investigated. Reynolds offers convincing data associating high maternal cortisol levels during pregnancy with low birth weight.\(^{43}\)
consequences of cortisol-induced low birth weight have now extended to disease risk in later life, for example, obesity; cardiovascular conditions, such as hypertension; and behavioral disorders attributed to altered brain structure.\textsuperscript{43-45} Thus, glucocorticoids dramatically affect human pathophysiology and, consequently, longevity.\textsuperscript{3,24,39}

The feedback mechanisms of the HPA axis sense and determine the circulating glucocorticoid levels, whereas other tissues passively accept the actions of circulating glucocorticoids.\textsuperscript{24} Thus, discrepancy in the glucocorticoid sensing network between the HPA axis and peripheral tissues could possibly produce peripheral tissue hypercortisolism or hypocortisolism. For example, both high HPA axis reactivity to stress and increased peripheral tissue sensitivity to glucocorticoids are associated with the severity of coronary artery disease (see \textit{Health Alert: Psychosocial Stress and Progression to Coronary Heart Disease}).\textsuperscript{46,47}

### Health Alert

**Psychosocial Stress and Progression to Coronary Heart Disease**

The link between stress and coronary heart disease was proposed as early as the 1970s; however, it was only recently that conclusive evidence and proposed mechanisms for development of the disease were identified. Much work continues to focus on elucidating the interaction between stress and cardiovascular disease.

One of the primary risk factors for coronary heart disease is hypertension. A new designation of prehypertension was recently created and found to be a good predictor for future cardiovascular events. Prehypertension is defined as a systolic blood pressure of 120 to 139 mm Hg or a diastolic blood pressure of 80 to 90 mm Hg. Individuals with prehypertension are much more likely to develop frank hypertension and, eventually, coronary heart disease.

Studies show that persons with a highly reactive personality type who experience high levels of anxiety with stress are much more likely to progress from prehypertension to hypertension and then to develop cardiac disease, specifically coronary heart disease, than those who have better coping abilities. Further long-term psychologic stress, such as that experienced in a strained marriage or an unhappy work environment, not only was shown to accelerate the progression of hypertension and coronary heart disease but also is correlated with higher mortality rates from coronary heart disease.

Trait anger, defined as a stable personality trait characterized by frequency, intensity, and duration of anger, also was shown to be a factor in the development
of coronary heart disease at higher rates than the general population. Individuals with trait anger also experienced more strokes. Hostile individuals with advanced cardiovascular disease may be particularly susceptible to stress-induced increases in sympathetic activity and inflammation.

One popular mechanism for the interaction between psychosocial stress and cardiovascular disease suggests that stress triggers an inflammatory response that, over time, increases the chances of developing coronary heart disease. The primary mechanisms proposed are chronically elevated cortisol levels and dysregulation of the circadian rhythm for cortisol release. Further, chronic stress alters hypothalamic-pituitary-adrenal (HPA) function, resulting in an abnormal stress response pattern. This alteration in HPA activity was found in persons with coronary heart disease along with increased inflammatory markers. A newer and emerging mechanism is the involvement of regulatory T cells (Tregs). Tregs play an important role in maintaining peripheral tolerance of tissue antigens, preventing autoimmune diseases, and decreasing chronic inflammatory diseases. Studies have shown that naturally occurring CD4+CD25+ Tregs are down-regulated in individuals with acute coronary syndrome (ACS). Additionally, the sympathetic nervous system plays an important role in immune homeostasis by maintaining the number of Tregs in the periphery and this may be affected by psychologic stress. The Treg lineage, however, is heterogenous.

Because coronary heart disease is one of the major causes of death in industrialized countries, development of successful interventional programs is of high priority. Programs in which dietary changes, exercise, stress management, and positive support systems are implemented continue to show positive results for slowing the progression of heart disease and decreasing the risk factors for disease development. Further, individuals in these programs report decreased levels of depression and stress as well as overall improvement in mental health.

Cortisol secretion during stress exerts beneficial effects by inhibiting initial inflammatory effects, for example, vasodilation and increased capillary permeability. Cortisol also promotes resolution and repair. These actions are
mainly accomplished by facilitating the effects of glucocorticoid receptor (GR), namely, the transcription of genetic material (through DNA binding) within leukocytes.\textsuperscript{38} Because glucocorticoids are so widely expressed, they influence virtually all immune cells. The adaptiveness or destructiveness of cortisol-induced effects may depend on the intensity, type, and duration of the stressor; the tissue involved; and the subsequent concentration and length of cortisol exposure. Finally, glucocorticoids have been shown to induce T-cell apoptosis.\textsuperscript{38,48}

**Effects of Exogenous Glucocorticoids**

Stress hormones, especially glucocorticoids (cortisol), are used therapeutically as powerful anti-inflammatory/immunosuppressive agents. The synthetic forms of glucocorticoid hormones (exogenous types of anti-inflammatory glucocorticoids administered for a pharmaceutical reaction) are poorly metabolized when compared with endogenous glucocorticoids, leading to a longer half-life and no circadian rhythm for these compounds. Moreover, these synthetic compounds bind with different targets, so each has a unique effect.\textsuperscript{49}

Elevated levels of glucocorticoids and catecholamines (epinephrine and norepinephrine), both endogenous and exogenously administered, may decrease innate immunity and increase autoimmune responses. In addition, prolonged effects of cortisol may accentuate inflammation and potentially increase neuronal death (e.g., in stroke victims)\textsuperscript{49} and induce T-cell apoptosis.\textsuperscript{38,48}

Initially, immune responses are regulated by cells of innate immunity called antigen-presenting cells (APCs), such as monocytes/macrophages (see Chapter 7), dendritic cells, and other phagocytic cells, and by Th1 and Th2 lymphocytes (cells involved in adaptive immunity; see Chapter 7). These cells secrete cytokines, the chemical messengers that regulate innate and adaptive immune responses. Antigen-presenting cells also release cytokines that induce T cells to differentiate into Th1 cells. Th1 cells and APC cytokines work together to stimulate the activity of cytotoxic T cells, natural killer (NK) cells, and activated macrophages—the major components of innate immunity (see Chapter 6).

Cytokines secreted by Th2 cells also act to inhibit Th1 cells and can promote adaptive immunity by stimulating growth and activating mast cells and eosinophils, as well as the differentiation of B-cell immunoglobulins. Thus, these cytokines are considered to be the major anti-inflammatory cytokines (Figure 9-5).\textsuperscript{25} The decrease in Th1 activity and increase in Th2 activity is sometimes called a **Th1 to Th2 shift**.
Stress interactions are nonlinear and complex. Nonlinearity means that when one mediator is increased or decreased, the subsequent compensatory changes in other mediators depend on time and level of change, causing multiple interacting variables. The inevitable consequences from adapting to daily life over time include changes in behavioral responses. For example, these changes include sleeping patterns, smoking, alcohol consumption, physical activity, and social interactions. These behavioral patterns are a part of the allostatic overload with chronic elevations in cortisol level, sympathetic activity, and levels of proinflammatory cytokines, and a decrease in parasympathetic activity. (From McEwen BS: Eur J Pharmacol 503[2-3]:174-185, 2008.)

**Neuroendocrine Regulation: Autonomic Nervous System**

**Sympathetic Nervous System**

The sympathetic nervous system is aroused, simultaneously with the HPA system during stress, to release norepinephrine (adrenergic stimulation) and stimulate the medulla of the adrenal gland to release catecholamines (80% epinephrine and 20%
norepinephrine) into the bloodstream. Sympathetic nerves also contain nonadrenergic mediators that amplify or antagonize the effects of adrenal catecholamines.

Circulating catecholamines essentially mimic direct sympathetic stimulation. Catecholamines cannot cross the blood-brain barrier and are synthesized locally in the brain. The physiologic effects of the catecholamines on organs and tissues are summarized in Table 9-3. Norepinephrine regulates blood pressure, promotes arousal, and increases vigilance, anxiety, and other protective emotional responses.

The catecholamines stimulate two major classes of receptors: α-adrenergic receptors (α₁ and α₂) and β-adrenergic receptors (β₁ and β₂). Table 13-7 summarizes the actions of the two subclasses of adrenergic receptors. (A discussion of receptors can be found in Chapters 1, 18, and 23.) Epinephrine binds with and activates both α and β receptors whereas norepinephrine binds primarily with α receptors.

Epinephrine in the liver and skeletal muscles is rapidly metabolized. Epinephrine influences cardiac action by enhancing myocardial contractility (inotropic effect), increasing heart rate (chronotropic effect), and increasing venous return to the heart, ultimately increasing both cardiac output and blood pressure. Epinephrine
dilates blood vessels supplying skeletal muscles, allowing for greater oxygenation. Metabolically, it causes transient hyperglycemia (high blood sugar), reduces glucose uptake in the muscles and other organs, and decreases insulin release from the pancreas, thus preventing glucose uptake by peripheral tissue and preserving it for the CNS. Epinephrine also mobilizes free fatty acids and cholesterol.

Catecholamine secretion also increases proinflammatory cytokine production, which elevates heart rate and blood pressure and impairs wound healing. Recent research further indicates that chronic stress-induced increases in norepinephrine levels ultimately result in increased production of inflammatory leukocytes that adhere to vessel walls and promote the development of plaque. Proteases released from these inflammatory leukocytes further promote risk of myocardial infarction and stroke by weakening the fibrous cap of the plaque, which can promote plaque rupture. In addition to a stress-induced increased risk of cardiovascular disease, the effects of stress on inflammatory cytokine secretion also influence depression, autoimmune disorders, and virally-mediated cancers, and may be important in functional decline that leads to frailty, disability, and untimely death. Finally, stress-induced excessive levels of inflammatory cytokines during infection or inflammatory illness may activate a collection of nonspecific symptoms called the “sickness syndrome.”

**Parasympathetic Nervous System**

The parasympathetic system balances the sympathetic nervous system and thus also influences adaptation or maladaptation to stressful events. The parasympathetic system generally opposes the sympathetic system; for example, the parasympathetic nervous system slows the heart rate. The parasympathetic system also has anti-inflammatory effects. Under conditions of allostatic overload, the parasympathetic system may decrease its containment of the sympathetic system, resulting in increased or prolonged inflammatory responses. Researchers evaluate the relative balance of the parasympathetic and sympathetic nervous systems using a technique known as heart rate variability (the measurement of R wave variability from heartbeat to heartbeat).

**Histamine and Other Hormones**

The immune system is integrated with other physiologic processes and is sensitive to changes in CNS and endocrine functioning, such as those that accompany psychologic states. Stressors can elicit the stress response through the action of the nervous and endocrine systems, specifically CRH from the hypothalamus and from peripheral inflammatory sites (called peripheral or immune CRH).
Peripheral (immune) CRH is proinflammatory, causing an increase in vasodilation and vascular permeability. Therefore it appears that mast cells are the target of peripheral CRH. Mast cells release histamine, which is a well-known mediator of acute inflammation and allergic reactions (Figure 9-6). Histamine induces acute inflammation and allergic reactions while suppressing Th1 activity (decreasing innate immunity) and promoting Th2 activity (increasing adaptive immunity).

![Figure 9-6](image)

**FIGURE 9-6** Effect of Corticotropin-Releasing Hormone (CRH)—Mast Cell—Histamine Axis, Cortisol, and Catecholamines on the Th1/Th2 Balance—Innate and Adaptive Immunity. Adaptive immunity provides protection against multicellular parasites, extracellular bacteria, some viruses, soluble toxins, and allergens. Innate immunity provides protection against intracellular bacteria, fungi, protozoa, and several viruses. Type 1 cytokines or proinflammatory cytokines include IL-12, interferon-gamma (IFN-γ), and tumor necrosis factor-alpha (TNF-α). Type 2 cytokines or anti-inflammatory cytokines include IL-10 and IL-4. Solid lines (black) represent stimulation, whereas dashed lines (blue) represent inhibition (i.e., Th1 and Th2 are mutually inhibitory; IL-12 and IFN-γ inhibit Th2, and vice versa; IL-4 and IL-10 inhibit Th1 responses).

Stress and CRH modulate inflammatory/immune and allergic responses by stimulating cortisol (glucocorticoid), catecholamines, and peripheral (immune) CRH secretion and by changing the production of regulatory cytokines and histamines. CRH (peripheral, immune), corticotropin-releasing hormone; IL, interleukin; NE, norepinephrine; Tc, cytotoxic T cell; Th, helper T cell; NK, natural killer cell; dashed lines, decreased (inhibited); solid lines, increased (stimulation). (Redrawn from Elenkov IJ, Chrousos GP: Trends Endocrinol Metab 10(9):359-368, 1999.)

Thyroid hormone synthesis, which is involved in growth and reproduction, is suppressed during stress, which may conserve energy. Neuropeptide Y (NPY), a sympathetic neurotransmitter, has recently been shown to be a stress mediator. Because NPY is a growth factor for many cells, it is implicated in atherosclerosis
and tissue remodeling. Other hormones that influence the stress response are listed in Table 9-4.

²Rabin BS: The nervous system—immune system connection. In Stress, immune function, and health: the
Locally, stress can exert proinflammatory or anti-inflammatory effects. Moreover, some evidence indicates that stress is not a uniform, nonspecific reaction. Different types of stressors might have variable effects on the immune response. Thus, stress may systemically cause a decrease in innate immunity and enhance adaptive immunity, whereas locally, under certain conditions, it can induce proinflammatory activities that may influence the onset and cause of infection, autoimmune/inflammatory, and allergic responses. In summary, stress can activate an excessive immune response and, through cortisol and the catecholamines, suppress Th1 responses while enhancing Th2 responses.

**Role of the Immune System**

The immune, nervous, and endocrine systems communicate through similar (and highly complex) pathways using hormones, neurotransmitters, neuropeptides, and immune cell products. Various components of immune system responses are affected by neuroendocrine-produced factors involved in the stress reaction. Conversely, immune cell–derived cytokines and other products affect neurocrine and endocrine cells. Several pathways regulate communication among these systems (Figure 9-7).
Stress-induced secretion of HPA hormones and catecholamines of the ANS sympathetic branch directly influences the immune system. Immune cells have receptors for ACTH, CRH, endorphins, norepinephrine, growth hormone, steroids, and other products of the stress response. In addition, cholinergic, adrenergic, and peptidergic nerves innervate lymphoid organs, such as the thymus, spleen, lymph nodes, and bone marrow. Exposure to stress increases endogenous opiate secretion to enhance or suppress immune cell functions in a concentration-dependent manner (see Table 9-4).

Lymphocytes also produce ACTH and endorphins in small amounts that influence the immune response in an autocrine (same cell stimulation) or paracrine (cell to cell) manner in ongoing immune and memory cytotoxic responses. The T-cell growth factor interleukin-2 (IL-2) can up-regulate pituitary ACTH. Immune-derived cytokines have direct and indirect effects on HPA and adrenal cell functions. Thus, the immune system has an adaptive role as a signal organ to alert other systems of internally threatening stimuli (e.g., infection, tissue damage, tumor cells). The release of immune inflammatory mediators (IL-6, tumor necrosis factor-beta [TNF-β], interferon) is triggered by bacterial or viral infections, cancer, tissue injury, and other stressors that in turn initiate a stress response through the HPA pathway. Enhanced systemic production of these cytokines also induces other CNS and
behavior changes during an acute infectious episode.\textsuperscript{72-75}

Although acute stress activates HPA hormone secretion and immune system products, such as interleukin-1 (IL-1), continued stress-induced secretion of glucocorticoids (GCs) inhibits production of IL-1 by activated macrophages and monocytes.\textsuperscript{64,76} Prolonged severe stress may lead to enlargement of the adrenal gland with simultaneous involution of the thymus and lymph nodes. Increased secretion of GCs may be an important mechanism underlying stress-related immune structure alterations and suppression of the immune response.\textsuperscript{55}

In addition to the HPA and sympathetic nervous system, the pineal gland regulates the immune response and mediates the effects of circadian rhythm on immunity. When melatonin production by the pineal gland is blocked (by continuous light or by pharmacologic means), the immune response is suppressed, whereas administration of melatonin reverses these effects.\textsuperscript{77} This immunomodulation pathway may effect immune changes found with sleep disturbance and dysregulated circadian rhythm,\textsuperscript{78} which are common among acutely ill, stressed persons.

In summary, neuropeptides and hormones have significant effects on the immune system. Whether this impact on immune system functions is suppressive or potentiating depends on the type of factor secreted (some factors enhance, some suppress, and some both enhance and suppress), the concentration and length of exposure, and the target cell.\textsuperscript{75} Neuropeptides and neuroendocrine hormones may directly control biochemical events affecting cell proliferation, differentiation, and function or may indirectly control immune cell behavior by affecting the production or activity of cytokines.\textsuperscript{64,65} Chronic stress affects many immune cell functions, including decreased natural killer cell and T-cell cytotoxicity and impaired B-cell function.\textsuperscript{33,71} Importantly, these impairments in the immune system may have negative health consequences for stressed individuals, such as increased risk of infection and some types of cancer.\textsuperscript{79,80} Common pathophysiologic origins relating to chronic inflammatory processes include cardiovascular disease, osteoporosis, arthritis, type 2 diabetes mellitus, chronic obstructive pulmonary disease (COPD), other diseases associated with aging, and some cancers; all are characterized by the prolonged presence of proinflammatory cytokines.\textsuperscript{15,81}

It is important to note that although inflammation is a normal response and considered beneficial, excessive inflammation can damage tissue. Stress and negative emotions are associated directly with the production of increased levels of proinflammatory cytokines, providing a link between stress, immune function, and disease.\textsuperscript{82-84}
Stress, Personality, Coping, and Illness

Extreme physiologic stressors, such as severe burn injury, represent a predictable stimulus for stress responses. A less severe and defined event or situation, however, can be a stressor for one person and not for another. As discussed previously, stress itself is not an independent entity but a system of interdependent processes moderated by the nature, intensity, and duration of the stressor and the perception, appraisal, and coping efficacy of the affected individual, all of which in turn mediate the psychologic and physiologic response to stress. Further, adjustment to repetitive stressors is known to be individualized, based on a person's appraisal of a situation.\(^3,29\) Illustrating the influence of an individualized stress appraisal on physiologic processes, a meta-analysis of the relationship between stressors and immunity found that a higher perception of stress was associated with reduced Tc-cell cytotoxicity, although not with levels of circulating T-helper or Tc lymphocytes.

Psychosocial distress may be predictive of psychologic, social, and physical health outcomes (see Health Alert: Acute Emotional Stress and Adverse Heart Effects). A psychologically distressed individual may experience a general stress-induced state of unpleasant arousal that manifests as physiologic, emotional, cognitive, and behavior changes.\(^85\) Periods of depression and emotional upheaval associated with adverse life events may place the affected individual at increased risk for immunologic deficits accompanied by ill health.\(^55\) For example, studies showed a relationship between depression and reduction in lymphocyte proliferation and NK-cell activity.\(^86\) Multiple moderating factors may be important in immune modulation in depressed individuals, including alcoholism and other lifestyle factors, such as social support. Examples of triggering circumstances include bereavement, academic pressures, and marital conflict. Aging also may increase psychosocial distress and is associated with immune changes (see Health Alert: Partner's Survival and Spouse's Hospitalizations and/or Death).\(^81,82\)

Health Alert

Acute Emotional Stress and Adverse Heart Effects

Myocardial Ischemia

- Individuals with coronary heart disease may develop myocardial ischemia during mental or acute emotional stress even though their exercise or chemical nuclear test results are negative.
• Systemic vascular resistance increases during periods of mental or acute emotional stress with concomitant increased myocardial oxygen demand.

Left Ventricular Dysfunction

• More evidence for left ventricular dysfunction exists in older women.

• After acute emotional stress or trauma, there is an increase in sudden chest pain and shortness of breath.

• Left ventricular dysfunction is more common in the cardiac apex.

• Alterations are possibly a result of increased levels of catecholamines.

Ventricular Dysrhythmias

• Intense or unusual acute stress precipitates about 20% of serious ventricular dysrhythmias or sudden cardiac death.

• Altered brain activity may lead to changes in ventricular repolarization and electrical instability of the cardiac muscle.

Health Alert

Partner's Survival and Spouse's Hospitalizations and/or Death

A Harvard study shows that a spouse's chances of dying increase not only when the partner dies but also when that partner becomes seriously ill. The 9-year follow-up study consisted of 518,240 elderly couples. Mortality after the partner's hospitalization varied according to the spouse's diagnosis. For elderly people whose spouse had been hospitalized, the short-term risk of dying approaches that of an elderly person after his or her spouse's death. A wife's hospitalization increased her husband's chances of dying within 1 month by 35%; a husband's hospitalization increased his wife's chances of dying by 44%. Likewise, a wife's death increased her partner's 1-month mortality risk by 53%, and a husband's death raised his partner's risk by 61%. The researchers commented that a spouse's illness or death
can increase a partner's mortality by causing severe stress and removing a primary source of emotional, psychologic, practical, and financial support.

Personality characteristics are associated with differences in appraisal and response to stressors. Specific personality characteristics, such as academic achievement, motivation, optimism, and aggression, are correlated with immunologic alterations. For example, aggression is positively associated with changes in T- and B-cell numbers in male military personnel. In addition, optimism, perceived stress, and anxiety enhance responses to influenza vaccinations after age 50.69,87

Stressful life events and mood are important factors that exacerbate symptoms in acquired immunodeficiency syndrome (AIDS) infection, diabetes, and multiple sclerosis.65,88,89 In addition, the interaction with healthcare providers in a clinical setting, the diagnosis of a major illness, and the process of undergoing various clinical procedures (e.g., blood sampling, injections, examinations, surgical procedures) may represent significant negative life events to many individuals (Figure 9-8). These additional stresses may interfere with the efficacy of the medical intervention. Identifying and reducing stress in the clinical setting have particular applicability for both preventing disease and managing illness.
Many studies have linked severe psychosocial stress resulting from negative life events to chronic disorders with mental and physical consequences. A life-threatening event may lead to the development of posttraumatic stress disorder (PTSD). Early research with breast cancer survivors demonstrated a link between sympathetic activity and HPA axis activation, noting that some women reported symptoms of PTSD (heart palpitations, panic, shakiness, nausea) when they thought about cancer recurrence or when they found themselves near the hospital where treatment began. Furthermore, the threat of cancer recurrence (using a simulated mammography event as a stressor to elicit thoughts of cancer recurrence) elicited greater alterations in heart rate variability when compared with another simulated controlled stressor. These studies show a connection between reexposure to mammography, which occurred repeatedly throughout breast cancer survivorship, and activation of the autonomic nervous system.

These uncontrolled stressful events may negatively affect the course of illness and interfere with the efficacy of the medical intervention. Identifying and reducing stress in the clinical setting have particular applicability in both disease prevention and illness management. In addition to medical procedures, patient-provider communication provides an important area for future research. Recent studies of cancer communication and patient-provider interaction indicate a link between
communication events and emotional outcomes, such as uncertainty and mood state in breast cancer survivors.⁹⁶,⁹⁷

**Coping**

*Coping* is the process of managing stressful challenges that tax the individual's resources.⁶⁸ Coping responses may be adaptive or maladaptive and the extent to which an individual responds to distress, using effective positive coping strategies, determines the degree of successful moderation of the stress challenge. For example, studies are beginning to support a role for stress reduction in slowing human immunodeficiency virus (HIV) progression.⁴³,⁴⁷,⁵²,⁹⁸ Other investigations are underway to determine the benefits offered by exercise and mindfulness, as well as others such as inclusion of green space in urban environments.³² Studies also are focusing on mediating factors that influence stress susceptibility or resilience, such as age, socioeconomic status, gender, social support, religious or spiritual factors, personality, self-esteem, genetics, past experiences, and current health status (Figure 9-9).³⁹,⁹⁹,¹⁰⁰
FIGURE 9-9  Staying on the Good Side of the Stress Spectrum. GOOD stress is shown on the left of the spectrum and involves a rapid biologic response to the stressor, followed by a rapid shutdown of the response upon cessation of the stressor. These responses support physiologic conditions that are likely to enhance protective immunity, cognitive and physical performance, and overall health. BAD stress, represented on the right of the spectrum, involves exposure to chronic or long-term biologic changes that are likely to result in dysregulation or suppression of immune function, a decrease in cognitive and physical performance, and an increased likelihood of disease. Short- and/or long-term stress is generally superimposed on a psychophyslogic RESTING ZONE of low/no stress that also represents a state of health maintenance/ restoration. To maintain health, one needs to optimize GOOD stress, maximize the RESTING ZONE, and minimize BAD stress. Achieving psychologic and physiologic resilience involves a multi-pronged approach. Sleep of a quality and duration that helps one feel rested in the morning, a moderate and healthy diet, and consistent and moderate exercise or physical activity are three LIFESTYLE FACTORS that are likely to enable one to stay on the “good” side of the stress spectrum. Effective appraisal and coping mechanisms, genuine gratitude, social support, and compassion toward others and oneself are likely to maintain PSYCHOSOCIAL BUFFERS against bad stress and enable one to stay on the “good” side of the stress spectrum. Additionally, depending on individual preferences, ACTIVITIES, such as, meditation, yoga, being in nature, exercise/physical activity, music, art, craft, dance, fishing, painting, also may reduce BAD stress, extend The RESTING ZONE, and optimize GOOD stress. Such personal activities are likely to involve different strokes for different folks and need not always be meditative or reflective in nature.  (Adapted from Dhabhar FS, McEwen BS. Bidirectional effects of stress on immune function: possible explanations for salubrious as well as harmful effects. In Ader R, editor. Psychoneuroimmunology IV, San Diego, 2007, Elsevier.)
Coping strategies are especially beneficial when they are problem-focused and individuals seek social support. Evidence suggests that effective interventions may result in greater stress resilience and improved psychologic and physiologic outcomes. For example, women with recurrent metastatic breast cancer and provided weekly group counseling in conjunction with routine medical treatment lived an average of 19 months longer than control subjects, suggesting a positive influence of group support for these women.

Maladaptive coping can result in a change in behavior contributing to potentially adverse health effects (e.g., increased smoking, change in eating habits). Serious disturbances of the sleep-wake cycle observed in many stressed people and in experimental and many clinical settings may exacerbate the pathophysiologic status of some individuals. Sleep deprivation and circadian disruption, even in young otherwise healthy individuals, have detrimental influences on respiratory and immune system function. Even partial sleep deprivation was associated with reduced NK-cell activity in healthy subjects, and only recently have seriously ill individuals been assessed for adequacy and structure of sleep during recovery.

Behavioral styles, such as overcommitment to employment-related tasks, repression, denial, escape-avoidance, and concealment, are associated with altered immune functions. Repression is associated with lower monocyte counts, higher eosinophil counts, higher serum glucose levels, and more self-reported medication reactions in medical outpatients, and with higher Epstein-Barr virus (EBV) antibody titers in students. A prospective long-term study also found increased markers of accelerated human immunodeficiency virus (HIV) infection in gay men who concealed their homosexual identity. School teachers who devoted long hours without reward and who were unable to disengage from work-related tasks were found to have lowered innate immune responses.

The importance of social support for seriously ill individuals also has focused attention on the health of caregivers. Significant stress manifested as depression, anxiety, and fatigue has been noted in family caregivers of those with cancer, Alzheimer disease, and burn trauma. Enhanced social support of caregivers improves measures of immune function.

Interventions to potentially prevent or manage stress-related psychologic or physical problems include both short- and long-term education on evaluating and adopting effective coping strategies. Approaches may be used or investigated on an individual or group basis. Incorporation of effective stress management approaches into clinical education facilitates their use in the clinical arena. Future research could focus on the efficacy of such approaches with different populations because it is clear one size does not fit all (coping of cancer survivors may be vastly different from coping of combat veterans).
In summary, the mind and body are connected through a multitude of complex physical and emotional interactions. Understanding the complexity of these interactions is a challenge for researchers. Areas of promise include investigating relationships between the effects of stress on illness, as well as developing effective stress management techniques and approaches that improve health outcomes.

**Geriatric Considerations**

**Aging & the Stress-Age Syndrome**

With aging, sometimes a set of neurohormonal and immune alterations, as well as tissue and cellular changes, develops. These changes have been defined as stress-age syndrome and include the following:

- Alterations in the excitability of structures of the limbic system and hypothalamus
- Increase of the blood concentrations of catecholamines, ADH, ACTH, and cortisol
- Decrease of the concentrations of testosterone, thyroxine, and others
- Alterations of opioid peptides
- Immunodepression and pattern of chronic inflammation
- Alterations in lipoproteins
- Hypercoagulation of the blood
- Free radical damage of cells

Some of the alterations are adaptational, whereas others are potentially damaging. These stress-related alterations of aging can influence the course of developing stress reactions and lower adaptive reserve and coping capacity.

*ACTH*, Adrenocorticotropic hormone; *ADH*, antidiuretic hormone.

**Quick Check 9-2**

1. Define the HPA axis.
2. Define psychoneuroimmunology.

3. How does the immune system participate in stress-related diseases?

4. Why do stress-related diseases occur?

5. What intervention or prevention activities reduce stress-related diseases?
Did You Understand?

Concepts of Stress

1. Stress is broadly defined as a threat that is perceived or anticipated, resulting in interactions between the body and the brain (the stress response).

2. Originally proposed by Cannon in 1914, the idea that stressful events could cause physiologic responses was further developed by Selye in 1946. Selye's work demonstrated that internal or external stressors could result in adrenal gland enlargement, immune alterations (increased leukocytes), and gastrointestinal manifestations (ulcers). These global physiologic responses were labeled the General Adaptation Syndrome (GAS).

3. The GAS occurs in three stages: the alarm stage; the stage of resistance or adaptation; and the stage of exhaustion, which is now referred to as allostatic overload. Diseases of adaptation develop if the stage of resistance or adaptation does not restore homeostasis. Although important, this approach is now thought to be greatly oversimplified.

4. Continuing the evolution of this research, adrenal gland hormone responses to stressors were suggested in the 1950s and CNS and endocrine responses were proposed in the 1970s. The study of the body's response to stressors continues to evolve and has become known by the term Psychoneuroimmunology (PNI).

5. Psychologic stressors can be anticipatory and triggered by expectations of an upcoming stressor or can be reactive to a stressor. Both of these psychologic stressors are capable of eliciting a physiologic stress response.

The Stress Response

1. The concepts of allostasis (stability through change; monitoring the environment for adaptive response) and homeostasis (return to base levels reflecting an unchanging set point) both indicate physiologic responses. Allostatic overload can occur when there is overactivation of adaptive responses that may in turn increase susceptibility to disease.

2. The stress response involves the nervous system (sympathetic branch of the autonomic nervous system), the endocrine system (pituitary and adrenal glands),
and the immune system. More simply, these relationships are often cited together as the hypothalamic-pituitary-adrenal (HPA) axis.

3. The stress response is initiated when a stressor is present in the body or perceived by the mind. Psychologic stress may cause or worsen several diseases or disorders including anxiety, depression, insomnia, chronic pain and fatigue syndromes, obesity, metabolic syndrome, essential hypertension, type 2 diabetes, atherosclerosis and its cardiovascular consequences, osteoporosis, and autoimmune inflammatory and allergic disorders. A classic example of stress and allostatic overload is sleep alteration and the associated damaging effects of elevated evening cortisol, insulin, and glucose.

4. The physiology of managing stressful events is complex, involving mechanisms of both protection and injury. The two major stress systems include the autonomic and hypothalamic-pituitary-adrenal (HPA) system.

5. Activation of the autonomic nervous system consists of sympathetic stimulation of the adrenal medulla and nerve endings to rapidly secrete catecholamines (norepinephrine, epinephrine, neuropeptide Y).

6. Activation of the HPA system involves sequential secretion of corticotropin-releasing hormone from the hypothalamus, which stimulates receptors in the anterior pituitary to secrete ACTH that, in turn, stimulates the adrenal cortex to secrete glucocorticoids, particularly cortisol.

7. Chronic dysregulation of the HPA axis, especially abnormal elevated levels of cortisol, has been linked to a wide variety of disorders, including obesity, sleep deprivation, lipid abnormalities, hypertension, diabetes, atherosclerosis, and loss of bone density.

8. Glucocorticoids from the adrenal cortex, in response to ACTH from the pituitary gland, comprise the major stress hormones along with the catecholamines epinephrine and norepinephrine.

9. In general, catecholamines of the sympathetic system prepare the body to act; for example, cortisol mobilizes glucose (for energy) and other substances. The parasympathetic system balances or restrains the sympathetic system, resulting in slowed heart rates, and anti-inflammatory effects. During prolonged stress (allostatic overload) the parasympathetic system is less effective in opposing the sympathetic system.
10. Epinephrine exerts its chief effects on the cardiovascular system. Epinephrine increases cardiac output and increases blood flow to the heart, brain, and skeletal muscles by dilating vessels that supply these organs. It also dilates the airways, thereby increasing delivery of oxygen to the bloodstream.

11. Norepinephrine's chief effects complement those of epinephrine. Norepinephrine constricts blood vessels of the viscera and skin; this has the effect of shifting blood flow to the vessels dilated by epinephrine. Norepinephrine also increases mental alertness.

12. Glucocorticoids reach all tissues, including the brain, easily penetrate cell membranes, and react with numerous intracellular glucocorticoid receptors. Because they spare almost no tissue or organ and influence a large proportion of the human genome, they broadly exert diverse biologic actions. For example, glucocorticoids have an important modulatory role in the CNS. These hormones regulate memory, cognition, mood, and sleep and influence many other body systems.

13. Cortisol is the primary glucocorticoid produced during stress.

14. Cortisol's chief effects involve metabolic processes. By inhibiting the use of metabolic substances while promoting their formation, cortisol mobilizes glucose, amino acids, lipids, and fatty acids and delivers them to the bloodstream. As an example, anabolic effects of cortisol increase the rate of protein synthesis in the liver, whereas the catabolic effects of cortisol increase levels of amino acids, ultimately depleting protein stores in muscle, bone, skin, and connective tissue.

15. Cortisol contributes to elevated blood glucose and inhibits glucose uptake by body cells providing energy to combat perceived or anticipated stressors.

16. Glucocorticoids contribute to the development of metabolic syndrome and the pathogenesis of obesity. They can directly cause insulin resistance and influence genetic variations that predispose to obesity.

17. Elevated levels of glucocorticoids and catecholamines (epinephrine and norepinephrine), both endogenous and exogenous (synthetic pharmaceuticals), may decrease innate immunity and increase autoimmune responses. However, prolonged effects of cortisol may accentuate inflammation. Overall, stress activates an excessive immune response and, through cortisol and the catecholamines, suppresses Th1 responses while enhancing Th2 responses.
18. The impact of cortisol on fetal development and subsequent risk of future disease is being considered.

19. Other hormones, including β-endorphins, growth hormone, prolactin, oxytocin, the steroid sex hormones, and antidiuretic hormone, influence the stress response by their diverse actions.

**Stress, Personality, Coping, and Illness**

1. Stress is a system of interdependent processes that are moderated by the nature, intensity, and duration of the stressor and the coping efficacy of the affected individual, all of which in turn mediate the psychologic and physiologic response to stress.

2. Personality characteristics are associated with individual differences in appraisal and response to stressors. Further, the appraisal of events as distressful may be predictive of psychological, social, and physical health outcomes (maladaptive coping, depression, PTSD, heart disease, altered immunity).

3. Coping styles associated with altered immunity include repression, denial, escape-avoidance, and concealment. Coping strategies are more beneficial when they are problem-focused and may result in improved resilience and better psychological and physiologic outcomes.

**Geriatric Considerations: Aging & the Stress-Age Syndrome**

1. With aging, often a set of neurohormonal and immune alterations, including tissue and cellular changes, occur. These changes are collectively called stress-age syndromes.

2. The changes are numerous, with some being adaptive whereas others are potentially damaging.

3. Coping techniques for managing stress may mitigate the effects of stress on maladaptive behaviors such as excessive alcohol ingestion and smoking, and by extension impact the effects of existing chronic illness.

Cancer is a leading cause of suffering and death in the developed world. Over the past 35 years, intensive research has led to a significantly enhanced understanding of this complex and frightening disease. We now understand that cancer is a collection of more than 100 different diseases, each caused by a specific and often unique age-related accumulation of genetic and epigenetic alterations. Environment, heredity, and behavior interact to modify the risk of developing cancer and the response to treatment. Improvements in treatment strategies and supportive care, coupled with new, often individualized therapies based on advances in our fundamental understanding of the basic pathophysiology of malignancy, have contributed to an increasing number of effective options for these diverse, often
lethal, disorders collectively called cancer.
Cancer Terminology and Characteristics

Any discussion of cancer must start with a definition of what it is and what it is not. Although most readers may have an intuitive understanding of this disorder, composing an exact definition that encompasses this broad category is more challenging. The National Cancer Institute (NCI) of the National Institutes of Health (NIH) defines cancer as “diseases in which abnormal cells divide without control and are able to invade other tissues.”

The term **cancer** comes from the Latin translation of the Greek word for crab, *karkinoma*, which the physician Hippocrates used to describe the appendage-like projections extending from tumors into adjacent tissue. The word **tumor** originally referred to any swelling that is caused by inflammation but is now generally reserved for describing a new growth, or **neoplasm**.

Tumor Classification and Nomenclature

The careful evaluation of each cancer is important for many reasons. Different cancers will have different causes, different rates and patterns of progression, and different responses to treatment. The classification starts with knowing the tissue and organ of origin, the extent of distribution to other sites, and the microscopic appearance of the lesion. Increasingly, it also includes a detailed description of the critical genetic changes in the cancer.

Benign and Malignant

Not all tumors or neoplasms, however, are cancer; they can be benign or malignant (cancerous). **Benign tumors** are usually encapsulated with connective tissue and contain fairly well-differentiated cells and well-organized **stroma** (Figure 10-1). They retain recognizable normal tissue structure and do not invade beyond their capsule, nor do they spread to regional lymph nodes or distant locations. Mitotic cells are very rarely present during microscopic analysis. Benign tumors are generally named according to the tissues from which they arise with the suffix “-oma,” which indicates a tumor or mass. For example, a benign tumor of the smooth muscle of the uterus is a **leiomyoma**, and a benign tumor of fat cells is a **lipoma**. It is important to understand that benign tumors can become extremely large and, depending on their location in the body, can cause morbidity or be life-threatening. For example, a benign meningioma at the base of the skull may cause symptoms by compressing adjacent normal brain tissue.
Some tumors initially described as benign can progress to cancer and then are referred to as **malignant tumors**, which are distinguished from benign tumors by more rapid growth rates and specific microscopic alterations, including loss of differentiation and absence of normal tissue organization (Figure 10-2). One of the microscopic hallmarks of cancer cells is **anaplasia**, the loss of cellular differentiation. Malignant cells are also **pleomorphic**, with marked variability of size and shape. They often have large darkly stained nuclei and mitotic cells are common. Malignant tumors may have a substantial amount of stroma, but it is disorganized, with loss of normal tissue structure. Malignant tumors lack a capsule and grow to invade nearby blood vessels, lymphatics, and surrounding structures. The most important and most deadly characteristic of malignant tumors is their ability to spread far beyond the tissue of origin, a process known as **metastasis**.
FIGURE 10-2  Loss of Cellular and Tissue Differentiation During the Development of Cancer. The cells of a benign neoplasm (B) resemble those of the normal colonic epithelium (A), in that they are columnar and have an orderly arrangement. Loss of some degree of differentiation is evident in that the neoplastic cells do not show much mucin vacuolization (large, clear cytoplasmic vacuoles in A). Cells of the well-differentiated malignant neoplasm (C) of the colon have a haphazard arrangement, and although gland lumina are formed they are architecturally abnormal and irregular. Nuclei vary in shape and size, especially when compared with those illustrated in (A). Cells in the poorly-differentiated malignant neoplasm (D) have an even more haphazard arrangement, with very poor formation of gland lumina. Nuclei show greater variation in shape and size compared with the well-differentiated malignant neoplasm (C). Cells in anaplastic malignant neoplasms (E) bear no relation to the normal epithelium, with no recognizable gland formation. Tremendous variation is found in the size of cells and their nuclei, with very intense staining (hyperchromatic nuclei). Not knowing the site of origin makes it impossible to classify this tumor by microscopic appearance alone. Well-differentiated tumors often resemble their cell of origin, as shown in the example of a benign tumor of smooth muscles (F). (From Stevens A, Lowe J: Pathology, ed 2, London, 2000, Mosby)

Unlike benign tumors, which are named related to the tissue of origin, cancers generally are named according to the cell type from which they originate. Cancers
arising in epithelial tissue are called **carcinomas**, and if they arise from or form ductal or glandular structures are named **adenocarcinomas**. Hence, a malignant tumor arising from breast glandular tissue is a mammary adenocarcinoma, whereas an example of a benign breast tumor is a fibroadenoma. Cancers arising from mesenchymal tissue (including connective tissue, muscle, and bone) usually have the suffix **sarcoma**. For example, malignant cancers of skeletal muscle are known as rhabdomyosarcomas. Cancers of lymphatic tissue are called **lymphomas**, whereas cancers of blood-forming cells are called **leukemias**. However, many cancers, such as Hodgkin disease and Ewing sarcoma, are named for historical reasons that do not follow this nomenclature convention.

**Carcinoma in Situ**

**Carcinoma in situ** (often abbreviated **CIS**) refers to preinvasive epithelial tumors of glandular or squamous cell origin. Cancers develop incrementally, as they accumulate specific genetic lesions. Careful surveillance for cancer often detects abnormal growths in epithelial tissues that have atypical cells and increased proliferation rate compared with normal surrounding tissues. These early-stage cancers are localized to the epithelium and have not penetrated the local basement membrane or invaded the surrounding stroma. Based on these characteristics, they are not malignant. **CIS** occurs in a number of sites, including the cervix, skin, oral cavity, esophagus, and bronchus. In glandular epithelium, in situ lesions occur in the stomach, endometrium, breast, and large bowel. In the breast, ductal carcinoma in situ (DCIS) fills the mammary ducts but has not progressed to local tissue invasion. DCIS lesions are readily treatable, although the optimal therapeutic approach is controversial. CIS lesions can have one of the following three fates: (1) they can remain stable for a long time, (2) they can progress to invasive and metastatic cancers, or (3) they can regress and disappear. CIS can vary from low-grade to high-grade dysplasia, with the high-grade lesions having the highest likelihood of becoming invasive cancers. The time that such preinvasive lesions remain in situ before becoming invasive is unknown. Some carcinomas of the cervix appear as preinvasive lesions in situ for several years before they progress to invasive carcinoma and metastatic tumors ([Figure 10-3](#)). Knowing how to best treat low-grade CIS lesions is challenging, because the proportion that progress to cancer versus the proportion that will never cause clinical problems is usually not known. Although most persons prefer removal of any CIS as opposed to “watchful waiting,” this topic continues to be a source of great debate.

[^Quick Check 10-1]
1. What is cancer?

2. Identify the major differences between benign and malignant tumors.

3. What is carcinoma in situ?

**FIGURE 10-3**  Progression from Normal to Neoplasm in the Uterine Cervix. A sequence of cellular and tissue changes progressing from low-grade to high-grade intraepithelial neoplasms (also called carcinoma in situ) and then to invasive cancer is seen often in the development of cancer. In this example of the early stages of cervical neoplastic changes, the presence of anaplastic cells and loss of normal tissue architecture signify the development of cancer. The high rate of cell division and the presence of local mutagens and inflammatory mediators all contribute to the accumulation of genetic abnormalities that lead to cancer. (From Alberts B et al: Molecular biology of the cell, ed 5, New York, 2008, Garland.)
The Biology of Cancer Cells

In two seminal publications, Drs. Douglas Hanahan and Robert Weinberg\textsuperscript{3,4} described what they considered the hallmarks of cancer. Both articles stimulated considerable discussion and, especially, debate. The original publication contained six hallmarks, but with time and new research findings, increased to eight hallmarks and two traits that enable cancer progression. Their analysis remains the leading overview of why a cell is malignant. The following discussion is organized in the context of those ten hallmarks/enablers (Figure 10-4). Two fundamental concepts are the foundation for understanding the biology of cancer. Cancer is a complex genetic disease, and the microenvironment of a tumor is a heterogeneous mixture of cells, both cancerous and benign. These concepts affect every stage of cancer development and evolve during that development. \textbf{Tumor initiation}, the process that produces the initial cancer cells, is dependent on specific mutations and characteristics of the microenvironment. \textbf{Tumor promotion}, the process during which the population of cancer cells expands with diversity of cancer cell phenotypes, is dependent on additional mutations and a changing tumor microenvironment. \textbf{Tumor progression}, the process leading to spread of the tumor to adjacent and distal sites (metastasis), is governed by further mutations and changing microenvironments at the primary tumor and at sites of metastasis.
Cancer is a disease of cumulative genetic changes during aging. The fraction of individuals who develop cancer increases dramatically with age. Genetic changes may occur by both mutational and epigenetic mechanisms. Mutation generally means an alteration in the DNA sequence affecting expression or function of a gene (Figure 10-5). Mutations include small-scale changes in DNA, such as point mutations; the alteration of one or a few nucleotide base pairs (see Chapter 2). This type of mutation can have profound effects on the activity of resultant proteins. Chromosome translocations are large changes in chromosome structure in which a piece of one chromosome is translocated to another chromosome. Gene amplification is the result of repeated duplication of a region of a chromosome, so that instead of the normal two copies of a gene, tens or even hundreds of copies are present. Gene expression also may be altered indirectly by epigenetic effects including DNA methylation, histone acetylation, or altered expression of non-coding RNA (see Chapter 3). Some mutations, referred to as driver mutations, “drive” the progression of cancer. There may be as many as 140 different driver mutations, although some are more critical than others, and each cancer only has a relatively small number of these. Not all mutations in cancer contribute to the malignant phenotype. Some are just random events and are referred to as passenger mutations; they are just along for the ride. After a critical number of driver mutations have occurred, the cell becomes cancerous. The cancer cell has a
selective advantage over its neighbors; its progeny can accumulate faster than its nonmutant neighbors. This is referred to as clonal proliferation or clonal expansion (Figure 10-6). As a clone with mutations proliferates, it may become an early-stage tumor, for example, a carcinoma in situ or a benign colonic polyp. The increasingly rapid cell division and impaired DNA repair mechanisms of cancer cells result in a continuing accumulation of mutations throughout the progression to the most aggressive metastatic lesion. Thus, transformation, the process by which a normal cell becomes a cancer cell, is directed by progressive accumulation of genetic changes that alter the basic nature of the cell and drive it to malignancy. The process of tumor development is a form of darwinian evolution; cells with a heritable change that confers a survival advantage out-compete their neighbors. Each cancer cell may develop its own set of mutations resulting in a genomically heterogeneous mixture of cells with subsets that have accumulated more and more mutations that increase the cell's malignant potential. Thus many cancer cells that do not accumulate a critical set of mutations lose the competition and die during this process.
FIGURE 10-5 Oncogene Activation Mechanisms. Cellular genes may become cancerous oncogenes as a result of (A) point mutations that alter one or a few nucleotide base pairs, causing the production of a protein that is activated as a result of the altered sequence (e.g., RAS); (B) amplification of the cellular gene, resulting in higher levels of protein expression (e.g., MYCN in neuroblastoma); or (C) chromosomal translocations that either (1) lead to the juxtaposition of a strong promoter, causing increased protein expression (MYC in Burkitt lymphoma), or (2) produce a novel fusion protein that is derived from gene fragments normally present on different chromosomes (BCR-ABL in chronic myeloid leukemia). (From Haber DA. Molecular genetics of cancer. In ACP medicine, Danbury Conn, 2004, WebMD.)
The processes occurring during the development of cancer are, in many ways, analogous to wound healing. The initial proliferation of cancer cells and enlargement of the tumor elicit the synthesis of pro-inflammatory mediators by the cancer cells and adjacent nonmalignant cells. As with wound healing, mediators recruit inflammatory/immune cells (primarily T lymphocytes and macrophages, but also B cells and neutrophils) and cells normally associated with tissue repair (fibroblasts, adipocytes, mesenchymal stem cells, endothelial cells, and pericytes). These cells form the stroma (tumor microenvironment) that surrounds and infiltrates the tumor (Figure 10-7). In some conditions, stromal cells may make up 90% of the tumor mass. Extensive paracrine signaling among the stromal and cancer cells affects both populations; cancer cells increase proliferation and become more heterogeneous during tumor growth, and several populations of stromal cells undergo evolution to phenotypes that promote cancer progression and metastatic potential. Cancer heterogeneity arises from ongoing proliferation and mutation. Tumor-associated endothelial cells, fibroblasts, and inflammatory cells develop different and distinct gene expression profiles with unique cell surface molecules and patterns of secreted molecules. During this process there is generally a great deal of cancer cell death, but the surviving cells are more aggressive and many take on a metastatic phenotype. Because continuing somatic mutations may be random, cancer cells in different regions of the tumor may be genetically diverse.
Additionally, a population of cancer stem cells may arise, the origin of which is still unclear. Many of the hallmarks of cancer are consequences of cancer-stromal interactions (discussed later).
Cancers Live in a Complex Microenvironment. Cancer cells express tumor-specific antigens that ideally can be recognized by cells of the immune system and inflammatory systems (natural killer cells, antitumor M1 macrophages, T-cytotoxic cells) and destroyed by apoptosis or undergo growth suppression by type I cytokines. However, successful cancers produce a variety of cytokines and chemokines that are chemoattractants for stromal cells that infiltrate the tumor and undergo change to pro-tumor phenotypes. These include tumor-associated M2 macrophages (TAMs), cancer-associated fibroblasts (CAFs), mesenchymal stem cells (MSCs), and immune suppressor cells of T-cell origin (T-regulatory cells) and myeloid origin (myeloid-derived suppressor cells). Through multiple receptor-mediated interactions between other stromal cells and the cancer cells, the stromal cells, as well as the cancer cells, collectively produce a battery of additional cytokines (e.g., TGF-β, type II cytokines), chemokines (e.g., CXCL5), growth factors (e.g., VEGF, EGF, CSF-1, FGF, PDGF), and proteases (e.g., MMPs) and secrete components of the extracellular matrix (ECM). The stromal reaction promotes tumor progression, including new blood vessel growth (angiogenesis), tumor cell proliferation and differentiation, suppression of immune rejection and tumor cell apoptosis, invasion, and commitment to metastasis. CAF, Cancer-associated fibroblast; CSF-1, colony-stimulating factor-1; CXCL5, C-X-C motif chemokine 5; ECM, extracellular matrix; EGF, epidermal growth factor; FGF, fibroblast growth factor; MSC, mesenchymal stem cell; MMP, matrix metalloproteinase; NK, natural killer cell; PDGF, platelet-derived growth factor; TAM, tumor-associated macrophage; TGF-β, tumor growth factor-beta; Treg, T-regulatory cell; VEGF, vascular endothelial cell growth factor. (Modified from Quail DF, Joyce JA: Microenvironmental regulation of tumor progression and metastasis, Nat Med 19[11]:1423-1437, 2013.)
Several of the hallmarks/enablers are primarily genomic alterations that initiate and maintain development of cancer. These will be discussed first and include sustained proliferative signaling, evading growth suppression, genomic instability, and replicative immortality (see Figure 10-4). Other hallmarks/enablers are secondary to genomic change and include inducing angiogenesis and reprogramming energy metabolism. A third group, tumor resistance to destruction by the host's protective mechanisms, includes resistance to apoptotic cell death, tumor-promoting inflammation, and avoiding immune destruction. The last hallmark is the culmination of the previous nine: activating invasion and metastasis.

Quick Check 10-2

1. Describe the differences between point mutations, chromosomal translocations, and gene amplification in the process of cancer.

2. Why is the tumor microenvironment important to cancer progression?

Sustained Proliferative Signaling

The first and foremost hallmark of cancer is uncontrolled cellular proliferation. Normal cells generally only enter proliferative phases in response to growth factors that bind to specific receptors on the cell surface. The cytoplasmic components of the receptors are associated with signaling molecules that undergo activation and in turn activate intracellular signaling pathways leading to induction/activation of regulatory factors affecting DNA synthesis, entrance into the cell cycle, and changes in expression of other genes related to cell metabolism for optimal growth (Figure 10-8). One example is initiation of proliferation by epidermal growth factor (EGF). EGF binds and cross-links two EGF receptors on the cell surface. The cytoplasmic portions of the receptors are tyrosine kinases that attach phosphorus to tyrosine in neighboring proteins, including each other (autophosphorylation). Phosphorylation allows the receptor to attach to bridging protein, which links the EGF receptors to plasma membrane–associated inactive RAS. RAS is an acronym for “rat sarcoma,” where it was found originally. Inactive RAS is associated with guanine diphosphate (GDP). Association between the EGF receptor and inactive RAS modifies the binding of GDP, which is replaced with guanine triphosphate (GTP). GTP activates RAS, which is a GTPase that converts GTP to GDP, during which it can activate signaling pathways such as the mitogen-activated protein kinase (MAPK) pathway and the phosphatidylinositol-3-kinase (PI3K) pathway. These signaling pathways
phosphorylate other cytoplasmic proteins and affect activity and nuclear localization of transcription factors, such as MYC (myelocytomatosis viral oncogene homolog), that govern the transcription of cell cycle regulators, such as cyclins, and entrance into cellular proliferation. Proliferation can be discontinued through this pathway by decreased levels of growth factors in the environment or inactivation of signaling pathway components.
The genes that encode components of receptor-mediated pathways designed to regulate normal cellular proliferation are collectively called **proto-oncogenes**. Cancerous cells characteristically express mutated or overexpressed proto-
oncogenes, which are referred to as **oncogenes**. Oncogenes are independent of normal regulatory mechanisms; thus the cell is driven into a state of unregulated constitutive expression of proliferation signals and uncontrolled cell growth. Oncogenes can affect any portion of the growth factor pathways, such as described for EGF. For instance, most growth factors originate from neighboring cells, but some cancers acquire the ability to secrete growth factors that stimulate their own growth, a process known as **autocrine stimulation**. As described later in this chapter, noncancerous stromal cells within a tumor are frequently modified to benefit the cancer. In some instances, stromal cells produce excessive growth factors that drive the proliferation of cancer cells. Other cancers increase the expression of growth factor receptors; for example, in breast cancer production of the human epidermal growth factor receptor 2 (HER2, also known as the epidermal growth factor receptor gene \([ERBB-2]\)) is up-regulated and is hyperresponsive to low levels of EGF. Some breast and lung cancers are effectively treated by inhibitors of HER2 and other EGF receptors that block this pathway.  

Oncogenes may lead to constant activation of the signal cascade from the cell surface receptor to the nucleus. Up to a third of all cancers have an activating mutation in the RAS gene resulting in a continuous cell growth signal even when growth factors are missing (see **Figure 10-8**). Other mutations in the EGF receptor pathway include excessive proliferation signaling by hyperactivation of the PI3 kinase.

Several types of genetic events can activate oncogenes. A point mutation that is frequently observed in lung cancer results in continuous activation of the EGF receptor **tyrosine kinase**. A point mutation in the RAS gene converts it from a regulated proto-oncogene to an unregulated oncogene. Activating point mutations in RAS are found in many cancers, especially pancreatic and colorectal cancer. Specialized tests, such as direct DNA sequencing, can detect such point mutations in clinical samples.

Translocations can activate oncogenes in one of two distinct mechanisms (**Figure 10-9**). First, a translocation can cause excess and inappropriate production of a proliferation factor. One of the best examples is the t(8;14) translocation found in many Burkitt lymphomas; t(8;14) designates a chromosome that has a piece of chromosome 8 fused to a piece of chromosome 14 (see **Chapter 21**). Burkitt lymphoma is an aggressive cancer of B lymphocytes. The MYC proto-oncogene found on chromosome 8 is normally activated at low levels in proliferating lymphocytes and is inactivated in mature lymphocytes. If the t(8;14) translocation occurs, the MYC gene is aberrantly placed under the control of a B-cell immunoglobulin gene \((IG)\) present on chromosome 14. The IG gene is very active in maturing B lymphocytes. The t(8;14) translocation alters the control of MYC; its
normal low level expression is switched to high levels, as directed by an IG gene promoter. Hyperproduction of MYC protein drives proliferation and blocks differentiation.
Second, chromosome translocations can lead to production of novel proteins with growth-promoting properties. In chronic myeloid leukemia (CML) a specific
chromosome translocation is almost always present (see Figure 10-9). This translocation, t(9;22), was first identified in association with CML in Philadelphia in 1960 and is often referred to as the *Philadelphia chromosome*. Translocation fuses two chromosomes in the middle of two different genes: *BCR* (break point cluster region gene) on chromosome 9 and *ABL* (Abelson gene) on chromosome 22. The result is production of a BCR-ABL fusion protein containing the first half of *BCR* and the second half of *ABL* (a nonreceptor tyrosine kinase). BCR-ABL is an unregulated protein tyrosine kinase that promotes growth of myeloid cells. Imatinib, a drug that specifically targets this tyrosine kinase, represents the first successful chemotherapy targeted against the product of a specific oncogenic mutation. Imatinib and related tyrosine kinase inhibitors (TKIs) are highly effective in the treatment of CML and, because of their specificity, lack the toxic side effects noted with nonspecific anticancer drugs. However, imatinib is not effective in cancers that do not have the t(9;22) translocation or related mutations. In modern personalized cancer therapy, knowledge of the specific genetic alteration can dictate the optimal drugs for the individual.

Oncogenes also may be activated by gene amplification (Figure 10-10). Gene amplification results in increased expression of an oncogene, or in some cases drug resistance genes. The N-*MYC* oncogene, a member of the *MYC* family, is amplified in 25% of childhood neuroblastoma and confers a poor prognosis. The HER2 gene (*ERBB2*) is amplified in 20% of breast cancers.
Evading Growth Suppressors

Uncontrolled cancer cell proliferation also is related to inactivation of tumor-suppressor genes. **Tumor-suppressor genes** normally regulate the cell cycle, inhibit proliferation resulting from growth signals, stop cell division when cells are damaged, and prevent mutations. Hence, they also have been referred to as anti-oncogenes. Whereas oncogenes are *activated* in cancers, tumor suppressors must be *inactivated* to allow cancer to occur (*Table 10-1* and *Figure 10-11*). A single genetic event can activate an oncogene because it can act in a dominant manner in the cell. However, we have two copies of each tumor-suppressor gene, one from each parent. Both copies must be inactivated; therefore two mutations are necessary.

*Nonmutant state referred to as proto-oncogene.
Tumor-suppressor genes can be deactivated by a variety of mechanisms. (A) In this example, the first hit is a point mutation in a tumor-suppressor gene (white box), followed by either epigenetic silencing or chromosome loss of the second allele (red box). (B) Genes can normally be silenced by a variety of interacting processes including DNA methylation, histone modification, nucleosomal remodeling, and microRNA changes (not shown). A number of cellular enzymes contribute to these modifications, including DNA methyltransferases (DNMTs), histone deacetylases (HDACs), histone methyltransferases (HMTs), and complex nucleosomal remodeling factors (NURFs). Gene silencing is essential for normal development and differentiation. (C) Histone modification and promoter methylation regulate gene expression. Genes are transcribed when chromatin is modified by addition of acetyl (Ac) groups to specific lysine groups in histones. Gene expression can be turned off when specific acetyl groups are removed (by HDACs) or when the Cpg-rich promoter regions of genes are modified by direct DNA methylation (by DNA methyltransferase).

In addition, small endogenous RNA molecules (microRNAs or miRNA) can bind to mRNA and
A prototypical tumor-suppressor gene is the **retinoblastoma (RB) gene**. Normal cells receive diverse “antigrowth” signals from their normal environment. Contact with other cells, with basement membranes, and with some soluble factors normally signal cells to stop proliferating. Tumor-suppressor genes, such as RB, monitor antigrowth cellular signals and block activation of the growth/division phase in the cell cycle; thus mutations in RB lead to persistent cell growth. Anti-proliferative activity of RB depends on the degree of protein phosphorylation. Low levels of phosphorylation (hypophosphorylation) result in RB binding to and inhibiting transcription factors that regulate genes controlling passage through the cell cycle. Growth factor–regulated kinases increase phosphorylation (hyperphosphorylation) and inactivation of RB. A variety of genetic mutations in cancers also inactivate RB, resulting in unregulated and continuous cellular proliferation. RB is mutated in childhood retinoblastoma, and in many lung, breast, and bone cancers as well. The RB gene resides on chromosome 13, in a region referred to as q14 (13q14). Most individuals with RB mutations have a subtle mutation, such as a point mutation, in one allele. The RB gene in the other chromosome may be inactivated through loss of the 13q14 region or epigenetic mechanisms.

Another classic tumor-suppressor gene is **tumor protein p53 (TP53)**. The protein p53 has been called the *guardian of the genome*. TP53 monitors intracellular signals related to stress and activates **caretaker genes**—genes that are responsible for the maintenance of genomic integrity (Figure 10-12). Many types of cellular stress (e.g., anoxia, oncogene expression, nuclear damage) produce intracellular signals (e.g., levels of nucleotides and glucose, degree of oxygenation, DNA damage, and other indicators of cellular abnormalities) detectable by p53. Normally p53 is in an inactive complex with inhibitor molecules. Stress activates kinases that phosphorylate p53 into an active suppressor of cell division and activator of caretaker genes. Caretaker genes encode proteins that are involved in repairing damaged DNA, such as occurs with errors in DNA replication, mutations caused by ultraviolet or ionizing radiation, and mutations caused by chemicals and drugs. The p53 protein also controls initiation of cellular senescence or apoptosis, and suppresses cell division until DNA repair is complete or other effects of stress are corrected. If not corrected, the cell enters senescence or apoptosis, thus preventing further DNA damage and mutations. Loss of function of TP53 or caretaker genes leads to increased mutation rates and cancer.
Because inactivation of tumor-suppressor genes requires at least two mutations (one in each allele), a single germ cell mutation (sperm or egg) results in the transmission of cancer-causing genes from one generation to the next, producing
families with a high risk for specific cancers. These inherited mutations that predispose to cancer are almost invariably in tumor-suppressor genes because only a single additional mutation in any other cell (somatic cell mutation) is needed to inactivate completely the tumor-suppressor gene (Table 10-2).

An example of increased risk for cancer that can be inherited is the familial form of retinoblastoma. A mutation in one RB allele is inherited so that only one additional mutation in the normal allele will lead to cancer (see Table 10-2). Approximately half of children with retinoblastoma have the inheritable form and most will develop tumors in both eyes (bilateral retinoblastoma). Also, Li-Fraumeni syndrome is a very rare inheritable loss-of-function mutation in TP53 in one allele resulting in a 25-fold increase of developing malignancy at early age (<50 years of age). These malignancies may include breast cancer, brain tumors, acute leukemia, soft tissue sarcomas, bone sarcoma, and adrenal cortical carcinoma. Other familial cancers with inheritable mutations in tumor-suppressor genes include Wilms tumor, a childhood cancer of the kidney (WT1 gene); neurofibromatosis (NF1 gene); and familial polyposis coli or adenomas of the colon (APC gene). Characterization of cancer-causing genes and other genetic factors helps identify individuals prone to developing cancer and contributes to our understanding of sporadic cancers. Individuals known to carry mutations in tumor-suppressor genes are offered targeted cancer screening to facilitate early cancer detection and therapy.

Genomic Instability

Genomic instability refers to an increased tendency of alterations—mutability—in the genome during the life cycle of cells. Inherited and acquired mutations in caretaker genes that protect the integrity of the genome and DNA repair increase the level of genomic instability and risk for developing cancer. Acquired mutations in “guardians of the genome,” such as TP53, that detect DNA damage and activate repair mechanisms result in an increasing accumulation of mutations. Xeroderma
pigmentosum is a defect in the repair of DNA pyrimidine dimers created by ultraviolet (UV) light that increases the risk for skin cancers. Hereditary nonpolyposis colorectal cancer results from an inherited defect in repairing DNA base pair mismatches that occur occasionally during DNA replication. Affected individuals have an increased rate of small insertions and deletions in DNA, leading to a high rate of colon and other cancers. Some inherited mutations threaten the integrity of entire chromosomes. Bloom syndrome, caused by mutations in a DNA helicase, presents with an increased risk of several forms of cancer, and those with Fanconi aplastic anemia, caused by loss of function for repairing DNA double-strand breaks, have a particularly increased risk of acute myelogenous leukemia. These examples are autosomal recessive disorders in which affected individuals demonstrate marked chromosomal instability.

Genomic instability also may result from increased epigenetic silencing or modulation of gene function (Chapter 3). Many cancers have increased methylation of DNA in the promoter region of tumor-suppressor genes. They also have associated changes in the modification of histones in the chromatin, often correlated with methylation of DNA. These changes alter the promoter regions of genes, leading to their silencing or altered gene expression.

Changes in gene regulation can affect not just single genes, but also entire intracellular signaling networks. Gene expression networks can be regulated by changes in microRNAs (miRNAs, or miRs) and other non–coding RNAs (ncRNAs).\textsuperscript{16} miRs regulate diverse signaling pathways; the miRs that stimulate cancer development and progression are termed oncomirs.\textsuperscript{17} miRs decrease the stability and expression of other genes by pairing with mRNA.

Mutations in \textit{BRCA1} and \textit{BRCA2} (breast cancer 1 and 2, early onset genes) are currently of clinical importance. Both are tumor-suppressors and caretaker genes that repair double-stranded DNA breaks. Inherited mutations in either gene greatly increase the risk for a variety of tumors, especially breast cancer in both women and men, and ovarian or prostate cancers. Approximately 12% of women generally will develop breast cancer within their lifetime, whereas about 60% of women with a high-risk \textit{BRCA1} mutation and 45% with a \textit{BRCA2} mutation will develop cancer by age 70.\textsuperscript{18} Ovarian cancer occurs in approximately 1.4% of the general population, but about 39% of women with an inherited mutation in \textit{BRCA1} and about 15% with a mutation in \textit{BRCA2} will develop ovarian cancer by age 70. At-risk women are currently offered prophylactic surgery to reduce the risk of cancer.

In addition to specific gene mutations and abnormal epigenetic silencing, chromosome instability also appears to be increased in malignant cells, resulting in a high rate of chromosome loss, as well as loss of heterozygosity and chromosome amplification. The underlying mechanism of this instability is not clear but may be
caused by malfunctions in the cellular machinery that regulates chromosome segregation at mitosis.

**Enabling Replication Immortality**

A hallmark of cancer cells is their immortality, in that they seem to have an unlimited life span and will continue to divide for years under appropriate laboratory conditions. One of the most commonly used laboratory cell lines, HeLa cells, was derived from a cervical cancer specimen obtained in 1951 that continues to grow and divide in laboratories around the world.\(^\text{19}\) Most normal cells are not immortal and can divide only a limited number of times (known as the Hayflick limit) before they either enter senescence (cease dividing) or enter crisis (apoptosis) and die. One major block to unlimited cell division (i.e., immortality) is the size of a specialized structure called the telomere. **Telomeres** are protective ends, or caps, of repeating hexanucleotides (six nucleotide units) on each chromosome and are placed and maintained by a specialized enzyme called **telomerase** (Figure 10-13).\(^\text{20}\)

As one might expect, telomerase is usually active only in germ cells (in ovaries and testes) and in stem cells. All other cells of the body lack telomerase activity. Therefore, when non–germ cells begin to proliferate abnormally their telomere caps shorten with each cell division. Short telomeres normally signal the cell to cease cell division. If the telomeres become critically small, the chromosomes become unstable and fragment, and the cells die.
Normal adult somatic cells cannot divide indefinitely because the ends of their chromosomes are capped by telomeres. In the absence of the telomerase enzyme, telomeres become progressively shorter with each division until, when they are critically short, they signal to the cell to stop dividing. In germ cells, adult stem cells, and cancer cells the telomerase gene is “switched on,” producing an enzyme that rebuilds the telomeres. Thus, like germ cells, the cancer cell becomes immortal and able to divide indefinitely without losing its telomeres.

Cancer cells are very heterogeneous and many cells die as the cancer develops. When they reach a critical age, most cancer cells activate telomerase to restore and maintain their telomeres, thereby allowing continuous division. The trigger for reexpression of telomerase activity remains unclear, but seems to require expression of specific oncogenes, such as RAS or MYC, and loss of function of certain tumor-suppressor molecules, such as p53 and RB. Telomerase activity is restored in about 90% of cancers. The remaining cancers appear to recruit or originate from stem cells, becoming cancer stem cells that maintain levels of telomerase activity characteristically found in somatic stem cells. Because telomerase is specifically activated in cancer cells, and potentially in cancer stem cells, it is an attractive therapeutic target.
**Quick Check 10-3**

1. What are the heritable changes in cells that contribute to cancer development?

3. Biologically, why do tumor-suppressor genes have to be inactivated to cause cancer?

4. Define epigenetics and epigenetic silencing.

5. Distinguish between mutations in somatic cells versus in germ cells.

6. Define telomeres, telomerase, and senescence and describe their effects on cancer.

**Inducing Angiogenesis**

A major component of wound healing is the process of establishing new blood vessels within the tissue undergoing repair (called neovascularization or angiogenesis). Access to a blood supply also is obligatory to the growth and spread of cancer. Without a blood supply to deliver oxygen and nutrients, growth of a tumor is limited to about a millimeter in diameter.

**Angiogenic factors** and angiogenic inhibitors normally control development of new vessels. In cancerous tumors several mechanisms increase and maintain secretion of angiogenic factors by the cancer cells, as well as prevent release of angiogenic inhibitors. **Hypoxia-inducible factor-1α (HIF-1α)**, an oxygen-sensitive transcription factor, is a major regulator of angiogenesis in normal tissue; HIF-1α is stabilized under hypoxic conditions and induces expression of pro-angiogenic factors, such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF). Inactivation of tumor-suppressor genes (e.g., *p53*) or increased expression of oncogenes (e.g., *HER2*) leads to increased expression of HIF-1α–regulated angiogenic factors and increased vascularization. Increased expression of HIF-1α also is related to increased resistance to chemotherapy, increased tumor cell glycolysis, increased metastasis, and a poor prognosis. These effects may likely occur through an autocrine mechanism by which VEGF activates tumor-associated VEGF receptors. For instance, in soft tissue sarcomas VEGF induces increased expression of anti-apoptotic proteins (e.g., Bcl-2) and activation of intracellular survival signal pathways. The use of angiogenic inhibitors targeting VEGF signaling can inhibit angiogenesis and diminish tumor growth.
Other routes of angiogenic factor induction include mutations in cancer oncogenes (e.g., RAS, MYC) that increase transcription of VEGF by cancer cells. Most cells in the tumor microenvironment also secrete VEGF, including tumor-infiltrating monocytes, endothelial cells, adipocytes, and cancer-associated fibroblasts. Angiogenesis inhibitors, such as thrombospondin-1 (TSP-1), normally bind to cellular surface receptors on inflammatory cells and negatively regulate angiogenesis in wound healing and tissue remodeling. The expression of angiogenesis inhibitors is under the control of p53, which is suppressed in cancer cells, thus diminishing the control of stromal inflammatory cell secretion of angiogenic factors.

Cancer cells and stromal cells may increase production of matrix metalloproteinases (e.g., MMP-9) (Figure 10-14). MMPs are zinc-dependent proteases that digest the surrounding extracellular matrix (ECM). The ECM contains stored latent (inactive) forms of some angiogenic factors (e.g., bFGF, transforming growth factor-beta [TGF-β]). MMPs activate the stored forms into functional angiogenic factors.
FIGURE 10-14  Tumor-Induced Angiogenesis. Malignant tumors secrete angiogenic factors and tissue-remodeling matrix metalloproteinases (MMPs) that actively induce formation of new blood vessels. New blood vessels are formed from both local endothelial cells and circulating precursor cells recruited from the bone marrow. Circulating platelets can also release regulatory proteins into the tumor. bFGF and bFGFR, Basic fibroblast growth factor and its receptor, respectively; MMPs, matrix metalloproteinases; PDGF and PDGFR, platelet-derived growth factor and its receptor, respectively; VEGF and VEGFR, vascular endothelial growth factor and its receptor, respectively. (Adapted from Folkman J: Angiogenesis: an organizing principle for drug discovery? Nat Rev Drug Discov 6[4]:273-286, 2007.)

The vessels formed within tumors differ from those in healthy tissue. They originate from endothelial sprouting from existing capillaries and irregular
branching, rather than regular branching seen in healthy tissue. The interendothelial cell contact is less tight so the vessels are more porous and prone to hemorrhage, as well as allowing passage of tumor cells into the vascular system.

**Reprograming Energy Metabolism**

Cancer cells live in a distinct environment from normal cells and have different nutritional requirements from nonproliferating cells. The successful cancer cell divides rapidly, with the consequent requirement for the building blocks to construct new cells. Nonmalignant cells in the presence of adequate oxygen normally generate adenosine triphosphate (ATP) by mitochondrial oxidative phosphorylation (OXPHOS), generating 36 ATP molecules from each glucose molecule that is broken down to water and carbon dioxide. In the absence of sufficient oxygen (hypoxia) normal cells perform glycolysis (anaerobic glycolysis), generating only two ATP molecules per molecule of glucose, with lactic acid and pyruvate as byproducts.

Even in the presence of adequate oxygen, cancer cells may not use OXPHOS, but are reprogrammed to glycolysis (Warburg effect) ([Figure 10-15](#)). Thus, the Warburg effect is the use of glycolysis under normal oxygen conditions, hence the name *aerobic glycolysis*. Although aerobic glycolysis was postulated to arise from cancer-specific mitochondrial dysfunction, it is now apparent that this is instead a highly regulated and beneficial adaptation for cancer cells. The shift from OXPHOS to glycolysis allows lactate and other products of glycolysis to be used for the more efficient production of lipids, nucleosides, amino acids, and other molecular building blocks needed for rapid cell growth.
Cancers Have Altered Metabolism. Normal tissues use oxidative phosphorylation (OXPHOS) to turn glucose into $\text{CO}_2$ and energy (in the form of ATP). Cancers take a different approach; even in the presence of oxygen, they do not use OXPHOS. Instead, they consume large quantities of glucose to make cellular building blocks, supporting rapid proliferation. (From Van der Heiden MG et al: Understanding the Warburg effect: the metabolic requirements of cell proliferation, Science 324:1029-1033, 2009.)

A new model, the reverse Warburg effect, may play a role in certain cancers. Cancer cells may continue using the OXPHOS to generate large amounts of ATP. However, they also may manipulate the cancer-associated fibroblasts (CAFs), perhaps by inducing oxidative stress, to undergo aerobic glycolysis and secrete metabolites (e.g., lactate, pyruvate) that the cancer cells can use in the citric acid cycle (Krebs cycle) to feed OXPHOS and produce ATP. A secondary consequence would be induction of autophagy in the CAFs, resulting in consumption of the CAFs and release of materials needed by the cancer cell in the synthesis of new organelles.

Promoters of aerobic glycolysis are activated by oncogenes and mutated tumor-suppressor molecules. Up-regulation of GLUT1 (glucose transporter 1) under the control of oncogenes (e.g., $\text{RAS, MYC}$) and mutant tumor suppressors (e.g., $\text{TP53}$) increases transport of glucose into the cytoplasm. These and other oncogenes or mutant tumor-suppressor genes inhibit OXPHOS and promote the aerobic
glycolytic pathway and related metabolic pathways that support the rapid growth of cancers.\textsuperscript{25}

Clinically the high glucose utilization of a cancer can be exploited for its detection.\textsuperscript{26} \textsuperscript{18}F-Fluorodeoxyglucose (FDG) is incorporated into cells in the same way as glucose, with two key differences. Because it is missing a key hydroxyl group it cannot be broken down by glycolysis and, thus, FDG accumulates in cells. Because it is tagged with \textsuperscript{18}F, it can be imaged by a positron emission tomography (PET) scan. Small metastatic tumor masses that are consuming huge amounts of glucose can readily be detected with this imaging method (Figure 10-16).

\textbf{FIGURE 10-16} The Intense Glucose Requirement of Cancer Aids in Diagnosis. This 54-year-old woman had a non–small cell lung cancer (NSCLC) surgically removed. Five years later, these images were obtained. The positron emission tomography (PET) scan using \textsuperscript{18}F-deoxyglucose shows metastatic lesions in the brain, right shoulder, and mediastinal and cervical lymph nodes as well as the liver, left pelvis, and proximal femur. (Left) PET whole-body image. (Right) Representative coronal image from the whole-body FDG-PET/CT–fused image of the same patient. The fused image consists of the CT image with the metabolic information superimposed in color. The pattern of distribution is most likely from the primary tumor to the large mediastinal lymph nodes, followed by lymphatic spread to cervical lymph nodes. Blood-borne dissemination produced the bone, brain, and liver metastases. Normally, only the heart, brain, and bladder show a strong signal on PET scan. CT, Computed tomography; FDG, fluorodeoxyglucose. (Images courtesy John Hoffman, MD, Huntsman Cancer Institute, Salt Lake City Utah.)
Resisting Apoptotic Cell Death

Programmed cell death (apoptosis) is a mechanism by which individual cells can self-destruct under conditions of tissue remodeling or as a protection against aberrant cell growth that may lead to malignancy. Two pathways may trigger apoptosis (Figure 10-17). The intrinsic pathway (mitochondrial pathway) monitors cellular stress. Cellular stress may include DNA damage, genomic instability, aberrant proliferation, loss of adhesion to extracellular matrix or to adjacent cells, and other causes and characteristics of abnormal cellular physiology. The extrinsic pathway is activated through a plasma membrane receptor complex linked to intracellular activators of apoptosis (known as the death receptor).
Loss of p53 leading to reduced function of pro-apoptotic factors, such as BAX.
Reduced egress of cytochrome c from mitochondria as a result of up-regulation of anti-apoptotic factors, such as BCL-2.
Loss of apoptotic peptidase-activating factor 1 (APAF1).
Up-regulation of inhibitors of apoptosis (IAP).
Reduced CD95 levels.
Inactivation of death domain signaling complex (FADD).

(From Kumar V et al: Robbins and Cotran pathologic basis of disease, ed 9, Philadelphia, 2015, Saunders.)
The balance between pro-apoptotic (e.g., Bcl-2–associated X protein [BAX] and Bcl-2–homologous antagonist/killer [BAK]) and anti-apoptotic (e.g., BCL2 [B-cell lymphoma 2]) members of the Bcl-2 family regulates apoptosis. Both groups regulate mitochondrial release of pro-apoptotic molecules (e.g., cytochrome c). As mentioned previously, expression of the tumor-suppressor gene TP53 is affected by intracellular stress, particularly DNA damage. If DNA damage is irreparable, p53 is activated by phosphorylation and induces transcription of pro-apoptotic factors.

The extrinsic pathway is relatively dormant until the death receptor is activated. The principal apoptotic receptor is called Fas/CD95 (the CD95 nomenclature is an alternative for Fas) (see Figure 10-17). Fas is a receptor for Fas ligand (FasL) and similar molecules, such as tumor necrosis factor (TNF). Cytotoxic T lymphocytes and NK cells express surface and soluble FasL and can produce TNF, thus inducing apoptosis in target cells. The Fas receptor is linked to a complex of intracellular proteins (FADD, the Fas-associated death domain signaling complex) that triggers apoptosis.

Both pathways activate a series of intracellular effector enzymatic molecules (caspases). Pro-apoptotic molecules released by mitochondria in the intrinsic pathway activate caspase 9, which in turn activates caspase 3. Caspase 3 cuts DNA and other substrates, leading to cell death. Activation of the extrinsic pathway activates caspase 8, which can directly activate caspase 3.

Apoptotic pathways are dysregulated in most cancers. Most commonly, loss-of-function mutations to the TP53 gene suppress activation of apoptosis during DNA damage. The balance between pro- and anti-apoptotic molecules also can be affected by overexpression of anti-apoptotic molecules or diminished expression of anti-apoptotic molecules resulting from mutations. Overexpression of Bcl-2 occurs in the vast majority of follicular B-cell lymphomas. Excess expression of other anti-apoptotic members of the Bcl-2 family also may provide increased resistance to chemotherapeutic drugs, many of which act through induction of apoptosis. Other mechanisms of providing resistance to apoptosis include down-regulation of caspases or production of caspase inhibitors. By whatever mechanism, or combination of mechanisms, successful cancers suppressed apoptotic pathways and increased resistance to cell death.

**Tumor-Promoting Inflammation**

Historically, an immune/inflammatory response to cancer was considered a detrimental condition that successful tumors evolved methods of evading. We now realize that the relationship between a cancer and the inflammatory system is much
more complex. The inflammatory response may contribute to the onset of cancer and be manipulated throughout the process to benefit tumor progression and spread.

Chronic inflammation has been recognized for close to 150 years as being an important factor in the development of cancer. Chronic inflammations may result from many causes, for example, solar irradiation, asbestos exposure (mesothelioma), pancreatitis, and infection (Table 10-3). Additionally, some organs appear to be more susceptible to the oncogenic effects of chronic inflammation (e.g., the gastrointestinal [GI] tract, prostate, thyroid gland). Individuals who have suffered with ulcerative colitis for 10 years or more have up to a 30-fold increase in the risk of developing colon cancer. Chronic viral hepatitis caused by hepatitis B virus (HBV) or hepatitis C virus (HCV) infection markedly increases the risk of liver cancer.

A specific example is the association between gastric inflammation induced by infection with the bacterium *Helicobacter pylori* (*H. pylori*) and the risk for gastric cancer. *H. pylori* is a bacterium that infects more than half of the world's population. Chronic infection with *H. pylori* is an important cause of peptic ulcer disease and is
strongly associated with gastric carcinoma, a leading cause of cancer deaths worldwide. It also is associated with a less common cancer, gastric mucosa–associated lymphoid tissue (MALT) lymphomas. H. pylori infection is often acquired in childhood and disproportionately affects lower socioeconomic classes. Although most infections are asymptomatic, prolonged chronic inflammation can lead to increased gastric acid secretion, atrophic gastritis, and duodenal ulcers, or benign cellular proliferation that can in a small fraction of individuals progress to dysplastic changes and finally gastric adenocarcinoma. H. pylori infection can both directly and indirectly produce genetic and epigenetic changes in cells of infected stomachs, including mutations in TP53 and alterations in the methylation of specific genes. Eradication of H. pylori from infected individuals before the development of dysplasia may prevent the development of cancer. However, there is no expert consensus on the value of population screening and treatment strategies. The MALT lymphomas associated with chronic H. pylori infections may depend on chronic inflammation and antigenic stimulation associated with infections, and therefore treatment with antibiotics may be useful even in cases of early lymphoma.

Once cells with malignant phenotypes have developed, additional complex interactions occur between the tumor and the surrounding stroma and cells of the immune and inflammatory systems. Cancers disrupt the environment, initiate or enhance inflammation, and in turn recruit local and distant cells (macrophages, lymphocytes, and other cellular components of inflammation). The acute inflammatory response is initially designed to eliminate infection, but evolves to initiate and direct the healing process (see Chapter 6). Successful tumors appear capable of manipulating cells of the inflammatory response from a rejection response towards the phenotypes associated with wound healing and tissue regeneration; a process that includes induction in the damaged tissue of cellular proliferation, neovascularization, and local immune suppression. These activities benefit cancer progression, as well as increase resistance to chemotherapeutic agents.

One of the key cells that promote tumor survival is the **tumor-associated macrophage (TAM)**. Tumors commonly produce cytokines and chemokines that are chemotactic factors for monocytes/macrophages (e.g., colony-stimulating factor-1 [CSF1; also known as macrophage colony stimulating factor or M-CSF], the chemokine ligand 2 [CCL2; also known as monocyte chemotactic protein-1 or MCP-1]). Levels of CCL2 in human breast cancer and cancers of the esophagus are related to the degree of macrophage infiltration and progression of the tumor. Most tumors have large numbers of TAMs, whose presence frequently correlates with a worse prognosis. Thus, monocytes are attracted from the blood and into the tumor, where they mature into macrophages. Monocytes have the capacity to differentiate
into several macrophage phenotypes, depending upon the conditions in the microenvironment. The classic proinflammatory macrophage (M1) is the primary macrophage in the acute inflammatory response and is responsible for removal and destruction of infectious agents. During healing, however, a different phenotype (M2) produces anti-inflammatory mediators to suppress ongoing inflammation and induce cellular proliferation, angiogenesis, and wound healing. TAMs appear to phenotypically mimic the M2 phenotype.

TAMs have diminished cytotoxic response, and develop the capacity to block T-cytotoxic cell and NK-cell functions and produce cytokines that are advantageous for tumor growth and spread. TAMs secrete cellular growth factors (e.g., TGF-β and fibroblast growth factor-2 [FGF-2]) that favor tumor cell proliferation, angiogenesis, and tissue remodeling, similar to their activities in wound healing. They also secrete angiogenesis factors (e.g., VEGF) that induce neovascularization and matrix metalloproteinases (MMPs) that degrade intercellular matrix. The overall effect is increased tumor growth, invasion of the blood vessels, increased oxygen to the tumor, and invasion through the degraded matrix into the local tissue.

**Cancer-associated fibroblasts (CAFs)** synthesize the extracellular matrix that surrounds and permeates the tumor. Cytokines and growth factors stored in the matrix as well as growth factors, metalloproteases, proteoglycans, and other molecules secreted by CAFs contribute greatly to cancer progression, local spread, and metastasis.

### Evading Immune Destruction

Many cancers express cell surface antigens that are not generally found on normal cells from the same tissue. Tumor-associated antigens include products of oncogenes, antigens from oncogenic viruses, oncofetal antigens (expressed in embryonic tissues and tumors), and altered glycoproteins and glycolipids. Viral and tumor antigens are processed by the tumor cell and presented on the cell surface by MHC class I molecules and are targets of CD8+ T-cytotoxic cells (Tcyto) (see Chapter 7). NK cells recognize altered cell surface glycoproteins and glycolipids. Thus, cancer cells should be recognized as foreign and destroyed by the immune system. In the laboratory, T lymphocytes and NK cells recognize and kill cancer cells. This observation gave rise to two hypotheses—immune surveillance and immunotherapy. The immune surveillance hypothesis predicts that most developing malignancies are suppressed by an efficient immune response against tumor-associated antigens. The immunotherapy hypothesis predicts that the immune system could be used to target tumor-associated antigens and destroy tumors clinically. Immunotherapy could be either active, by immunization with tumor antigens to
elicit or enhance the immune response against a particular cancer, or passive, by injecting the cancer patient with antibodies or lymphocytes directed against the tumor antigens. However, the interactions between cancer and the immune system are more complex than originally envisioned and both hypotheses remain controversial.

What is the role of the immune system in protecting against cancer? The most clearly documented effective immune response is prophylactic and directed against oncogenic viruses. Several viruses have been associated with human cancer; human papillomavirus (HPV), Epstein-Barr virus (EBV; also known as HHV4), Kaposi sarcoma herpesvirus (KSHV; also known as HHV8), and hepatitis B and C viruses (HBV, HCV) are associated with about 15% of all human cancers worldwide (see Table 10-3). Cancer of the cervix and hepatocellular carcinoma account for approximately 80% of virus-linked cancer cases.

Virtually all cervical cancer is caused by infection with specific types of HPV, which infects basal skin cells and commonly causes warts. There are more than 120 HPV types, but only about 40 can infect human mucosal tissue, and only a few (HPV-16, -18, -31, and -45) are associated with the highest risk for developing cervical, anogenital, and penile cancer. Most HPV infection is handled effectively and rapidly by the immune system and does not cause cancer. Cancer is more common in people with prolonged infection with HPV (a decade or more), during which the viral DNA becomes integrated into the genomic DNA of the infected basal cell of the cervix and directs the persistent production of viral oncogenes. Early oncogenic HPV infection is readily detected by the Papanicolaou (Pap) test, an examination of cervical epithelial scrapings. Early detection of atypical cells in a Pap test alerts healthcare providers to the possibility of cervical carcinoma in situ, which can be effectively treated. The Pap test is probably the most effective cancer-screening test developed to date. For women age 30 to 65 years old, additional testing for HPV infection of cervical cells (HPV test) should be added. Vaccines protecting against the common oncogenic HPV types (HPV-16 and HPV-18 [types that cause 70% of cervical cancers] and HPV-6 and HPV-11 [types that cause 90% of genital warts]) were approved for clinical use beginning in 2006; if these vaccines are administered to young women and men before an initial HPV infection, this is likely to prevent many cases of cervical cancer.

Chronic hepatitis B infections are common in parts of Asia and Sub-Saharan Africa and confer up to a 200-fold increased risk of developing liver cancer. Chronic hepatitis C infections have become increasingly recognized in Western countries. Up to 80% of liver cancer cases worldwide are associated with chronic hepatitis caused either by HBV or by HCV. The initial infection with hepatitis B or C is not associated with cancer; instead, it is acquisition of a chronic viral hepatitis that
markedly increases cancer risk. In both cases, it appears that a lifetime of chronic liver inflammation predisposes to the development of hepatocellular carcinoma. Widespread use of the HBV vaccine is expected to significantly decrease the incidence of chronic hepatitis B and hence hepatocellular carcinoma. Unfortunately, a vaccine for HCV is not yet available.

For most other human tumor viruses, immunoprophylaxis is not yet available. EBV and HHV8 are members of the Herpesviridae family. More than 90% of adults have been infected with EBV, usually as children and without symptoms. EBV infection during adolescence may cause infectious mononucleosis. The virus infects B lymphocytes and stimulates their limited proliferation and usually becomes latent throughout the individual's life. If the individual is immunosuppressed because of HIV infection or because of drugs given for an organ transplant, persistent EBV infection can lead to the development of B-cell lymphomas. EBV infection also is associated with Burkitt lymphoma in areas of endemic malaria and with nasopharyngeal carcinoma, a cancer endemic in Chinese populations in Southeast Asia. HHV8 is linked to the development of Kaposi sarcoma, a cancer that was once seen primarily in older men but now occurs in a markedly more virulent form in immunosuppressed individuals, especially those with acquired immunodeficiency syndrome (AIDS). HHV8 also has been linked to several rare lymphomas. Human T-cell lymphotropic virus type 1 (HTLV-1) is an oncogenic retrovirus linked to the development of adult T-cell leukemia and lymphoma (ATLL). HTLV is transmitted vertically (that is, inherited by children from infected parents) and horizontally (e.g., by breast-feeding, sexual intercourse, blood transfusions, and exposure to infected needles). Infection with HTLV may be asymptomatic, and only a small fraction of infected individuals develop ATLL, often many years after acquiring the virus.

Thus immunization has proven beneficial in preventing viral-induced cancers. The immune surveillance hypothesis, however, would predict that components of the immune system, especially T cells, monitor the body and destroy most nascent tumors, even those not caused by viruses. If the immune surveillance hypothesis is correct, compromise of the immune system by immunosuppressive drugs or development of genetic or acquired immune deficiencies would result in increased incidences of all types of cancer. However, defective immune responses generally only increase the risk for lymphoid cancers, many of which are associated with viral infections. For instance, individuals taking chronic powerful immunosuppressive drugs, such as those given for kidney, heart, or liver transplant, have a much higher risk of developing viral-associated cancers, with a 10-fold increased risk of non-Hodgkin lymphoma (caused by EBV) and up to a 1000-fold increased risk of Kaposi sarcoma (caused by HHV8). The same immunosuppressed
individuals, however, have only a slight increase in the risk of common cancers such as lung and colon cancer (and this could well be because of increased inflammation at those sites), and no increase in the risk of breast or prostate cancer.

However, many tumors have an abundance of tumor-infiltrating lymphocytes (TILs). Although the immune cells frequently found in tumors were once thought to be futile attempts at an antitumor response, instead it appears that cancers actively recruit an immune and stromal response to assist in remodeling of tissues, formation of new blood vessels, and promotion of metastasis. NK cells are generally in low amounts in tumors. The predominant TILs are T-regulatory (Treg) cells. Treg cells are CD4+ cells that differentiate under the control of specific cytokines, primarily TGF-β. The role of Treg cells during wound healing is to control or limit the immune response to protect the host's own tissues against autoimmune reactions. Their role in tumors is manipulated to prevent a destructive antitumor immune response and provide cytokines that facilitate tumor cell proliferation and spread. Treg cells and TAMs, as well as other stromal cells, produce very high levels of TGF-β and interleukin-10 (IL-10). IL-10 is an immunosuppressive cytokine, which generally decreases T-helper cell 1 (Th1) and Th2 activity, suppresses antigen recognition and cell proliferation by Th cells, and suppresses the capacity of CD8+ T-cytotoxic (Tcyto) cells to recognize, proliferate, and kill tumor cells. The goal of current immunotherapy regimens is to reverse this relationship and facilitate T-cell–mediated cancer cell death (discussed later in this chapter).

The release of immunosuppressive factors into the tumor microenvironment also increases resistance of the tumor to chemotherapy and radiotherapy. Increased levels of Treg cells in blood and lymph nodes and infiltrating the tumor correlate with poor outcomes in breast and GI tumors. In advanced non–small cell lung cancer, an elevated ratio of Treg to Tcyto cells is related to a poor response to platinum-based chemotherapy. Immunosuppressive cytokines additionally lower the cancer cell's sensitivity to immune-mediated death (Figure 10-18). With increasing heterogeneity of cells within the tumor, subpopulations of antigen-negative cancer cell variants may selectively outgrow more immune-sensitive cells. Variants may suppress the production of particular antigens or suppress levels of antigen-presenting MHC class I. Other cytokines appear to increase the cancer cells' resistance to apoptosis. For example, the Th2 cytokine IL-4 increases the resistance of thyroid cancer to chemotherapy; IL-6 produced by Th cells, adipocytes, and fibroblasts activates survival pathways in breast cancer leading to resistance to radiotherapy; and adipocytes enhance the transcription of the anti-apoptotic factor Bcl-2 in leukemia cells.
FIGURE 10-18  Mechanisms by Which Tumor Cells Evade the Immune System. Tumors may evade the immune response by losing expression of antigens or major histocompatibility complex (MHC) molecules or by producing immunosuppressive cytokines or ligands for inhibitory receptors on T cells. (From Kumar V et al: Robbins and Cotran pathologic basis of disease, ed 9, Philadelphia, 2015, Saunders.)

Activating Invasion and Metastasis

**Metastasis** is the spread of cancer cells from the site of the original tumor to distant tissues and organs through the body. Metastasis is a defining characteristic of cancer.
and is the major cause of death from cancer. Cancer that has not metastasized can often be cured by a combination of surgery, chemotherapy, and radiation. These same therapies are frequently ineffective against cancer that has metastasized. For example, in appropriately treated women with localized low-stage breast cancer, the 5-year survival rate is often greater than 90%. Tragically, less than 30% of women with metastatic breast cancer are still alive 5 years after diagnosis. A growing body of basic and clinical research is defining the biologic principles of metastasis, with the hope that this improved understanding will lead to novel diagnostic approaches and better therapies to prevent and treat metastatic cancers.

How do cancer cells develop the ability to metastasize? Metastasis is a highly inefficient process. Cancer cells must surmount multiple physical and physiologic barriers in order to spread, survive, and proliferate in distant locations, and the destination must be receptive to the growth of the cancer. Changes in the tumor microenvironment initiate the metastatic process and may include stromal cell adaptation to increase tumor mass and intratumor hypoxia. As this diversity increases within the changing tumor microenvironment, some cancer cells evolve with multiple new abilities that can facilitate metastasis. The model for transition to metastatic cancer cells is called epithelial-mesenchymal transition.

**Epithelial-mesenchymal transition (EMT)** has been most extensively described for carcinomas, which originate from highly differentiated and polarized epithelial cells that form structured sheets stabilized by multiple adherences to neighboring cells and to a basement membrane (an extracellular meshwork of collagens and other connective tissue proteins) along the cell's basal surface. Although the degree of malignant transformation resulting in a primary carcinoma may be adequate for local expansion of the tumor, neoplastic cells usually retain some epithelial-like characteristics that prevent dissociation from the extracellular matrix and preclude successful metastasis to distal sites. A greater degree of cellular “dedifferentiation” is necessary to produce the phenotype that can separate from the primary tumor and flourish in a potentially hostile secondary site. This results from a programmed transition of the still partially epithelial-like carcinoma to a more undifferentiated mesenchymal-like phenotype (Figure 10-19). A similar process occurs with tumors of endothelial origin (endothelial-mesenchymal transition).
FIGURE 10-19 Epithelial-mesenchymal Transition and Metastasis. The microenvironment supports metastatic dissemination and colonization at secondary sites. Stromal cells (e.g., mesenchymal stem cells [MSC]) possibly facilitated by a relative decrease in oxygen levels in the tumor, contribute to the epithelial-to-mesenchymal transition (EMT) through which tumor cells develop a metastatic phenotype characterized by suppression of adhesion molecules and reduced adherence to adjacent cells and extracellular matrix, increased local invasion, and access to the blood and lymphatic circulations. One major mediator of this process is TGF-β, which is secreted by the tumor stroma. Intravascularization of tumor cells into the circulation is facilitated by protumorigenic TAMs, and CAFs tend to cluster at the leading edge of the invading cancer cells and secrete matrix metalloproteinases that promote digestion and remodeling of the surrounding ECM. Survival in the circulation is promoted by association with platelets and clotting factors that shield the cancer cells from cytotoxic immune cells (T-cytotoxic cells and NK cells) that also are suppressed by myeloid-derived suppressor cells (MDSC). Potential metastatic sites are prepared by induction of fibronectin, which provides a site for the influx of hematopoietic progenitor cells (HPC) that have receptors for VEGF. HPC appear essential for establishment of a metastatic site. At a metastatic site, cancer cells will adhere to local vascular endothelium, undergo extravascularization facilitated by the effects of ATP on the endothelium, and undergo mesenchymal-to-epithelial transition (MET). The premetastatic niche may have been prepared by molecular signaling from the cancer and initiation of a favorable microenvironment. CAF, Cancer-associated fibroblast; ECM, extracellular matrix; NK, natural killer cell; PDGF, platelet-derived growth factor; TAM, tumor-associated macrophage; TGF-β,
EMT is a process that occurs normally in embryonic development, as well as wound healing and tissue repair. Generally, cells that have transitioned into a mesenchymal-like phenotype have suppressed expression of adhesion molecules with a loss of polarity, increased migratory capacity, elevated resistance to apoptosis, and demonstrated the potential to redifferentiate into other cell types. The transition to a mesenchymal-like phenotype is, in most cases, driven by cytokines and chemokines produced within the tumor microenvironment. IL-8 is an effective driver of carcinoma cells into EMT.

Invasion, or local spread, is a prerequisite for metastasis. In its earliest stages local invasion may occur by direct tumor extension. Eventually, however, cells migrate away from the primary tumor and invade the surrounding tissues (see Figure 10-19). Invasion is a multistep process within EMT that includes diminished cell-to-cell adhesion, digestion of the surrounding extracellular matrix, and increased motility of individual cancer cells. TGF-β induces changes in expression of E-cadherin (an integral component of tight junctions) and of β₄-integrin in mammary gland tumor cells. The loss of E-cadherin in particular allows cells to detach from extracellular matrix and migrate more readily.

Recruitment of TAMs and other cell types is critical for invasion. Cells are normally attached to the extracellular matrix (ECM). TAMs and other stromal cells secrete proteases and protease activators, such as the MMPs and plasminogen activators, which promote digestion of connective tissue capsules and other structural barriers. Degradation of the surrounding ECM creates pathways through which cells can move, while releasing bioactive peptides as digestion products that further stimulate tumor growth and mobility.

Normal cells, when separated from their ECM, undergo anoikis, a form of apoptosis. Tumor cells adapted to a hypoxic environment have already been selected for resistance to apoptosis, often by loss of normal cell death pathways. The process of EMT frequently increases resistance to apoptosis. For example, neuroblastomas with loss of the pro-apoptotic caspase 8 genes are able to avoid apoptosis after loss of integrins and are more able to metastasize than the same cells with normal levels of caspase 8. Accordingly, individuals whose neuroblastomas have low levels of caspase 8 have a poor prognosis (see Chapter 1).

To transition from local to distant metastasis, the cancer cells must also be able to invade local blood and lymphatic vessels, a task facilitated by stimulation of neoangiogenesis and lymphangiogenesis by factors such as VEGF. After release from the ECM and digestion of basement membranes, mobile cancer cells gain
access to the circulation, perhaps facilitated by the leaky newly made vessels and attraction of the cells because of chemoattractants coming from these new vessels. Once in the circulation, metastatic cells must be able to withstand the physiologic stresses of travel in the blood and lymphatic circulation, including high shear rates and exposure to immune cells. One mechanism is for tumor cells to bind to blood platelets, giving them a protective coat of nonmalignant blood cells that both shields the tumor cells and creates a small tumor embolus, or cancer clot, that can promote cancer cell survival in distant locations (see Figure 10-19).

Cancer cells spread through vascular and lymphatic pathways. The neovascularization of a cancer offers malignant cells direct access into the venous blood and draining lymphatic vessels. The venous and lymphatic drainage networks associated with the primary tumor frequently determine the pattern of metastasis. Single cells, clumps, and even tumor fragments can disseminate by these routes. Anatomic patterns of lymphatic and venous blood flow help determine how colon cancers spread to the liver, liver cancers spread through the portal vein to the lungs, lung cancers spread through the systemic circulation to the brain, and breast cancer spreads through the lymphatics to axillary lymph nodes. Cancers often spread first to regional lymph nodes through the lymphatics and then to distant organs through the bloodstream.

There also is a major yet poorly understood selectivity of different cancers for different sites. Metastatic breast cancer often spreads through the bloodstream to bones but rarely to kidney or spleen, whereas lymphomas often spread to the spleen but uncommonly spread to bone. In a key study, different types of cancer cells were injected into the carotid artery of mice. In spite of identical blood flow–mediated distribution of the cancer cells, each cell type produced cancers in very different parts of the brain. This tissue selectivity is likely caused by specific interactions between the cancer cells and specific receptors on the small blood vessels in different organs. Experimental metastasis studies in mice are beginning to reveal additional molecular reasons for this tissue specificity. Examples include interaction between α3β1 integrins binding to laminin-5 receptors in the lung, and the chemokine receptor CXCR4 on breast cancer cells promoting homing to lung tissues expressing the ligand CXCL12.

A cancer’s ability to establish a metastatic lesion in a new location requires that the cancer survive in the specific environment and be capable of forming complex and heterogeneous tumors. In some cases, these tumor-initiating cells are very rare. Human cancers transplanted into special immune-deficient mice will grow and can metastases. Experiments have been performed to determine how few cancer cells are capable of establishing a tumor; only 1 in 10,000 human colon cancer cells are able to re-form a complex and heterogeneous colon cancer in mice; however, in
human melanomas 1 in 4 cells can initiate a complex tumor in the appropriate mouse model. Thus, the number of potentially metastatic cells may vary greatly with the particular cancer.

The degree of dedifferentiation may be variable, but most cells undergoing EMT acquire stem cell traits that facilitate initial growth in a new microenvironment. The EMT is not a stable transition; after taking residence in the metastatic site, the tumor tends to regain some characteristics of the primary tumor, thus reverting to some extent to its epithelial origins. Because metastasis requires successful completion of each and every step, there may be many opportunities to interrupt this potentially lethal pathway.

However, metastasis does not universally result in proliferation at a new site. Some cancer cells survive at a new site but do not proliferate to form a clinically relevant metastatic site. These cancer cells appear to exist in a state of dormancy. Dormancy is cellular quiescence—a stable, nonproliferative state that is reversible. Cells may remain quiescent for years before initiating proliferation. About two thirds of breast cancer deaths occur after a 5-year disease-free interval. In other conditions, solitary tumor cells can be detected in the blood years after a complete clinical remission in individuals, and many people with detectable micrometastases will not develop clinically obvious metastases. Cancer cell dormancy may be extremely common, even without a history of clinical cancer. Studies of deceased individuals without any history of cancer suggest that most of us have dormant cancer cells that never adjusted to form a malignant tumor.

The causes of dormancy and, more importantly, escape from dormancy and development of a malignant cancer are unknown. Dormancy may result from features of the cell or the environmental niche, or both. Individuals with clinical cancers may shed disseminated tumor cells very early from premalignant lesions. These early cells may have developed inadequately to a metastatic phenotype and thus cannot recruit cells into a supportive stroma or initiated angiogenesis. Another consideration is the niche itself. It is not clear whether a developing cancer secretes factors that enter the bloodstream and prepare potential metastatic niches. If so, early disseminated cancer cells may encounter nonsupportive niches that foster dormancy. A clear understanding of dormancy is needed because existing cancer therapies do not address this condition (also see p. 871).

Quick Check 10-4

1. Why is the stroma important for cancer growth and invasion?
2. Identify cancers that are the result of chronic inflammation.

3. Why does inflammation fuel cancer development/invasion?

4. Identify common viruses that can cause cancer.

5. How do cancers protect themselves from cell death?

6. Why is angiogenesis important to cancer development?
Clinical Manifestations of Cancer

The clinical manifestations of cancer are numerous and depend on the localization and type of tumor, and some are apparent before actual diagnosis of a malignancy. Generally, the variety and intensity of symptoms will increase as the malignancy progresses.

Paraneoplastic Syndromes

Paraneoplastic syndromes are symptom complexes that are triggered by a cancer but are not caused by direct local effects of the tumor mass. They are most commonly caused by biologic substances released from the tumor (e.g., hormones, cytokines) or by an immune response triggered by the tumor. For example, a small fraction of carcinoid tumors release substances, including serotonin, into the bloodstream that cause flushing, diarrhea, wheezing, and rapid heartbeat. A number of cancers trigger an antibody response that attacks the nervous system, causing a variety of neurologic disorders that can precede other symptoms of cancer by months.

Although infrequent, paraneoplastic syndromes are significant because they may be the earliest symptom of an unknown cancer and, in affected individuals, can be serious, often irreversible, and sometimes life-threatening. Table 10-4 presents the classifications of paraneoplastic syndromes.

**Pain**

Pain is one of the most feared complications of advanced cancer. Although pain can be one of the presenting symptoms of cancer, most commonly there is little or no pain during the early stages of malignant disease. Significant pain, however, occurs in a large fraction of those individuals who are terminally ill with cancer. Pain is strongly influenced by fear, anxiety, sleep loss, fatigue, and overall physical deterioration. It occurs through an interaction among physiologic, cultural, and
psychologic components. (The neurophysiology of pain is discussed in Chapter 14.)

Cancer-associated pain can arise from a variety of direct and indirect mechanisms. Direct pressure, obstruction, invasion of a sensitive structure, stretching of visceral surfaces, tissue destruction, infection, and inflammation all can cause pain. Pain can occur at the site of the primary tumor or can result from a distant metastatic lesion. Furthermore, pain may be referred away from the involved site and manifest, for example, as back pain.

Specific sites are more prone to cancer-associated pain. Bone metastases, common in advanced breast and prostate cancer, can cause significant pain because of periosteal irritation, medullary pressure, vertebral collapse, and pathologic fractures. Brain tumors (primary or metastatic) can, depending on the location, cause headache, seizures, or neurologic deficits. Pain in the abdomen may be caused by bowel obstruction, or inflammation and infection. Hepatic malignancies can stretch the liver, resulting in a dull pain or a feeling of fullness over the right upper abdominal quadrant. Mucosal surfaces can develop painful ulcerative lesions from the cancer, chemotherapy, and radiation or leukopenia (or both).

The diagnosis and treatment of pain is one of the primary responsibilities of the medical team. The individual's perception and, hence, reporting of pain can vary widely and be affected by such factors as age and cultural background. The first priority of treatment is to control pain rapidly and completely as judged by the individual. The second priority is to prevent recurrence of pain. Objective measurements of pain are increasingly being included along with the reporting of more traditional vital signs. Many institutions are using specialized pain management teams that are trained to recognize different types of acute and chronic pain, as well as the individual's response to that pain. Many modalities are available to treat pain, ranging from combinations of nonsteroidal anti-inflammatory drugs (NSAIDs) and narcotics to palliative surgery and radiation therapy. Individual-controlled analgesia provides many benefits, not the least of which is regaining some control over one's own body. Although cancer pain is a complex problem arising from multiple sources, individuals should be assured that suffering is not inevitable and that relief is attainable.

Fatigue

Fatigue is the most frequently reported symptom of cancer and cancer treatment. The exact mechanisms that produce fatigue are poorly understood. Suggested causes include sleep disturbances, various biochemical changes secondary to disease and treatment, numerous psychosocial factors, and environmental and physical factors.
The physiologic understanding of fatigue probably includes mechanisms for decreased muscle contractility. Overall, studies of muscle function suggest that some individuals with cancer may lose portions of muscle function needed to perform normal physical activities. Other areas of research include muscle function consequences from metabolic products of cancer treatment and associated muscle loss from circulating cytokines (e.g., tumor necrosis factor [TNF] and interleukin-1 [IL-1]). Similar to pain, fatigue is a subjective clinical manifestation. Individuals with cancer describe fatigue in many ways (e.g., weakness, lack of energy, depression). Some of these symptoms have been termed “chemo brain,” or mild cognitive impairment. The changes in cognitive function can be caused by the cancer itself or by the stress associated with the diagnosis of cancer, because symptoms similar to “chemo brain” also occur in individuals who have not received chemotherapy.

Cachexia

The multiorgan syndrome of cachexia includes a constellation of clinical manifestations, including anorexia; wasting, thermogenesis; altered heart and liver function; gut malabsorption; early satiety (filling); taste alterations; and altered protein, lipid, and carbohydrate metabolism (Figure 10-20).
Cachexia: A Multiorgan Syndrome. Loss of skeletal muscle and adipose tissue are major contributors to cachexia. But many other organs have a role in the cachexia syndrome and the wasting that takes place in muscle may be dependent on alterations in these other organs or tissues. Changes in hypothalamic function and activation of brown adipose tissue, as well as alterations in liver and heart function, also are involved in the syndrome. Recent studies support a role for gut microbiota in cancer cachexia and the possibility of a gut-microbiota-skeletal muscle relationship. Recent data suggest that the conversion of white adipose tissue to brown adipose tissue is triggered by both humoral inflammatory mediators, such as interleukin-6 (IL-6), and tumor derived compounds, such as parathyroid-hormone–related protein (PTHrP). (From Bindels LB, Delzenne NM: Muscle wasting: the gut microbiota as a new therapeutic target? Int J Biochem Cell Biol 45:2186-2190, 2013; Bindels LB et al: Restoring specific lactobacilli levels decreases inflammation and muscle atrophy markers in an acute leukemia mouse model, PLoS One 7(6):e37971, 2012.)

Although several definitions of cachexia exist two factors are significant: weight loss and inflammation. Severe weight loss is primarily from loss of skeletal muscle and body fat. The wasting that occurs in muscle may be dependent on alterations in other organs or tissues including white adipose tissue. Important is that cachexia is multifactorial, involving changes in many metabolic pathways. The cachetic syndrome involves abnormalities in heart function, alterations in liver protein synthesis, changes in hypothalamic mediators, and activation of brown adipose tissue and gastrointestinal function. All of these changes result in a major decrease in quality of life and indirectly result in death in some individuals. The incidence of the syndrome among individuals with cancer is very high and varies by tumor type.
Molecular Basis of Cachexia

Cachexia has been discussed as a type of energy balance disorder where energy intake is decreased and energy expenditure is increased.52 Energy intake and expenditure depends on the tumor type and its growth phase. Because individuals who are being administered total parenteral nutrition still lose weight, increased resting energy expenditure may be the cause of the wasting syndrome.52 Investigators are studying the role of both mitochondria and sarcoplasmic reticulum (SR) in muscle function and its relationship to cachexia. Hypotheses related to these functions include increased production of peroxisome-proliferator–activated receptor-γ co-activator-1α (PGC1α), which can activate a mitochondrial protein (mitofusin-2 [MFN2]) that interacts with muscle SR and controls interorganelle calcium (Ca\(^{2+}\)) signaling. Therefore, one hypothesis is the overexpression of PGC1α can activate MFN2 expression, leading to Ca\(^{2+}\) deregulation, which is closely associated with muscle wasting.52 Muscle weakness and fatigue is related to loss of myofibrillar proteins in muscle cells. Abnormalities in protein and amino acid metabolism are noted in cachetic muscle (Figure 10-21).
Contributing further to muscle wasting is an increase in apoptosis and an impaired capacity for regeneration. Many signaling pathways are involved in protein turnover leading to the wasting process and are activated by inflammatory mediators including cytokines, myostatin, and tumor-derived factors. In addition to muscle wasting, miRNAs may be involved in stimulating the breakdown of adipose tissue. In cancer cachexia, skeletal muscle loss includes major loss of white adipose tissue (WAT). The WAT loss is thought to be caused by (1) increased lipolysis, (2) decreased activity of lipoprotein lipase (LPL), and (3) decreased new or de novo lipogenesis in adipose tissue. New data show that WAT cells undergo a “browning” process during cancer cachexia where they change to beige cells called BAT-like cells. Browning is associated with increased thermogenesis. Tumor-derived compounds, such as IL-6 (which also may be released by immune cells) and
parathyroid-hormone–related protein (PTHRP), may be the drivers of thermogenesis.\textsuperscript{55}

An unusual and frustrating component of cancer care is the person's early satiety, or a sense of being full after only a few mouthfuls of food. Brain mediators are involved in the regulation of food intake and include appetite, satiation, taste, and smell of food. Therefore, the brain is an important organ in anorexia and consequently altered energy balance. Profoundly altered are both orexigenic (appetite-stimulating) and anorexigenic (appetite-suppressing) brain pathways.\textsuperscript{57} (Cytokines are discussed in detail in Chapters 6 and 7.)

**Anemia**

Anemia is commonly associated with malignancy; 20% of persons diagnosed with cancer have hemoglobin concentrations less than 9 g/dl (normal value = 15 g/dl). Mechanisms that cause anemia include chronic bleeding (resulting in iron deficiency), severe malnutrition, cytotoxic chemotherapy, and malignancy in blood-forming organs. Chronic bleeding and iron deficiency can accompany colorectal or genitourinary malignancy. Iron also is malabsorbed in persons with gastric, pancreatic, or upper intestinal cancer. Often there is a defect in the reutilization of iron because of lack of transfer of iron from the storage pool to blood cell precursors. This defect may be caused by increased secretion of IL-6 and hepcidin (a hormone secreted by the liver that regulates the body's iron distribution) (see Chapter 20). Defects in erythropoietin production and shortened duration of red cell survival also have been documented. In addition, anorexia can cause both iron and folate deficiency. Megaloblastic (large red cell) anemias also may develop after methotrexate treatment.

Administration of erythropoietin, which stimulates production of erythrocytes, has been effective in correcting anemia in persons with cancer; fewer red blood cell transfusions were required in most of the studied subjects. In addition, anemias occurring after chemotherapy or radiotherapy have been treated successfully with erythropoietin. However, recent studies have shown that aggressive use of erythropoietin increases the risk of blood clots and can decrease cancer survival.

**Leukopenia and Thrombocytopenia**

Direct tumor invasion of the bone marrow causes both leukopenia (a decreased total white blood cell count) and thrombocytopenia (a decreased number of platelets). More commonly, many chemotherapeutic drugs, which primarily affect rapidly dividing cells, are toxic to the bone marrow, often causing granulocytopenia and
thrombocytopenia. Granulocytopenia also can result from radiation therapy if it encompasses significant areas of the bone marrow. The duration of granulocytopenia and hence the risk of serious infection can be lessened by treatment with recombinant human granulocyte colony–stimulating factor (rhG-CSF, filgrastim). rhG-CSF stimulates white blood cell precursors in the marrow to proliferate and differentiate rapidly. Thrombocytopenia is a major cause of hemorrhage in persons with cancer and is often treated with platelet transfusions. Thrombocytopenia also is an accompanying disorder of disseminated intravascular coagulation that occurs in persons with acute promyelocytic leukemia (see Chapter 21) and severe infections.

**Infection**

Infection is the most significant cause of complications and death in persons with malignant disease. Advanced malignancies are highly immunosuppressive, as well as the radiotherapy and chemotherapy used to treat it. (Factors that predispose persons with cancer to infection are summarized in Table 10-5.) When the absolute granulocyte count falls below 500 cells per microliter, the risk of serious microbial (bacterial and fungal) infection increases. Surgery also can lower resistance to infection because removal of large quantities of tissue, together with hemorrhage, dead spaces, and poor tissue perfusion, can create favorable sites for infection. Hospital-related (nosocomial) infections increase because of indwelling medical devices, inadequate wound care, and the introduction of microorganisms from visitors and other individuals.
**TABLE 10-5**

Factors Predisposing Individuals with Cancer to Infection

<table>
<thead>
<tr>
<th>Factor</th>
<th>Basis</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Age</strong></td>
<td>Many common malignancies occur mostly in older age. Immunologic functions decline with age. General debility reduces immunocompetence. Immobility predisposes to infection. Far-advanced cancer often results in immobility and general debility that worsen with age. Elderly persons are predisposed to nutritional inadequacies. Malnutrition impairs immunocompetence.</td>
</tr>
<tr>
<td><strong>Tumor</strong></td>
<td>Nutritional derangements can result. Sites and circumstances favorable to growth of microorganisms (obstruction, serous or blood effusion, ulceration) can be created. Far-advanced disease predisposes individuals to debility and immobility. Humoral or cellular immune defects may result. Metastasis to bone marrow may cause leukopenia or other defects in immunity.</td>
</tr>
<tr>
<td><strong>Leukemias</strong></td>
<td>Inadequate granulocyte production (impaired phagocytosis) results. Thrombocytopenia (bleeding) can occur. Late effect: chronic lung disease from <em>Pneumocystis carinii</em> pneumonia can develop during therapy.</td>
</tr>
<tr>
<td><strong>Lymphomas and other mononuclear phagocyte malignancies</strong></td>
<td>Humoral and cellular immune defects (anergy, altered immunoglobulin production) result. Late effect: splenectomy in children can cause increased susceptibility to infection.</td>
</tr>
<tr>
<td><strong>Surgical treatment</strong></td>
<td>Invasive procedure interrupts first lines of defense. Radical nature of surgery (removal of large blocks of tissue in lengthy procedures) causes hemorrhage, decreased tissue perfusion, creation of dead spaces, devitalization of tissues. Procedure may be &quot;dirty&quot; surgery (bowel, infected or contaminated areas). Surgery patients are often older and at poor risk. Long preoperative hospitalization often precedes surgery. Patients may have received previous adrenocorticosteroid therapy. Patients may have infections at sites remote from operative area. Nutritional derangements (especially important in head and neck surgery) may result. Lymph node dissection may predispose patient to local infection and impair containment to area. Gynecologic surgery may result in fistulae. Lung surgery may cause bronchopleural fistulae. Debility and immobility may result.</td>
</tr>
</tbody>
</table>

**Gastrointestinal Tract**

The entire gastrointestinal (GI) tract relies on rapidly growing cells to produce an effective barrier to trauma and infection and to provide an absorptive surface for nutrients. Both chemotherapy and radiation therapy may cause a decreased cell turnover, thereby leading to oral ulcers (stomatitis), malabsorption, and diarrhea. The disruption of barrier defenses also increases the risk for infection, especially invasion by a person's own GI microbiome.

Therapy-induced nausea, thought to be caused by an agent's direct action upon the central nervous system's vomiting centers, historically has been a major obstacle for continuing therapy. Aggressive antinausea (antiemetic) therapy, including the centrally acting serotonin 5-hydroxytryptamine (5-HT3) antagonists (such as ondansetron or dolasetron), has allowed better tolerance of highly emetogenic protocols. Other popular antiemetics include steroids and phenothiazines. Synthetic cannabinoids, the active ingredients in marijuana, increase appetite in addition to having antinausea properties. Analgesia often includes opiate agents, vital in treating severe cases of mucosal lesions. Supplemental nutrition through enteral or parenteral routes may be needed to combat malnutrition. Good oral hygiene may help prevent complications arising from mucosal membrane breakdown.
Hair and Skin

Alopecia (hair loss) results from chemotherapy effects on hair follicles. Alopecia is usually temporary, although hair may regrow with a different texture initially. Not all chemotherapeutic agents cause alopecia. Decreased renewal rates of the epidermal layers in the skin may lead to skin breakdown and dryness, altering the normal barrier protection against infection. Radiation therapy may cause skin erythema (redness) and contribute to breakdown.
Diagnosis, Characterization, and Treatment of Cancer

The diagnosis of cancer has a profound effect on individuals and their families. Responses range from depression to resigned fatalism to an aggressive no-holds-barred pursuit of therapy. The choice of therapy should be based on full consideration by the individual, the family, and the medical team of the individual's diagnosis, prognosis, and therapeutic options. Many types of cancer can be effectively treated with chemotherapy, radiotherapy, surgery, and combinations of these modalities. Caregivers must recognize that many individuals seek additional non–science-based explanations and therapies and often use these therapies, either concurrently or sequentially.

Diagnosis and Staging

Histologic Staging

Cancer can be discovered in many ways: after screening tests, from routine exams, and after investigation of symptoms. The symptoms a cancer produces are as diverse as the types of cancer. The location of the cancer can determine symptoms by physical pressure, obstruction, and loss of normal function, or a cancer can cause problems far away from its source by pressing on nerves or secreting bioactive compounds. Whatever the initial complaint, once the diagnosis is suspected and a tumor has been identified, it is essential that tumor tissue be obtained to establish a definitive diagnosis and correctly classify the disease. Various methods of obtaining tissue are described in Table 10-6.

Once tissue is obtained, it is examined microscopically by the pathologist for the histologic hallmarks of cancer detailed in the beginning of this chapter. The classification of the cancer can be further facilitated by a variety of clinically available tests, including immunohistochemical stains, flow cytometry, electron microscopy, chromosome analysis, and genetic studies.
If the diagnosis of cancer is established, it is critical to determine if the cancer has spread, known as the **stage of the cancer**. Staging initially involves determining the size of the tumor, the degree to which it has locally invaded, and the extent to which it has spread (metastasized) (**Figure 10-22**). Specific molecular tests are increasingly used in staging as well. Diverse schemes are used for staging different tumors. In general, a four-stage system is used, with carcinoma in situ regarded as a special case. Cancer confined to the organ of origin is stage 1; cancer that is locally invasive is stage 2; cancer that has spread to regional structures, such as lymph nodes, is stage 3; and cancer that has spread to distant sites, such as a liver cancer spreading to lung or a prostate cancer spreading to bone, is stage 4. One common scheme for standardizing staging is the World Health Organization's TNM system: *T* indicates tumor spread, *N* indicates node involvement, and *M* indicates the presence of distant metastasis (see **Figure 10-22**). The prognosis generally worsens with increasing tumor size, lymph node involvement, and metastasis. Staging also may alter the choice of therapy, with more aggressive therapy being delivered to more invasive disease.

**Tumor Markers**

During surveillance or diagnosis of cancer as well as following therapy, specific
biochemical markers of tumors have proven to be helpful. These tumor markers are substances produced by both benign and malignant cells that are either present in or on tumor cells or found in blood, spinal fluid, or urine. Some tumor markers have been known for many decades. Tumor markers include hormones, enzymes, genes, antigens, and antibodies (Table 10-7). If the tumor marker itself has biologic activity, then it can cause symptoms, such as those described in Table 10-7. For example, the adrenal medulla normally secretes the catecholamine epinephrine (adrenaline). Benign tumors of the adrenal medulla (pheochromocytoma) can produce catecholamines (e.g., adrenaline) in vast excess, leading to rapid pulse rate, high blood pressure, diaphoresis (i.e., sweating), and tremors. Detection of elevated blood or urine levels of catecholamines helps to confirm the diagnosis, and treatment of the disease relieves the symptoms. Tumor markers can be used in three ways: (1) to screen and identify individuals at high risk for cancer; (2) to help diagnose the specific type of tumor in individuals with clinical manifestations relating to their tumor, as in adrenal tumors or enlarged liver or prostate; and (3) to follow the clinical course of a tumor.

To date, no tumor marker has proven satisfactory to screen populations of healthy individuals for cancer. Testing large populations will always detect a few normal individuals with test results at the high end of the normal distribution (the “false positives”), which can lead to expensive and invasive additional tests, and unnecessary concern. Similarly, some individuals with disease will have test results in the normal range (“false negatives”). More importantly, some nonmalignant conditions also can produce tumor markers. The presence of an elevated tumor marker therefore may suggest a specific diagnosis, but it is not used alone as a definitive diagnostic test. For instance, prostate tumors secrete prostate specific antigen (PSA) into the blood. But, enthusiasm has waned for routine testing for PSA
levels. Most men (approximately 75%) with elevated levels of PSA do not have cancer upon biopsy. A taskforce to study the use of PSA detection concluded that for every 1000 men (ages 55 to 69) screened repeatedly, only zero to 1 prostate cancer–related death would be avoided, 100 to 120 men would undergo unnecessary biopsies with some complications, and 110 men would be diagnosed with prostate cancer (frequently slow growing and not life-threatening) and 50 of these would have major complications related to treatment. However, falling levels of PSA after radiation or surgical therapy may indicate successful treatment for prostate cancer, and a later rise may indicate a recurrence. Identification of ideal sensitive and specific tumor markers that are elevated early in the course of common cancers remains a high priority because the early detection of cancer often improves the treatment outcome.

Classification of Tumors—Classic Histology and Modern Genetics

Because our knowledge about the cellular and molecular alterations in individual cancers can influence the choices of therapy, it becomes increasingly important for clinicians to accurately classify each cancer (Box 10-1). The classification, and hence the treatment decisions, of cancers was originally based on gross and light microscopic appearance and is now commonly accompanied by immunohistochemical analysis of protein expression. Increasingly, this is supplemented by a more extensive genetic analysis of the tumors. The range of genetic analysis is expanding rapidly. A single gene may be examined (for example, to determine if there is a characteristic chromosomal translocation diagnostic of chronic myelogenous leukemia [CML]), or a panel of genes and proteins may be examined (e.g., in breast cancer) to determine if the tumor expresses estrogen receptor, progesterone receptor, and the epidermal growth factor (EGF) receptor HER2, or if there are mutations in specific genes that modify response to therapy. In a research setting and increasingly in clinical settings, global gene expression and mutation analysis can be measured using polymerase chain reaction (PCR), microarray, or advanced DNA sequencing technology. These analyses can be used to classify tumors more precisely and may predict the most effective therapy. This detailed analysis of each tumor is a form of personalized medicine that offers therapy based on a very detailed knowledge of the characteristics of each individual's specific cancer. This enhanced molecular characterization subdivides cancers into therapeutically and prognostically relevant smaller groups. As an example, breast cancers can now be subclassified into over four types (luminal A, luminal B, basal-like, and others) based on their expression of specific markers,
such as estrogen receptor, HER2/Neu, and other specific genes and proteins. Each subtype has a different response to therapy and a different prognosis.

### Box 10-1

**Types of Genetic Lesions in Cancer**

1. Point mutations
2. Subtle alterations (insertions, deletions)
3. Chromosome changes (aneuploidy and loss of heterozygosity)
4. Amplifications
5. Gene silencing (DNA methylation, histone modification, microRNAs)
6. Exogenous sequences (tumor viruses)

### Treatment

Until late in the last century the mainstays of cancer therapy have been surgery, chemotherapy, and radiation therapy. These approaches have been highly successful for certain types of cancer, but have many limitations. Immunotherapy has been the Holy Grail of cancer therapists, but successes have been few. Cancer therapy is now in a process of rapid evolution. Armed with a more clear understanding that cancer is in fact multiple diseases that share general hallmarks/enablers and that the specific mechanisms underlying each hallmark may vary considerably among cancers (e.g., the large variety of oncogenes that may be used to differentiate cancers), modern cancer therapy is reaching a stage where complete genetic analysis of an individual cancer may determine the appropriate combination of therapies. Thus, effective therapy may include a combination of reagents targeting several hallmarks and under constant modification to target the evolving cancer cells.

### Surgery

Surgery plays many roles in the care of individuals with cancer. The multiple approaches to obtaining tissue for diagnosis have been discussed. Surgery is often the definitive treatment of cancers that do not spread beyond the limits of surgical
excision. It also is indicated for the relief of symptoms, for instance, those caused by tumor mass obstruction. In selected high-risk diseases, surgery plays a role in the prevention of cancer. For example, individuals with familial adenomatous polyposis because of germline mutations of the *APC* gene have close to a 100% lifetime risk of colon cancer, so a prophylactic colectomy is indicated. Similarly, women with *BRCA1/2* mutations have a markedly increased risk of breast and ovarian cancer, and often choose prophylactic mastectomy or bilateral salpingo-oophorectomy (removal of ovaries and fallopian tubes), or both.

Key principles apply specifically to cancer surgery, including obtaining adequate surgical margins during a resection to prevent local recurrences, placing needle tracks and biopsy incision scars (that may be contaminated with cancer cells) carefully so they can be removed in subsequent incisions, avoiding the spread of cancer cells during surgical procedures through careful technique, and paying attention to obtaining adequate tissue specimens during biopsies so that the pathologist can be confident of the diagnosis. Additionally, the surgeon provides critical staging information by inspection, sampling, and removal of local and region lymph nodes during procedures.

**Radiation Therapy**

Radiation therapy is used to kill cancer cells while minimizing damage to normal structures. Ionizing radiation damages cells by imparting enough energy to cause molecular damage, especially to DNA. The damage may be lethal, in which the cell is killed by radiation; potentially lethal, in which the cell is so severely affected by radiation that modifications in its environment will cause it to die; or sublethal, in which the cell can subsequently repair itself. Cellular compartments with rapidly renewing cells are, in general, more radiosensitive. Effective cell killing by radiation also requires good local delivery of oxygen, something not always present in large cancers. Radiation produces slow changes in most cancers and irreversible changes in normal tissues as well. Because of these irreversible changes, each tissue has a maximum lifetime dose of radiation it can tolerate. Radiation is well suited to treat localized disease in areas that are hard to reach surgically, for example, in the brain and pelvis. A number of radiation delivery methods are available, with external beam being the most common. Radiation sources, such as small $^{125}$I-labeled capsules (also called seeds), can also be temporarily placed into body cavities, a delivery method termed **brachytherapy**. Brachytherapy is useful in the treatment of cervical, prostate, and head and neck cancers.
Chemotherapy

The era of modern chemotherapy began with the observation in World War II that mustard gas exposure caused suppression of the bone marrow. Related compounds, such as nitrogen mustard and cyclophosphamide, were then tested and produced clinical responses in hematologic malignancies, including lymphomas. Also in the late 1940s, based on the remarkable clinical observation that the vitamin folic acid could increase leukemia growth, antifolate drugs were developed (leading ultimately to methotrexate) that produced remissions in previously untreatable leukemia.

All chemotherapeutic agents take advantage of specific vulnerabilities in target cancer cells. Antimetabolites, such as methotrexate and L-asparaginase, block normal growth pathways in all cells, but leukemia and other cancer cells are exquisitely sensitive to folic acid and asparagine deprivation, whereas nonmalignant cells are far less sensitive. Similarly, some cancer cells are highly sensitive to DNA-damaging agents, such as cyclophosphamide and anthracyclines, because of the oncogenic mutations that accelerate the cell cycle and DNA synthesis. Cellular checkpoints prevent normal cells treated with microtubule-directed drugs, such as vincristine and the taxanes, from undergoing mitosis, whereas cancer cells treated with these agents lack normal checkpoints, continue through mitosis, and undergo mitotic catastrophe (see Chapter 1).

Single chemotherapeutic agents often shrink cancers, but these drugs given alone rarely, if ever, provide a cure. Hence, chemotherapy drugs are usually given in combinations designed to attack a cancer from many different weaknesses at the same time and to limit the dose and therefore the toxicity of any single agent. Cancers contain a very large number of cells, and commonly a small fraction of those cells may be resistant to a particular drug. However, those cells are likely to be sensitive to the second or third drug in a chemotherapy cocktail. Scheduling of drug administration is also very important, with many studies showing cancers are more likely to develop drug resistance if there are significant delays between planned courses of chemotherapy.

Chemotherapy can be used for several distinct purposes. **Induction chemotherapy** seeks to cause shrinkage or disappearance of tumors. In Hodgkin disease, for example, chemotherapy alone can be used in some cases to cure the disease. In other settings, chemotherapy may shrink the tumor and improve symptoms without ultimately providing a cure. **Adjuvant chemotherapy** is given after surgical excision of a cancer with the goal of eliminating micrometastases. **Neoadjuvant chemotherapy** is given before localized (surgical or radiation) treatment of a cancer. As with induction chemotherapy, the effectiveness, or lack
of neoadjuvant therapy can be measured (for example, with follow-up scans). Neoadjuvant therapy can shrink a cancer so that surgery may spare more normal tissue. For example, in the bone cancer osteogenic sarcoma, neoadjuvant therapy often converts a large tumor mass into a much smaller mass, allowing the surgeon to perform a limb-sparing excision rather than an amputation.

**Immunotherapy**

The expression of unique antigens on cancer cells that can be targeted by T cells has driven the quest for effective therapies to initiate an immune response, boost a currently inadequate immune response, or convert a tumor-protective immune response to a destructive one. Since the 1950s this quest has been characterized by promises and frustrations.

Vaccines have been extremely effective in protecting us against infective agents. Although they generally induce a prophylactic immune response, at least one vaccine (against rabies) is administered after the infection. Vaccines against oncogenic viruses provide protection and prevent the onset of viral-induced tumors. For approximately 50 years, numerous potential therapeutic vaccines have been tested with little success. Initially, whole tumor cell vaccines prepared from an individual's own cancer (autologous) or from cancers from other individuals (allogeneic) were used, with or without adjuvants that induced inflammatory responses (e.g., BCG) or augmented the vaccine's immunogenicity. Several allogeneic cancer cell vaccines continue to be tested. So far, none has been shown to be effective enough to be licensed. Other approaches included immunization with the following:

- Protein extracts from cancers
- Peptides that represented the epitope from these proteins
- Dendritic cells that have processed and present cancer antigens
- DNA containing the genetic sequence for cancer antigens that transfects the recipient's cells and expresses that antigen
- Viral vectors that contain the genetic information for cancer antigens

Several trials are underway, and one approach has been approved by the FDA. Sipuleucel-T (Provenge®) has been approved for the treatment of metastatic prostate cancer that is resistant to conventional therapy. Dendritic cells are obtained from an individual with prostate cancer and incubated with a protein resulting from the fusion of prostatic acid phosphatase, a cancer antigen found in 95% of prostate cancers, and granulocyte-macrophage colony–stimulating factor (GM-CSF), an immune cell stimulating cytokine. The dendritic cells process and present the
antigen and are infused back into the patient. In clinical trials treatment with sipuleucel-T extended the lives of patients by 4.1 months. These results may not seem spectacular, but were meaningful in this group of patients with very advanced and terminal disease. Other vaccine approaches against B-cell lymphoma and melanoma have shown promising results.  

Passive immunotherapy using lymphocytes against cancer cell antigens has been attempted, with limited success, since the early 1970s. In recent years, passive administration of tumor-targeting lymphocytes (adoptive cell therapy, ACT) has developed more promise as a result of various pretreatment ex vivo techniques that improve treatment efficacy. A major source of patient's lymphocytes is those that have infiltrated the tumor (tumor-infiltrating lymphocytes, TIL). The efficacy of these cells is increased by depleting the Treg cells within the population or by engineering the T-cell receptor for greater specificity against the tumor.

A family of monoclonal antibodies, called checkpoint inhibitors, is under investigation. These antibodies are directed against co-stimulatory molecules involved in repressing T-cell immune responses (see Chapter 7). By blocking inhibitory signals, T-cytotoxic cells may retain tumor-killing capacity.

**Targeted Disruption of Cancer**

As discussed previously, cancers appear to share a variety of hallmarks that contribute to the malignant phenotype. Recent molecular and genetic analyses of groups of cancer can classify an individual's cancer by the spectrum of mutations underlying the cancer phenotype. However, each of the therapeutic approaches described previously generally treats specific vulnerabilities of the cancer rather than a variety of contributing factors. That approach is not successful in most invasive cancers because some cancer cells may undergo further mutation leading to therapeutic resistance.

Exceptions include targeted drugs, used in combination with conventional chemotherapy, against very specific characteristics of selected cancers. For example, imatinib is a competitive inhibitor of tyrosine kinases, primarily the BCR-ABL tyrosine kinase (Table 10-8). It is highly effective in treating CML but ineffective in virtually all other cancers. Monoclonal antibodies against the CD20 antigen expressed on some B-cell lymphomas, the epidermal growth factor (EGF) receptor on colon cancers and head and neck cancers, and the HER2 EGF receptor on breast cancer are relatively successful. These drugs are so tightly targeted they have much less toxicity than conventional chemotherapies that have targets in virtually all cells.

Tumor growth and progression is dependent on a variety of mutations leading to expression of oncogenes, inactivation of tumor-suppressor molecules, and interactions with inflammatory cells in the tumor microenvironment that foster angiogenesis, resistance to apoptosis and immune-mediated cancer cell death, altered tumor cell metabolism, and metastasis. A more efficacious therapeutic approach, therefore, may be a combination of drugs highly targeted to cancer hallmarks.68

More than 25 drugs are listed at the National Cancer Institute as cancer-targeting agents that inactivate oncogenes, block angiogenesis, and affect cancer cell metabolism.69 Monoclonal antibodies are available that induce apoptosis in tumor-infiltrating cells such as TAM, Treg cells, and tumor endothelium.70 Additionally, specific antagonists may neutralize the effects of cytokines, chemokines, and other tumor-enhancing mediators produced in the tumor microenvironment.71 These are usually in the form of monoclonal antibodies, which are available against TNF-α, VEGF, HER-2, and other ligands and their receptors. Such highly specific targeting would minimize secondary toxic effects.

Quick Check 10-5

1. Describe the major clinical manifestations of cancer.

2. How is cancer diagnosed?

3. What are the most common treatments of cancer?
Did You Understand?

Cancer Terminology and Characteristics

1. Benign tumors are usually encapsulated and well differentiated and do not spread to distant locations.

2. Malignant tumors, compared with benign tumors, have more rapid growth rates, specific microscopic alterations (anaplasia, loss of differentiation), absence of normal tissue organization, and no capsule. They invade blood vessels and lymphatics and have distant metastases.

3. Carcinomas arise from epithelial tissue, and leukemias are cancers of blood-forming cells. Carcinoma in situ (CIS) refers to noninvasive epithelial tumors of glandular or squamous cell origin.

The Biology of Cancer Cells

1. Genetic changes are the basis of cancer. These changes include small and large DNA mutations that alter genes, chromosomes, and non–coding RNAs, as well as epigenetic changes because of altered chemical modifications of DNA and histones.

2. The incidence of cancer increases with age as the individual acquires genetic hits or mutations with time. Mutations activate growth-promotion pathways, block antigrowth signals, prevent apoptosis, stimulate telomerase and new blood vessel growth, and allow tissue invasion and distant metastasis.

3. Key genetic mechanisms have a role in human carcinogenesis: (1) mutations of proto-oncogenes, resulting in hyperactivity of growth-related gene products (such genes are called oncogenes); (2) mutation of genes, resulting in loss or inactivity of gene products that normally would inhibit growth (such genes are called tumor-suppressor genes); and (3) mutation of caretaker genes that normally prevent mutations.

4. Some mutations are more important for cancer progression. These mutations can be called driver mutations. Passenger mutations are random mutations that presumably do not contribute to cancer progression.

5. Cancerous cells characteristically express mutated or overexpressed proto-
oncogenes, referred to as oncogenes, which are independent of normal regulatory mechanisms and signal uncontrolled proliferation.

6. Some oncogenes, such as RAS, result from point mutations.

7. Oncogenes can result from genetic translocations. The Philadelphia chromosome in chronic myeloid leukemias (CML) results from a translocation that creates a novel protein fusion of the BCR and ABL genes and expression of an unregulated promoter of cell growth.

8. Tumor-suppressor genes must be inactivated in cancer cells by mutations to each allele, one from each parent.

10. In rare families, an initial inheritable mutation in a tumor-suppressor gene, such as TP53, the retinoblastoma gene (RB), or the breast cancer genes (BRCA1 and BRCA2), may lead to a greatly increased risk for developing particular cancers.

11. Caretaker genes are responsible for maintaining genomic integrity. Inherited mutations can disrupt caretaker genes and cause chromosome instability.

12. Abnormal gene silencing is emerging as a major factor in cancer progression. Gene expression can be regulated in a heritable manner (i.e., passed from a parent to a child or from a single cell to its progeny) by an “epigenetic” mechanism called silencing.

13. Changes in gene regulation can affect not just single genes, but entire networks of signaling. Gene expression networks can be regulated by changes in microRNAs (miRNAs or miRs) and other non–coding RNAs (ncRNAs).

14. Cancer cells are immortal.

15. When they reach a critical age, cancer cells activate telomerase to restore and maintain their telomeres, thereby allowing cancer cells to divide repeatedly or become immortal.
16. Like many normal adult tissues, cancers can contain rare stem cells that provide a source of immortal cells. To fully eradicate a cancer, it may be necessary to target the cancer stem cell.

17. Most of the genetic and epigenetic alterations that cause cancer occur within the somatic tissues during the lifetime of the individual.

18. Access to the vascular system is essential for tumor growth.

19. Stromal cells and cancer cells can secrete multiple factors, such as vascular endothelial growth factor (VEGF), that stimulate new blood vessel growth (called neovascularization or angiogenesis).

20. The successful cancer cell divides rapidly, with the consequent requirement for the building blocks of new cells; cancer cell division often occurs in a hypoxic and acidic environment. Many cancer genes also encourage aerobic glycolysis and promote high glucose utilization of a cancer.

21. In cancer, defects in the intrinsic or extrinsic pathways, or both, provide resistance to apoptotic cell death.

22. Overexpression of BCL-2 blocks apoptosis in most follicular B-cell lymphomas.

23. Some conditions of chronic inflammation increase the risk of developing cancer. A prime example is the association between gastric cancer and infection with Helicobacter pylori.

24. Cells recruited to the tumor microenvironment are essential to the growth and spread of cancer and are active participants in induction of cellular proliferation, angiogenesis, degradation of extracellular matrix, suppression of infiltrating immune cells, and the development and spread of metastatic cells.

25. Defects in the immune system increase the risk of viral-associated cancers but have a minimal effect on the risk of other cancers.

26. Antibodies induced by vaccines against oncogenic viruses, such as human papillomavirus (HPV) and hepatitis B virus (HBV), protect against initial infection and development of cervical and liver tumors, respectively.

27. Unique antigens and other markers on tumor cells can be recognized by T cells
and NK cells of the immune system, leading to destruction of the tumor cell.

28. Cancer cells can evade rejection by the immune system by production of immunosuppressive factors, induction of immunosuppressive T-regulator cells, evolution of tumor-antigen negative variants, or suppressed expression of antigen-presenting MHC class I molecules.

29. Metastasis is the major cause of death from cancer.

30. Metastasis is a complex process that requires cells to have many new abilities, including the ability to invade, survive, and proliferate in a new environment.

31. Invasion consists of loss of cell-to-cell contact, degradation of the extracellular matrix (ECM), and migration of tumor cells to the vascular or lymphatic systems. Stromal cells, particularly tumor-associated macrophages (TAMs), are essential to this process.

32. Carcinomas undergo a process of epithelial-mesenchymal transition (EMT) during which many epithelial-like characteristics are lost (e.g., polarity, adhesion to basement membrane), resulting in increased migratory capacity, increased resistance to apoptosis, and a dedifferentiated stem cell–like state that favors growth in foreign microenvironments and establishment of metastatic disease.

33. Some cancers appear to selectively home to particular metastatic sites, which may be a result of expression of particular receptors for ligands expressed by cells at the site.

**Clinical Manifestations of Cancer**

1. Paraneoplastic syndromes are rare symptom complexes, often caused by biologically active substances released from a tumor or by an immune response triggered by a tumor, that manifest as symptoms not directly caused by the local effects of the cancer.

2. Clinical manifestations of cancer include pain, cachexia, anemia, leukopenia, thrombocytopenia, and infection.

3. Pain is generally associated with the late stages of cancer. It can be caused by pressure, obstruction, invasion of a structure sensitive to pain, stretching, tissue destruction, and inflammation.
4. Fatigue is the most frequently reported symptom of cancer and cancer treatment.

5. Cachexia is a multiorgan syndrome with many clinical manifestations including anorexia; muscle wasting; thermogenesis; altered heart and liver function; gut malabsorption; early satiety; taste alterations; and altered protein, lipid, and carbohydrate metabolism. Two factors are most significant: muscle loss and inflammation. Muscle wasting involves many protein signaling pathways and inflammatory mediators. Profoundly altered are both appetite-stimulating and appetite-suppressing brain pathways.

6. Anemia associated with cancer usually occurs because of malnutrition, chronic bleeding and resultant iron deficiency, chemotherapy, radiation, and malignancies in the blood-forming organs.

7. Leukopenia is usually a result of chemotherapy (which is toxic to bone marrow) or radiation (which kills circulating leukocytes).

8. Thrombocytopenia is usually the result of chemotherapy or malignancy in the bone marrow.

9. Infection may be caused by leukopenia, immunosuppression, or debility associated with advanced disease. It is the most significant cause of complications and death.

10. The gastrointestinal tract relies on rapidly growing cells to provide an absorptive surface for nutrients. Both chemotherapy and radiation therapy may cause decreased cell turnover, thereby leading to oral ulcers (stomatitis), malabsorption, and diarrhea.

11. Alopecia (hair loss) results from chemotherapy effects on hair follicles. Alopecia is usually temporary, although hair may initially regrow with a different texture. Not all chemotherapeutic agents cause alopecia. Decreased renewal rates of the epidermal layers in the skin may lead to skin breakdown and dryness, altering the normal barrier protection against infection.

**Diagnosis, Characterization, and Treatment of Cancer**

1. The diagnosis of cancer requires a biopsy and examination of tumor tissue by a
pathologist. Cancer classification is established by a variety of tests.

2. Tumor staging involves the size of the tumor, the degree to which it has locally invaded, and the extent to which it has spread. A standard scheme for staging is the T (tumor spread), N (node involvement), and M (metastasis) system.

3. The classification, and hence the treatment decisions, of cancers was originally based on gross and light microscopic appearance, and is now commonly accompanied by immunohistochemical analysis of protein expression. Increasingly, this is supplemented by a more extensive molecular analysis of the tumors.

4. Tumor markers are substances (i.e., hormones, enzymes, genes, antigens, antibodies) found in cancer cells and in blood, spinal fluid, or urine. They are used to screen and identify individuals at high risk for cancer, to help diagnose specific types of tumors, and to follow the clinical course of cancer.

5. Cancer is treated routinely with surgery, radiation therapy, chemotherapy, and combinations of these modalities.

6. Surgical therapy is used for nonmetastatic disease (in which cure is possible by removing the tumor) and as a palliative measure to alleviate symptoms.

7. Ionizing radiation causes cell damage; therefore the goal of radiation therapy is to damage the tumor without causing excessive toxicity or damage to nondiseased structures.

8. The theoretic basis of chemotherapy is the vulnerability of tumor cells in various stages of the cell cycle.

9. Modern chemotherapy uses combinations of drugs with different targets and different toxicities.

10. Immunotherapy attempts to modify the immune system from a cancer-protective state to a destructive condition.

11. Future treatment of tumors will, most likely, use a careful histologic and genetic analysis of individual cancers that prescribes a combination of tumor-targeting drugs to simultaneously disrupt multiple hallmarks of that particular cancer.

Chemical and Occupational Hazards as Carcinogens, 293
Although cancer arises from a complicated and an interacting web of multiple etiologies, avoiding high-risk behaviors and exposure to individual carcinogens, or cancer-causing substances, will prevent many types of cancer (Figure 11-1). Research has shown that lifestyle behaviors, dietary and environmental factors, and occupational exposure contribute to the number of cancer cases and deaths.\textsuperscript{1-3} In this context, any of the following factors can contribute to the development of cancer\textsuperscript{4-6}:

• Lifestyle choices, such as smoking, alcohol use, nutritional intake
• Lack of physical exercise and overweight/obesity
• Infections, sexual practices
• Environmental conditions, including exposure to sunlight, natural and medical radiation, workplace exposures, and involuntary or unknown exposures
• Prescribed and illicit medications
• Socioeconomic factors that affect exposures and susceptibility
• Carcinogenic substances present in air, water, and soil
Estimates of environmental factors and their attributable risk for cancer vary. The International Agency for Research on Cancer (IARC) completed a review of the more than 100 chemicals, occupations, physical agents, biologic agents, and other agents classified as carcinogenic to humans. Simplified tables with a list of classifications by cancer sites with sufficient or limited evidence in humans are contained in Table 11-1.

*FIGURE 11-1 Key Associations and Causes of Cancer. Tobacco, diet and alcohol, obesity, lack of physical activity, hormones, infections, ionizing radiation, occupational hazards, reproductive factors, and ultraviolet light are key factors for cancer. Although diet is key and known to affect cancer risk, determining specific dietary factors has been very difficult and is emerging.*

Genetics, Epigenetics, and Tissue

Cancers are caused by environmental-lifestyle factors and genetic factors (Figure 11-2). Patterns of cancer incidence around the world are environmental in origin—and not primarily genetic. At the level of the cell, cancer is driven by genetic alterations and epigenetic abnormalities with included variations in detoxifying enzymes or DNA repair genes. Interacting factors causing cancer risk are weaker immune systems and differences in hormone levels and metabolic factors (see Chapter 10). These interacting factors are influenced by the greater external environment and the cell's immediate environment. The biologic environment surrounding cells includes metabolic and hormonal factors, for example, excess estrogen production, inflammation, and disordered glucose and lipid metabolism. Thus, the biologic environment is modified by metabolic requirements, physical activity, infections, nutrition, occupational carcinogens, air pollution, and many other environmental factors. Investigators are challenged to connect the complex web between genotype, phenotype, and the environment to understand a person's chances of developing cancer.
Cancer development and progression involves the tissue microenvironment, or stroma. Emerging is the importance of the microenvironment's interaction with environmental factors because stromal tissue has various immune cells that can promote inflammation. Chronic inflammation is at the interface of environmental factors and genetics. Inflammation caused by environmental factors includes, for example, inhaled tobacco smoke, asbestos fibers, or fine particles in the air from diesel engine exhaust and other industrial sources. These sources are major factors in lung and other respiratory tract cancers.\textsuperscript{7,8} In summary, once malignant phenotypes have developed, complex interactions occur between the tumor, the surrounding stroma, and the cells of the immune and inflammatory systems (see Chapter 10).

Quick Check 11-1

1. Discuss what is meant by “environment is the main cause of cancer.”

2. What is the role of the microenvironment in cancer development and
Incidence and Mortality Trends

Incidence Trends

Globally, cancer is reported to become a major cause of morbidity and mortality in the coming decades in all regions of the world⁹ (see Health Alert: Global Cancer Statistics and Risk Factors Associated with Causes of Cancer Death). According to a report by GLOBACAN, an estimated 14.1 million new cancer cases and 8.2 million cancer deaths were reported and 32.6 million people were found to be living with cancer (diagnosed in the past 5 years) in 2012 worldwide.¹⁰ The global cancer burden is shifting from the more developed countries to economically disadvantaged countries.¹¹ In the 2013 annual report to the nation, the National Cancer Institute, American Cancer Society, the Centers for Disease Control and Prevention, and the North American Association of Central Cancer Registries collaborated to provide updates on cancer incidence, death rates, and trends in these rates for the United States.¹² Incidence rates were calculated for all cancer sites combined, childhood cancers (ages 0 to 14 and 0 to 19 years), and the 17 most common cancers among men and 18 most common cancers among women to enable the overall 15 most common cancers for all races and ethnicities combined and for the 5 major racial and ethnic groups (black, white, Asian and Pacific Islander [API], American Indian/Alaska Native [AI/AN], and Hispanic) by gender.¹² Overall, cancer incidence rates in all racial and ethnic groups and genders combined were stable from 2000 to 2009.

Among men, overall cancer incidence decreased on average by 0.6% annually from 1994 to 2009. For women, overall cancer incidence rates decreased 0.5% annually from 1998 to 2006, but rates were stable from 2006 to 2009.¹² For children, overall cancer incidence rates increased by 0.6% per year aged 0 to 14 years and by 0.7% per year among children aged 0 to 19 years from 2000 to 2009, a trend continuing from 1992. Among men, incidence rates from 2000 to 2009 decreased for 5 of the 17 most common cancers: prostate, lung and bronchus (lung), colon and rectum (colorectal), stomach, and larynx. In contrast, rates among men during the same time period increased for 6 cancers: kidney and renal pelvis (kidney), pancreas, liver and intrahepatic bile duct (liver), thyroid, melanoma of the skin (melanoma), and myeloma. Incidence rates among women decreased from 2000 to 2009 for 7 of the 18 most common cancers: lung, colorectal, urinary bladder (bladder), cervix uteri (cervix), oral cavity and pharynx, ovary, and stomach. Among women, incidence rates increased for 7 cancers from 2000 to 2009: thyroid, melanoma, kidney, pancreas, leukemia, liver, and corpus and uterus (uterus).
Incidence rates were stable for the remaining cancers from 2000 to 2009, including breast cancer and non-Hodgkin lymphoma in men and women.\textsuperscript{12}

From 2005 to 2009 for all cancer sites combined and all racial and ethnic groups, cancer incidence rates were higher among men than women.\textsuperscript{12} For all racial and ethnic groups black men had the highest overall cancer incidence rate. The highest incidence rates among men were reported for prostate cancer, followed by lung and colorectal cancer in each group, except for Hispanics, and for them colorectal cancer ranked second.\textsuperscript{12} For the same time period, among women the highest incidence rates were in whites followed by blacks. Breast cancer had the highest incidence rate, followed by lung and colorectal cancers, except among API and Hispanic women, for them colorectal cancer was more common than lung cancer.\textsuperscript{12} Uterine cancer ranked fourth among women for each group except API women, for them thyroid cancer was the fourth most common cancer. During the period 2000 to 2009, incidence rates for all cancers declined among men of each racial and ethnic group except the decline for AI/AN men that was not statistically significant.\textsuperscript{12} In contrast, rates for all cancers combined among women decreased only in whites and Hispanics.\textsuperscript{12} Among children 0 to 19 years of age, cancer incidence rates increased for black and Hispanic children and were stable for children of all other racial and ethnic groups; however, blacks had the lowest rates of any racial and ethnic group.\textsuperscript{12}

**Health Alert**

**Global Cancer Statistics and Risk Factors Associated with Causes of Cancer Death**
The growth of an aging population and increasing prevalence of established risk factors—smoking, overweight, physical inactivity, changing reproductive patterns associated with urbanization, and economic development—are increasing the occurrence of cancer. In 2012 worldwide, based on GLOBOCAN, about 14.1 million new cancer cases and 8.2 million deaths occurred. Lung cancer is the leading cause of cancer death among males in both developed and developing countries and lung cancer has surpassed breast cancer as the leading cause of cancer death among females in more developed countries. Breast cancer is the leading cause of cancer death among females in less developed countries. In developed countries, other leading causes of cancer death include colorectal cancer among males and females and prostate cancer among males. In less developed countries, the leading causes of cancer death are liver and stomach cancer among...
males and cervical cancer among females. Of concern is that cancer incidence rates for all cancers combined are nearly twice as high in more developed countries in both genders, but mortality rates are only 8% to 15% higher in more developed countries. This disparity reflects many factors including geographic regional differences in the mix of types of cancer, which is effected by risk factors, detection practices, and availability of treatment. Risk factors associated with leading causes of cancer death include tobacco use (lung, colorectal, stomach, and liver cancer), overweight/obesity and physical inactivity (breast and colorectal cancer), and infection (liver, stomach, and cervical cancer). Effective application of tobacco control, vaccination, and use of early detection tests could prevent a substantial portion of cancer cases and deaths.

**Mortality Trends**

Overall cancer death rates have been declining since the early 1990s, with rates decreasing approximately 1.8% per year in men and by 1.4% per year in women from 2000 to 2009. Rates in children have continued to decrease since 1975 with a brief interruption in the decrease from 1998 to 2003. From the period 2000 to 2009 and the period from 2005 to 2009, death rates among men decreased for 10 of the 17 most common cancers (lung, prostate, colorectal, leukemia, non-Hodgkin lymphoma, kidney, stomach, myeloma, oral cavity and pharynx, and larynx). Rates increased for men for cancers of the pancreas, liver, and melanoma. For the same time periods, death rates among women decreased for 15 of the 18 most common cancers (lung, breast, colorectal, ovary, leukemia, non-Hodgkin lymphoma, brain and central nervous system, myeloma, kidney, stomach, cervix, bladder, esophagus, oral cavity and pharynx, and gallbladder). Death rates increased for women for cancers of the pancreas, liver, and uterus.

For all racial and ethnic groups, for both genders, and children for the time period 2000 to 2009, overall cancer death rates declined. Among men, death rates for the most common cancers (lung, colorectal, and prostate) decreased in all racial and ethnic groups, except among AI/AN men, where the decreases for lung and colorectal cancers were not statistically significant. Among women, death rates for lung, breast, and colorectal cancers decreased in all racial and ethnic groups, except among AI/AN women for all three cancers and among API women for lung cancer. Increased death rates occurred for liver cancer in white, black, and Hispanic men and among white and Hispanic women, but rates decreased among API men and women. Death rates for pancreatic cancer were stable among population groups except they increased among white men and women and API
men. Melanoma death rates increased only among white men.¹²
In Utero and Early Life Conditions

From studies of the etiology of certain cancers, it is widely accepted that a long latency period precedes the onset of adult cancers. Accumulating data suggest early life events influence later susceptibility to certain chronic diseases (Figure 11-3). Developmental plasticity is the degree to which an organism's development is contingent (external cues) on its environment. Specifically, the developmental origins' hypothesis postulates that nutrition and other environmental factors affect cellular pathways during gestation, enabling a single genotype to produce a broad range of adult phenotypes. Plasticity refers to the ability of genes to organize physiologically or structurally in response to environmental conditions during fetal development. The hypothesis also postulates that persistent epigenetic adaptations that occur early in development in response to maternal nutrition and the environment are associated with increased susceptibility to cancer and other adult-onset chronic diseases. Throughout in utero development, the placenta plays a major role in controlling growth and development. Because the placenta is a regulator of the intrauterine environment and can be influenced by exposures throughout pregnancy, much research is being done with DNA methylation linking environmental cues to placental pathologies and adult life. The Dutch Famine Birth Cohort is a well-known study of the effects of prenatal undernutrition in humans. Undernutrition was linked to increased heart disease, metabolic disorders, and a possible link with breast cancer decades later. Early versus late undernutrition in pregnancy indicated that the first trimester of pregnancy is particularly vulnerable to disease outcome in adulthood. Much research is needed to understand nutrition in pregnancy and child vulnerabilities later in life. Recently, a striking experiment in mice demonstrated how extra vitamin doses during pregnancy in the mother's diet changed the fur color of pups. This was the first study to show maternal nutrition and subsequent phenotype changes. The nutrients (B_{12}, folic acid, choline, and betaine) silenced the gene that rendered mice fat and yellow but did not alter its DNA sequence. Silencing, or switching the gene off, linked prenatal diet to such diseases as diabetes, obesity, and cancer. These concepts, called the developmental basis of health and disease, are defining the hypothesis of disease onset. Subsequently, the focus of disease prevention and intervention needs to include the decades before onset—that is, in utero and neonatal periods. Emerging studies on epigenetic mechanisms in dietary-associated transgenerational human disease will, hopefully, lead to beneficial health outcomes in the next generation.
FIGURE 11-3  Fetal Vulnerability to External and Internal Environments. The fetus is particularly vulnerable to changes in the external and internal environments, which can have immediate and lifelong consequences. Such environmentally induced changes can occur at multiple levels, including molecular and behavioral. Ultimately these alterations may be epigenetic, inducing mitotically heritable alterations in gene expression without changing the DNA. (Adapted from Crews E, McLachlan JA: Endocrinology 147[6 suppl]:S4-S10, 2006.)

Perhaps one of the best examples of early life events and future cancer is the chemical exposure to diethylstilbestrol (DES), a synthetic nonsteroidal estrogen. This medication was prescribed between 1938 and 1971 to attempt to prevent multiple pregnancy-related problems, such as miscarriage, premature birth, and abnormal bleeding. By the 1950s it became clear that DES interfered with the development of the reproductive system in the fetus and did not prevent miscarriage. Data suggest that a DES-associated increase in cancer of the female genital tract is elevated throughout a woman's reproductive years. More recent studies have revealed that daughters of women who took DES during pregnancy may have a slight increased risk of breast cancer before age 40 (i.e., 1.9 times the risk compared with unexposed women at age 40). For every 1000 DES-exposed women ages 45 to 49, it is estimated that four will be diagnosed with breast cancer.

Research from animal studies has demonstrated a relationship between DES exposure and an increased rate of a rare type of testicular cancer (rete testis) and
Whether DES-exposed sons have increased risks of testicular cancer and prostate cancer are unclear and more evidence is needed as the cohort of men age. Meta-analysis provides evidence that testicular cancer, hypospadias, and cryptorchidism are all positively associated with prenatal exposure to DES. Although controversial, according to the NCI, DES inhibits the hypothalamic-pituitary-gonadal axis, thereby blocking testicular synthesis of testosterone, lowering plasma testosterone levels, and inducing a chemical castration. Testicular cancer is becoming more common in low- and middle-income countries where optimal treatment may not exist.

In summary, fetal programming defines, in part, the developmental origins of health and disease. The evidence for specific DNA methylation marks, in utero environments, and future phenotypes is growing. Increasing the complexity is the recent report that genotype and gene-environmental interactions explain substantial proportions of interindividual variation in the methylome (set of nucleic acid methylation modifications in the genome or cell) at birth. This new report suggests the possible importance in both fixed genetic variation and environmental factors in understanding epigenetic variation. In addition, epigenetic effects may help explain transgenerational effects (Tables 11-2 and 11-3). For example, Newbold and colleagues demonstrated that DES-related reproductive cancers in mice also occurred in the grandsons and granddaughters of mothers treated with DES.

Quick Check 11-2

1. Discuss briefly the incidence rates and death rates of common cancers among racial and ethnic groups

1. Define developmental plasticity.

2. Discuss how epigenetic processes can be modified by environmental factors.

3. Define the developmental basis of health and disease.

Environmental-Lifestyle Factors

Tobacco Use

Cigarette smoking is carcinogenic and remains the most important cause of cancer. Tobacco smoking causes cancer in more than 15 organ sites, and exposure to secondhand smoke and parental smoking causes cancer in daughters and sons and in other nonsmokers. The largest preventable cause for cancer is tobacco use. More than 20 million premature deaths are attributable to smoking and exposure to secondhand smoke. The risk is greatest in those who begin to smoke when young and continue throughout life, but tobacco smoking is pandemic, affecting more than 1 billion people of all ages. Importantly, the eradication of tobacco use can only be achieved by preventing children and adolescents from starting tobacco use. Globally, tobacco use is greatest in developing countries, where 84% of 1.3 billion current smokers live. Asia is now considered the largest tobacco producer and consumer in the world. The World Health Organization (WHO) reports tobacco use causes more than 6 million deaths per year from cancer, chronic lung disease, cardiovascular disease, and stroke. On average, smokers die 13 to 14 years earlier than nonsmokers, about 25% will die prematurely during middle age (35 to 69 years).

Cigarette smoking is the leading cause of preventable death in the United States, accounting for more than 480,000 deaths or 1 of every 5 deaths each year. About 18.1% of all U.S. adults smoke cigarettes. Estimates of cigarette smoking by age are as follows: 17.3%, ages 18 to 24; 21.6%, ages 25 to 44; 19.5%, ages 45 to 64; and 8.9%, ages 65 and older. Cigarette smoking is more common among men (20.5%) than women (15.8%), and the prevalence varies by race or ethnicity, or both, with American Indians/Alaska Natives (21.8%) having the highest prevalence and Asians (10.7%) having the lowest. It is more common among adults living below the poverty level (27.9%) than those at or above the poverty level (17.0%); it is significantly higher in the South (19.7%) and Midwest (20.6%) than in the West (14.2%) and Northeast (16.5%); and it is more prevalent in those having a disability/limitation (22.7%) than in those without a disability/limitation (16.5%). During the period from 2005 to 2012, cigarette smoking prevalence declined among U.S. adults and the quit ratio increased. Although the incidence of smoking is lower in women, the disease risks have risen sharply and are now equal to those in men for lung cancer, chronic obstructive pulmonary disease, and cardiovascular disease.

Smoking affects nearly every organ of the body (Figure 11-4). Since the first Surgeon General's report on smoking and health in 1964, more than 20 million
Americans have died as a result of smoking. Most of these deaths were adults with a history of smoking, but about 2.5 million were nonsmokers who died from lung cancer and heart disease from secondhand smoke (see Figure 11-4). Secondhand smoke, also called environmental tobacco smoke (ETS), is the combination of sidestream smoke (burning end of a cigarette, cigar, or pipe) and mainstream smoke (exhaled by the smoker). More than 7000 chemicals have been identified in mainstream tobacco smoke. Nonsmokers who live with smokers are at greatest risk for lung cancer as well as numerous noncancerous conditions. Additionally, another 100,000 fatalities were babies who died of sudden infant death syndrome (SIDS) or complications from low birth weight or other conditions as a result of parental smoking, particularly from the mother.
FIGURE 11-4  The Health Consequences Linked to Smoking. NOTE: The conditions in red are new diseases that have causally been linked to smoking. See text for discussion.
Smoking tobacco is linked to cancers of the lung, upper aerodigestive tract (oral cavity, pharynx, larynx, nasal cavity, paranasal sinuses, esophagus, and stomach), lower urinary tract (renal pelvis, penis, and bladder), kidney, pancreas, cervix, and uterus, as well as myeloid leukemia (see Figure 11-4). The new list of disease risks includes liver cancer and colorectal cancer. Secondhand smoke is a cause of stroke; increases the risk of death in people with cancer and cancer survivors as well as those with age-related macular degeneration, tuberculosis, ectopic pregnancy, and diabetes mellitus; increases inflammation; impairs immunity; and is a cause of rheumatoid arthritis. Smoking causes even more deaths from vascular, respiratory, and other diseases than from cancer. The epidemic of smoking ranks among the greatest health catastrophes of the century and has caused an enormous avoidable public health tragedy.\(^34\)

Cigar or pipe smoking, or both, is strongly and causally related to cancers of the oral cavity, oropharynx, hypopharynx, larynx, esophagus, and lung. Cigar smokers who inhale deeply may be at increased risk for developing coronary heart disease and chronic obstructive pulmonary disease.\(^44\) Pipe smokers have an increased risk of dying from cancers of the lung, lip, throat, esophagus, larynx, pancreas, and colon and rectum.\(^45\) Consumption of loose tobacco (i.e., roll-your-own cigarette tobacco and pipe tobacco) changed substantially from 2000 to 2011.\(^46\) Roll-your-own cigarette equivalent consumption decreased by 56.3%, whereas pipe tobacco consumption increased by 482.1%. Changes also were observed with cigars whereby consumption of small cigars decreased 65% and consumption of large cigars increased 233.1%. Consumption of pipe smoking and large cigars has increased substantially since the federal tobacco excise tax was increased for cigarettes in 2009, making these products less expensive.\(^46\) Bidi smoking, a small amount of tobacco wrapped in the leaf of another plant (used in South Asia), delivers higher amounts of nicotine per gram of tobacco and comparable or greater amounts of tar compared with cigarettes.\(^47\) Case-controlled studies indicate bidi smoking can cause cancers of the respiratory and digestive sites. A recent study in India show esophageal cancer is associated with smoking (including bidi) and alcohol.\(^48\) The IARC reports *sufficient evidence* in humans that smokeless tobacco is associated with oral cavity, esophageal, and pancreatic cancers.\(^4\)

The U.S. Department of Health and Human Services and the WHO Framework Convention on Tobacco Control (WHO FCTC) are the national and global tobacco control organizations for reducing both demand for and supply of tobacco products. Control policies enforce bans on tobacco advertising, promotion, and sponsorship and provide evidence that calls for dramatic action.
Diet

Understanding dietary factors that increase the risk for cancer is most important but can be difficult. The ways in which diet affects one's likelihood of developing cancer are complicated by the variety of foods consumed, the many constituents of foods, the metabolic consequences of eating, and the temporal changes in the patterns of food use. Cancer risks in older adults may depend as much on diet in early life as on current eating practices. In addition, studies in humans targeting diet and disease associations face a variety of challenges including measurements of specific nutrients, food types, and dietary patterns.

Dietary sources of carcinogenic substances include compounds produced in the cooking of fat, meat, or protein and naturally occurring carcinogens associated with plant food substances, such as alkaloids or mold byproducts. Figure 11-5 is a summary of convincing and probable judgments related to food and physical activity risk factors and the prevention of cancer. Dietary components can act directly as mutagens or interfere with mutagen elimination. Abundant evidence exists that nutritional factors in many processes are related to cancer development (Figure 11-6).
Research is ongoing to understand the complexity of genomics, epigenomics,
transcription factors (transcriptomics), proteomics, and metabolic factors (metabolomics) and the way that modifying any one or more of these factors influences cancer risk. **Nutrigenomics** is the study of the effects of nutrition on the phenotypic variability of individuals based on genomic differences (see Figure 11-6). Investigators are focusing on the sequence and functions of genes, single nucleotide polymorphisms (SNPs), and amplifications and deletions within the DNA sequences as modifiers of the response to foods and drinks and their components.  

### Nutrition, Obesity, Alcohol Consumption, and Physical Activity: Impacts on Cancer

What we eat, how much we weigh, and how much we move influence our risks of developing cancer. Mounting evidence is clear—everyday *choices* impact our chances of getting or preventing cancer. Ongoing tedious and comprehensive investigative work is linking diet, body weight, and exercise to risk of specific cancers.

#### Nutrition

The implementation of dietary patterns (e.g., Mediterranean dietary pattern) and the promotion of specific dietary recommendations (e.g., dietary approaches to lower blood pressure) are becoming more widespread for fostering lifelong health. The results of decades of research activity on the association of specific nutrients and foods and many forms of cancer have been controversial. Although so much in the cancer literature regarding nutrition is argued, it is difficult to ignore the data showing changes in cancer risk among migrants in low-risk countries compared with those in high-risk countries. For example, much of the geologic variation in incidence across the world for colorectal cancer has been attributed to differences in diet, particularly the consumption of red and processed meat, fiber, and alcohol, as well as body weight and physical activity. With migration, these changes in risk are rapid and the most plausible determinants of such changes are the so-called adoption of the “Western” diet. Japan has seen a rapid increase in the incidence of colorectal cancer with westernization of diet. It seems clear that focusing on dietary patterns, as well as meaningful biomarkers reflecting specific nutritional factors relevant to carcinogenesis, may be a more successful approach. The following important cellular processes are affected by nutrition (Figure 11-7):

- The cell cycle
- The balance between cell proliferation and cell death (e.g., apoptosis)
- Cell differentiation
• Genes, including oncogenes and tumor-suppressor genes
• Cell signaling
• Gene expression
• Cellular microenvironment that influences gene expression
• Epigenetic regulation
• Hormonal regulation
• DNA damage and repair
• Carcinogen metabolism
• Inflammation and immunity

Figure 11-7

Food, nutrition, obesity, physical activity, and cellular processes linked to cancer. Food, nutrition, and physical activity can influence fundamental processes shown here, which may promote or inhibit cancer development and progression. (Adapted from World Cancer Research Fund/American Institute for Cancer Research: Food, nutrition, physical activity, and the prevention of cancer: a global perspective. Washington, DC, 2007, AICR.)

Gene expression is influenced by epigenetic processes such as DNA methylation or acetylation (addition of an acetyl group) (see Chapters 3 and 10). Dietary sources of methyl groups, including folate, methionine, betaine, serine, and choline, are primary potential donors as modulators of DNA methylation (Figure 11-8). A recent report from the European Prospective Investigation into Cancer and Nutrition (EPIC) found individuals with high plasma concentrations of methionine, choline,
and betaine may be at reduced risk of colorectal cancer.\textsuperscript{56}

FIGURE 11-8 Dietary Factors, DNA Methylation, and Cancer. Certain dietary factors (see Table 11-5) may supply methyl groups (+CH\textsubscript{3}) that can be donated through S-adenosylmethionine (SAM) to many acceptors in the cell (DNA, proteins, lipids, and metabolites). Donation and removal (demethylation) are affected by numerous enzymes, including DNA methyltransferase (DNMT). Increased DNMT activity occurs in many tumor cells. Hypermethylation can inhibit or silence tumor-suppressor genes (see Chapter 10), and DNA methylation inhibitors as anticancer agents can block DNMT, thus reactivating tumor-suppressor genes. DNA hypomethylation can reactivate and mutate genes, including cancer-causing oncogenes. SAH, S-Adenosylhomocysteine.

B vitamins, coenzymes in one-carbon metabolism (vitamins B\textsubscript{2}, B\textsubscript{6}, B\textsubscript{12}), also are modulators of DNA methylation.\textsuperscript{57} To date there are limited human studies of the effects of methyl donor supply on methylation of specific genomic sequences.\textsuperscript{55} However, a study\textsuperscript{58} found that periconceptional maternal supplementation with 400 micrograms (mcg) of folic acid per day was associated with increased methylation in offspring aged 17 months. In experimental animals, maternal diet during the
periconceptional period established DNA methylation in the offspring with permanent phenotypic changes.\textsuperscript{59} In the Waterland study,\textsuperscript{60} methylation effects were found to be similar in all tissues examined, suggesting that the mechanism may alter markings in stem cells early in embryogenesis before tissue differentiation, and persist into adult life. Choline deficiency in pregnancy results in hypermethylation of genomic DNA and of the \textit{IGF2} gene.\textsuperscript{61} Several studies have reported that severe folate deficiency (which increases the risk of hepatocellular cancer) induces hypomethylation of the \textit{p53} tumor-suppressor gene.\textsuperscript{62-64} In vitro studies have shown that several bioactive food components, including tea polyphenols and bioflavonoids, inhibit DNA methyltransferase (DNMT)-mediated DNA methylation in a dose-dependent manner\textsuperscript{65} (see Figure 11-8). Acetylation and deacetylation are mediated by enzyme histones, histone acetyl transferase (HAT), and histone deacetylation (HDAC). Dietary components have been identified that act as regulators of gene expression by epigenetic mechanisms.\textsuperscript{66,67} For example, there is strong evidence for the epigenetic effects of organosulfur compounds from garlic and of isothiocyanates from cruciferous vegetables.\textsuperscript{66} Butyrate produced in the colon by bacterial fermentation of non–starch polysaccharide (fiber), diallyl disulfide from garlic and other allium vegetables, and sulforaphane from cruciferous vegetables can act as histone deacetylase inhibitors to maintain DNA stability or modify transcription.\textsuperscript{50} A recent laboratory study found sulforaphane to inhibit modulators of inflammation in human mammary epithelial cells.\textsuperscript{68}

Studies involving cultured cancer cells and animal models have illustrated the potential protective role of dietary polyphenols, such as curcumin, resveratrol, genistein, epigallocatechin–3-gallate, and indole-3-carbinol and its derivative 3,3′-diindolylmethane. The effects of these dietary agents may include antiproliferation and pro-apoptosis through the epigenetic regulation of miRNAs.\textsuperscript{69} Because of the promising results from these in vitro and in vivo studies, the efficacies of these natural agents in cancer therapies are being investigated in clinical trials (see www.clinicaltrials.gov/). Interest in resveratrol, a polyphenolic compound with anti-inflammatory, antioxidant, and anticancer activities, is growing because of its demonstrable role in possibly delaying age-related diseases, including cancers.\textsuperscript{70} Feeding mice a diet supplemented with human equivalent doses of 105 and 210 mg of resveratrol daily resulted in inhibition of colorectal tumors through an epigenetic mechanism (miR-96, a miRNA).\textsuperscript{70} Yet, a recent prospective cohort study in older community-dwelling adults found total urinary resveratrol metabolite concentration was not associated with inflammatory markers, cardiovascular disease, or cancer or predictive of all-cause mortality.\textsuperscript{71} More research needs to be done with resveratrol.

MicroRNA (miRNA) expression in response to diet may be involved in several
Several dietary factors, including macronutrients (fat, protein, and alcohol) and micronutrients (folate and vitamin E, curcumin), alter the expression of many miRNAs in animals and humans (see Chapter 10). Curcumin analogs (compared with just curcumin) with increased anticancer activity and solubility, such as EF24 (3,5-bis(2-fluorobenzylidene)piperidin-4-one), show enhanced expression of potential tumor-suppressor miRNAs.

Bioactive components have a profound effect on differentiation and a major area of investigation is on the differentiation of cancer stem cells. Cancer stem cells have been isolated and identified in hematopoietic and epithelial cancers, including cancers of the brain, breast, ovary, prostate, colon, and stomach. Stem cells are found among most adult tissues, where they maintain and regenerate tissues. Stem cells can remodel organs in response to physiologic triggers—adaptive resizing. Cancer stem cells utilize several developmental mechanisms for self-renewal and these mechanisms appear to be fundamental to the initiation and recurrence of tumors. Even if chemotherapy or radiation eliminates cancer cells, it is only when the cancer stem cells are destroyed that a full recovery is achievable. Repopulation with radioresistant or chemoresistant stem cells may significantly contribute to therapy resistance. Evidence from both drug and bioactive food constituents shows modifications in cancer stem cell self-renewal capabilities; for example, retinoic acid may promote differentiation of breast cancer stem cells. Adequate consumption of specific food compounds, including vitamins A and D, genistein, green tea, epigallocatechin gallate (EGCG), sulforaphane, theanine, curcumin, choline, and possibly many others, may suppress cancer stem renewal. An uncontrolled self-renewal process may be initiated by abnormal developmental signals that come from the extracellular microenvironment known as “niches.” The loss of regulation in self-renewal signals, including Wnt, Notch, and hedgehog pathways, is a characteristic of cancer stem cells. Various food bioactive components can modulate the signaling pathway.

A variety of food constituents may influence DNA repair (Figure 11-9). Observational studies suggest that malnutrition can reduce DNA repair from damage. In vivo studies have demonstrated that healthy adults consuming kiwi fruits, cooked carrots, or supplemental coenzyme Q improved their DNA repair. Consumption of lycopene-rich vegetable juice was associated with significantly decreased damage to the DNA of lung epithelial cells in healthy adults.
Humans are constantly exposed to a variety of compounds termed xenobiotics (the Greek word xenos means “foreign”; bios means “life”) that include toxic, mutagenic, and carcinogenic chemicals. Many of these chemicals are found in the human diet. Most xenobiotics are transported in the blood by lipoproteins and penetrate lipid membranes (see Chapter 4). The body has two main defense systems for counteracting these effects: (1) detoxification enzymes and (2) antioxidant systems (see Chapter 4). Enzymes that activate xenobiotics are called phase I activation enzymes. Phase II detoxification enzymes then protect further against a large array of reactive intermediates and nonactivated xenobiotics. These enzymes are located predominantly in the liver and provide clearance of compounds through the portal circulation, thereby preventing the potentially carcinogenic agent(s) from entering the body through the gastrointestinal tract and portal circulation. They also occur in the skin epithelia and can be induced in other extrahepatic tissue, such as the lung. They represent a potential target to influence carcinogen metabolism.
Isothiocyanates from cruciferous vegetables induce the expression of phase II detoxification enzymes. Food and nutrition modify carcinogen metabolism and may modify carcinogenesis.

Glutathione-S-transferases (GSTs) are enzyme housekeepers involved in the metabolism of environmental carcinogens and reactive oxygen species. Individuals who lack these enzymes may be at higher risk for cancers because of decreased capacity to dispose of activated carcinogens. For example, the fungi that produce aflatoxins can grow on certain crops such as peanuts and some cereals (e.g., grains). Aflatoxins are carcinogens activated by phase I enzymes in the liver that can produce DNA adducts. Individuals lacking these enzymes are at higher risk of colon cancer. Diets high in isothiocyanates (from cruciferous vegetables) may decrease this risk. Individuals who consume diets high in red meat and processed meat and who carry certain genetic polymorphisms have an increased risk of developing colorectal cancer.\textsuperscript{50,81-83} Processed meats include those treated by preservatives or by smoking, curing, or salting. The European Prospective Investigation into Cancer and Nutrition (EPIC) study, which included 478,040 people from 10 countries, reports that the most convincing data are from meats, including sausages, bratwursts, frankfurters, and hot dogs, all of which have nitrates, nitrates, or other preservatives. These N-nitroso compounds can increase nitrogenous residues in the colon and cause DNA damage.\textsuperscript{50} Dietary components either can be activated into potential carcinogens through metabolic processes or can be inactivated and prevent DNA damage.\textsuperscript{50} High intake of red meat may result in the synthesis of higher levels of heme iron; iron can activate oxidative stress and inflammation in the colon. Meat may have certain thermoresistant oncogenic bovine viruses (e.g., polyoma-papilloma) or possible single-stranded DNA viruses.\textsuperscript{84} Certain single nucleotide polymorphisms (SNPs) in the N-acetyltransferase gene alter the activity of the enzyme involved in the activation of heterocyclic amines from cooking meat at high temperatures and may increase the risk of colon cancer.\textsuperscript{50}

Red cabbage leads to changes in meat-derived mutagens in urine.\textsuperscript{50} Flavonoids found in plants may alter carcinogen metabolism, and dietary indole-3-carbinol inhibited spontaneous occurrence of endometrial adenocarcinomas in rats.\textsuperscript{50}

Chronic inflammation and immune function may help explain patterns of cancer around the world. People who are undernourished or live in poverty may have impaired immune status, which can be a factor in cancers caused by infectious agents, for example, cancers of the liver and cervix.\textsuperscript{50}

Diet affects many pathways to cancer (see p. 276) and many of these processes are likely influenced, if not regulated, by DNA methylation, an epigenetic mechanism that affects gene function (also see Chapter 3). As illustrated in Figure 11-10, it is possible that many environmental factors interact with the genome to produce
altered epigenetic markers that change the expression of cancer-causing genes, tumor-suppressor genes, and oncogenes. Future research is needed to define robust biomarkers of cancer risk.
Obesity in most developed countries (and in urban areas of many developing countries) has been increasing rapidly over the past 20 years. Obesity in the United States is an epidemic and constitutes a startling setback to major improvements in other areas of health during the past century.\textsuperscript{85} In 2012, more than one third of children and adolescents were overweight or obese.\textsuperscript{86} Numerous health conditions are linked to obesity and physical inactivity. The substantial suffering and long-term human and societal costs of obesity underlie the urgency to accelerate progress in obesity prevention.\textsuperscript{85} Studies have significantly improved the understanding of the relationship between overweight/obesity, energy balance and cancer risk, cancer recurrence, and survival.\textsuperscript{50,87,88} Consensus now exists that obesity is a risk factor for cancers of the endometrium, colorectum, kidney, esophagus, breast (postmenopausal), and pancreas. Evidence is evolving of the association between obesity and cancers of the thyroid, gallbladder, liver, and ovary, as well as aggressive types of prostate cancer and non-Hodgkin lymphoma.\textsuperscript{50,87} Importantly, obesity is recognized as a poor prognostic factor for several cancers.\textsuperscript{89-91}

The only globally accepted criteria for overweightness and obesity are based on the body mass index (BMI). Widely accepted standards based on BMI criteria for overweightness and obesity are recommended by the WHO\textsuperscript{50} (Table 11-4) and supported by other panels and federal agencies. According to the WHO, worldwide obesity has doubled since 1980 and more than 1.4 billion adults, 20 years of age and older, were overweight. Of these, more than 200 million men and 300 million women were obese. Worldwide, more than 40 million children younger than age 5 years were overweight or obese in 2012.\textsuperscript{92}

The cutoffs are somewhat arbitrary, although they are derived from epidemiologic studies of BMI and overall mortality. It is important to understand that within each category of BMI there can be substantial individual variation in total and visceral adiposity and in related metabolic factors. These variations are also true for the normal range BMI.

\textit{WHO, World Health Organization.}

The mechanisms of obesity-associated cancer risks are unclear and may vary by
type of tumor and distribution of body fat. Emerging, however, are three main factors related to obesity and cancer: (1) the insulin–insulin-like growth factor 1 (IGF-1) axis, (2) sex hormones, and (3) adipokines or adipocyte-derived cytokines. These three factors are linked to metabolic dysregulation of adipose tissue and endocrine and paracrine altered signaling of adipose tissue in obesity. Metabolic changes in adipose tissue from obesity result in several alterations and include insulin resistance, hyperglycemia, dyslipidemia, hypoxia, and chronic inflammation. Because tumor growth is regulated by interactions between tumor cells and their tissue microenvironment or stromal compartments that are rich in adipose tissue, adipocytes function as endocrine cells and critically shape the tumor microenvironment. Dysfunctional adipose tissue can create altered signaling pathways that involve proinflammatory mediators, macrophages, and cancer-associated fibroblasts. All of these cells are tumor-promoting cell types and, with insulin resistance and hypoxia, can trigger compensatory angiogenesis and an energy reservoir for the embedded cancer cells. The cancer-associated adipocytes (CAAs) undergo both structural and functional alterations during cancer progression that altogether create an environment toward increased cancer invasiveness and aggression (Figure 11-11).
Alcohol Consumption

Alcohol is classified by the International Agency for Cancer Research as a human carcinogen. Excessive alcohol plays a contributory role in several common cancers. Overall, there are strong data linking alcohol with cancers of the mouth, pharynx, larynx, esophagus, liver, colorectum, and breast (Table 11-5). The evidence does not show any “safe limit” of intake, and the effect is from ethanol.

*I In the judgment of the Panel (WCRF/AICR), the factors listed modify the risk of cancer. Judgments are graded according to the strength of the evidence.

† The judgments for men and women are different because there are fewer data for women. Increased risk is only apparent above a threshold of 30 g/day of ethanol for both genders.

‡ Cirrhosis is an essential precursor of liver cancer caused by alcohol. The International Agency for Research on Cancer has graded alcohol as a class 1 carcinogen for liver cancer. Alcohol alone only causes cirrhosis in the presence of other factors.

§ The evidence was sufficient to judge that alcoholic drinks are unlikely to have an adverse effect on the risk of kidney cancer; it was inadequate to draw a conclusion regarding the protective effect.

Mechanisms involved in alcohol-related carcinogenesis include the effect of acetaldehyde, the first metabolite of ethanol oxidation; the induction of cytochrome P-450 2E1 (genetic variant CYP2E1) leading to the generation of reactive oxygen species (ROS); increased pro-carcinogen activation (e.g., nitrosamines); modulation of cellular regeneration (cell cycle); nutritional deficiencies (retinol, retinyl esters, folic acid, other vitamins) that may predispose to altered mucosal integrity and enzyme and metabolic dysfunction; and other structural abnormalities. Inherited factors also put some individuals at increased risk in DNA repair ability, carcinogen metabolism, and cell cycle control.84 Recent investigation is concerned with epigenetic mechanisms and alcohol metabolism.97,98 Figure 11-12 summarizes some of these epigenetic mechanisms and the effects of alcohol metabolism that may be important for cancer pathogenesis.
Alcohol Metabolism and Epigenetics.

Chronic alcohol intake leads to decreased methylation called hypomethylation by decreasing S-adenosylmethionine (SAM) that is used by DNA enzymes called methyltransferases (DNMTs) and histone enzymes called methyltransferases (HMTs) to methylate DNA and histones. Additionally, alcohol metabolism increases the ratio of the coenzyme reduced nicotinamide adenine dinucleotide (NADH) to the oxidized nicotinamide adenine dinucleotide (NAD+); this step inhibits the sirtuin enzyme SIRT1, which interferes with normal histone acetylation patterns. (Adapted from Zakhari S: Alcohol metabolism and epigenetic changes, Alcohol Res 35[1]:6-16, 2013.)

Physical Activity

Physical activity reduces the risk of breast and colon cancers and may reduce the risk of other cancers including endometrial, lung, and prostate cancers. Several biologic mechanisms causing this effect have been proposed and include decreasing insulin and IGF levels; decreasing obesity; increasing free radical scavenger systems; altering inflammatory mediators; decreasing levels of circulating sex hormones and metabolic hormones; improving immune function; enhancing cytochrome P-450, thus modifying carcinogen activation; and increasing gut motility. For colon cancer, physical activity increases gut motility, which reduces the length of time (transit time) that the bowel lining is exposed to potential mutagens. For breast cancer, vigorous physical activity may decrease exposure of breast tissue to ovarian hormones, insulin, and IGF. A randomized trial found that after 12 months of moderate-intensity exercise, postmenopausal women had significantly decreased levels of serum estrogens. Physical activity also helps prevent type 2 diabetes, which has been associated with risk of cancer of the colon and pancreas.

Many questions are unanswered regarding frequency, intensity, and duration of
exercise. Much of the literature suggests that between 3.5 and 4 hours of vigorous activity per week are necessary to optimize protection for colon cancer.102 There is likely a dose-response relationship for colon cancer and breast cancer, and 30 to 60 minutes per day of moderate to vigorous intensity activity is proposed to decrease breast cancer risk.106 A randomized controlled trial (12 months) recently supported the Institute of Medicine and Department of Agriculture guidelines of 60 minutes per day of moderate to vigorous physical activity for decreasing weight, BMI, and percent of body fat and intra-abdominal fat.107 A Cochrane review found that aerobic exercise was beneficial for adults with cancer-related fatigue during and after cancer treatment.108 Another Cochrane review found exercise in children with cancer was associated with improved body composition, flexibility, and cardiorespiratory fitness.109 More research on exercise for adults and children for prevention of cancer, postcancer treatment, and survivors of cancer is needed.

**Ionizing Radiation**

Much of the knowledge of the effects of ionizing radiation on human cancer has stemmed from observations of the Hiroshima and Nagasaki atomic bomb exposures, particularly the Life Span Study. These data provide the best estimate of human cancer risk over the dose range from 20 to 250 centigray (cGy) for low linear energy transfer (LET) radiation, such as x-rays or γ-rays. Other evidence is derived from groups exposed for medical reasons, underground miners exposed to radon gas, and other occupational exposures (Table 11-6). The atomic bomb exposures in Japan caused acute leukemias in adults and children and increased frequencies of thyroid and breast carcinomas. Lung, stomach, colon, esophageal, and urinary tract cancers and multiple myeloma have been added to the list. At Nagasaki and Hiroshima, leukemia incidence in individuals 15 years or younger reached its peak 6 to 7 years after the explosions and has steadily declined since 1952. People 45 years and older at the time of exposure had a latent period of 20 years before developing acute leukemia.

Data from Jones JA et al: Ionizing radiation as a carcinogen. In McQueen E, editor: CA comprehensive toxicology, ed 2, St Louis, 2010, Elsevier.

Recently, standard models and evaluations of age of exposure to radiation and radiation-induced cancer risks have been questioned.\textsuperscript{110-112} Epidemiologic data from Japanese atomic bomb survivors and from children exposed to radiation for medical intervention suggest that excess relative risks (ERRs) for radiation-induced cancers at a given age are exceptionally higher for individuals exposed during childhood than for those exposed at older ages.\textsuperscript{113} These data also are published by the International Commission on Radiological Protection (ICRP) and the National Academy of Sciences Committee on the Biological Effects of Ionizing Radiation (BEIR Committee).\textsuperscript{114} What is at question is the ERRs of radiation exposure in adulthood and radiation-induced cancer risk. Recent analyses of Japanese bomb survivors suggest that the ERR for cancer induction decreases with increasing age at exposure only until exposure ages of 30 to 40 years; with radiation exposure at older ages, the ERR does not decrease further and for many individual cancer sites (liver, colon, lung, stomach, and bladder) the EER may actually increase in all solid cancers combined.\textsuperscript{110,112,115} These new data present a challenge to conceptual understanding of the mechanisms of cancer induction.\textsuperscript{112} Biologic models of cancer development all predict that ERRs should decrease continuously with increasing age of radiation exposure. Recent models, however, of radiation carcinogenesis show ionizing radiation acts not only as an initiator of premalignant cell clones but also as a promoter of preexisting premalignant cell alterations.\textsuperscript{110,112,115} Promotion is used here to mean the process by which an initiated cell clonally expands. Therefore, promotional processes from radiation can result in increasing excess lifetime cancer risks with increasing age at exposure. From these new data investigators
propose that radiation-induced cancer risks after exposure in middle age may be almost twice as high as previously estimated.\textsuperscript{112}

Human exposure to ionizing radiation includes emissions from the environment (e.g., radon), x-rays, CT scans, radioisotopes, and other radioactive sources (\textbf{Figure 11-13}). Health risks involve not only neoplastic diseases but also cardiovascular disease and stroke following high doses in therapeutic medicine and lower doses in A-bomb survivors (BEIR VII).\textsuperscript{114,116} Late effects of radiation in A-bomb survivors show persistent elevations of inflammatory markers, implying immunologic damage may be the cause of later cardiovascular effects.\textsuperscript{117} For the first time, investigators using a model of umbilical vein endothelial cells showed that low doses (0.05 Gy) of x-rays induce DNA damage and apoptosis in endothelial cells. These findings will need continued research.\textsuperscript{118} Cardiac and blood vessel damage may manifest years after completion of radiation therapy.\textsuperscript{119} Other risks include somatic mutations that may contribute to other diseases (e.g., birth defects and eye maladies) and, from animal studies, inherited mutations that may affect the incidence of diseases in future generations. Exposure to diagnostic radiography in utero has been associated with childhood cancer, particularly leukemia.\textsuperscript{120-122} The link or association between in utero irradiation and childhood cancer is, however, controversial and varies with study methodology.\textsuperscript{123} Heritable mutations are of particular concern for women because the number of oocytes is presumably fixed at birth and mutations, if not repaired, are cumulative.\textsuperscript{124} An important summary point in BEIR VII\textsuperscript{114} is the concern from high-dose medical exposure, for example, computed tomography (CT) scans (see \textbf{Health Alert: Increasing Use of Computed Tomography Scans and Risks}). In 2009 the National Council on Radiation Protection and Measurements (NCRP)\textsuperscript{125} reported Americans were exposed to more than seven times as much ionizing radiation from medical procedures as compared with that in the 1980s. The increased exposure is mostly because of the rapid increase in the use of CT imaging.\textsuperscript{126} The increase in imaging is likely driven by several factors, including improvements in the technology, that have led to increased clinical applications, patient demand, physician demand, defensive medical practices, and medical uncertainty.\textsuperscript{127}

\textbf{Health Alert}

\textbf{Increasing Use of Computed Tomography Scans and Risks}

A review article in the \textit{New England Journal of Medicine} on computed tomography (CT) and radiation exposure has received much media attention. The article was
written by radiology researchers at Columbia University. In short, the numbers of CT scans have greatly increased in the United States. This increase has occurred both as a diagnostic treatment for individuals with symptoms and as a diagnostic modality for individuals without symptoms (heart, lung, colon, and whole-body screening). Faster scanning times are partly responsible for increased CT use in pediatric populations. Typical doses are larger from CT scans than for a conventional examination (e.g., 50 times more radiation to stomach than an x-ray). Based on data correlations from Japanese survivors of atomic bombs, the authors estimated that 1.5% to 2.0% of cancers in the United States might be attributable to CT radiation. The authors note that CT scans are sometimes ordered excessively and repeated unnecessarily because of defensive medicine. They also include three ways to reduce radiation exposure from CT: (1) reduce radiation doses in individual studies (i.e., use modern scanners), (2) substitute ultrasonography with magnetic resonance imaging (MRI) for CT whenever possible, and (3) order CT scans only when absolutely necessary.

NCRP estimates that 67 million CT scans (compared with 3 million in 1980), 18 million nuclear medicine procedures, 17 million interventional fluoroscopy procedures, and 18 million nuclear medicine procedures were performed in the United States in 2006.

The risks of low-dose radiation are being debated among radiobiologists, geneticists, physicists, and others because of the potential effect on the health of current and future generations. The expression of radiation-induced damage depends not only on dose, fractionation, and protraction but also on repair mechanisms; bystander effects; radioprotective substances, such as antioxidants; and the mechanism of radiation delivery.

**Radiation-Induced Cancer**

Ionizing radiation (IR) is a mutagen and carcinogen and can penetrate cells and tissues and deposit energy in tissues at random in the form of ionizations (e.g., excitation or removal of an electron from the target atom). These ionizations can lead to irreversible or indirect damage from formation and attack by water-based free radicals (radiolysis). The *general* characteristics of IR-induced carcinogenesis are well established. The past two decades have focused on
specific cellular and molecular mechanisms that relate to the induction of cancer, including dose-response relationships for chromosome aberrations, cell transformation, gene expression (genetic and epigenetic), alternative targets, mutagenesis in somatic cells, the biologic effects that occur in nonirradiated cells (i.e., nontargeted effects), and effects on the microenvironment.\textsuperscript{130} IR is a potent DNA-damaging agent causing cross-linking, nucleotide base damage, and single- and double-strand breaks\textsuperscript{131} to DNA and disrupted cellular regulation processes can lead to carcinogenesis.\textsuperscript{131} The double-strand break (DSB) (Figure 11-14) is considered the characteristic lesion observed for the effects of IR. In certain experimental systems, a single DSB may lead to cell cycle arrest and possible further repair. Yet many DSBs appear to result from clustered damage, a consequence of the pattern of distribution of ionizations with DNA. These patterns of clustered damage may be more difficult to accurately repair.\textsuperscript{132} Importantly, DSBs are mostly repaired by the nonhomologous end joining (NHEJ) pathway. This pathway is efficient for joining the DNA broken ends; however, errors can occur and repair may decline with age.\textsuperscript{133} Irradiated human cells unable to execute the NHEJ pathway are supersensitive to the introduction of large-scale mutations and chromosomal aberrations.\textsuperscript{128}

![Figure 11-14](image)

**Figure 11-14** Free Radicals. Free radicals formed by water nearby and around DNA cause indirect effects. These effects have a short life of single free radicals. Oxygen can modify the reaction, enabling longer lifetimes of oxidative free radicals.

Although evidence suggests that interindividual differences in radiation responses may be attributed to certain genes, IR can activate oncogenes, resulting in uncontrolled cell growth\textsuperscript{130,134} (see Chapter 10). Tumor-suppressor genes also are sensitive to IR. Several tumor-suppressor genes have been identified that are
deactivated by IR that promotes carcinogenesis.\textsuperscript{130,134} Recent research has shown that cells can detect and respond epigenetically, altering gene expression after low doses of radiation.\textsuperscript{130} Gene expression can change as a function of radiation dose and radiation type.\textsuperscript{130}

**Nontargeted Effects**

A long-held assumption is that cellular alterations—mutations and malignant transformation—occur only in cells directly radiated. It is now known that cells not directly exposed to radiation, but instead the progeny of cells that were irradiated many cell divisions previously, may express a high level of gene mutations, cell lethality, and chromosomal aberration. Altogether these effects are called **genomic instability**. Investigators are studying genomic instability as it may contribute to secondary cancers. The directly irradiated cells also can lead to genetic effects in so-called bystander cells or innocent cells (called **bystander effects**) even though they themselves received no direct radiation exposure.\textsuperscript{128} For example, using an in vivo mouse model, investigators found that localized radiation to the head led to induced bystander effects in the lead-shielded distant spleen tissue.\textsuperscript{135} These radiosensitive mice showed unexpected enhancement of medulloblastoma in their cerebellum. The bystander effect has been demonstrated in three-dimensional human tissues and recently in other whole animal organisms.\textsuperscript{101} Both double-strand DNA breaks and apoptotic cell death were induced by bystander effects, supporting the role of signaling between the irradiated cells (the targeted cells) and unirradiated cells (the nontargeted or bystander cells) (Figure 11-15). Such communication is thought to occur from direct physical connection between cells or gap junctions, called gap junctional intercellular communication (GJIC, see p. 12), and from signaling pathways. Numerous intercellular and intracellular signaling pathways are implicated in the bystander response and these effects have been shown to be transmitted to their descendants. These various effects demonstrated in vivo may reflect an ongoing inflammatory response (oxidative stress response) to the initial radiation-induced injury\textsuperscript{136} (Box 11-1). One hypothesis is the stress response is due to elevated reactive oxygen species (ROS) affecting genomic instability. Importantly, by therapeutic interference with specific signaling pathways (e.g., p38MAPK) may result in genome stabilization.\textsuperscript{137} Both the bystander and the genomic instability effects have been termed **“nontargeted” effects** (see pp. 285-287).
Radiation: Targeted and Nontargeted or Bystander Effects. Signaling from cells exposed to irradiation causes stressful effects, including oxidative stress, to those cells not directly radiated called bystander cells and their progeny. These induced effects may be similar to those reported in the progeny of irradiated cells. (Adapted from Azzam El et al: Ionizing radiation-induced metabolic oxidative stress and prolonged cell injury Cancer Lett 327[1-2]:48-60, 2012.)

**Box 11-1**

**A Paradigm Shift? Responses to Ionizing Radiation Mediated by Inflammatory Mechanisms**

Many observations have not been supportive of the conventional paradigm of biologic responses to ionizing radiation (IR). The conventional paradigm is that the consequences of exposure to IR have been attributed solely to mutational DNA damage or cell death induced in irradiated cells at the time of exposure. The challenges to this paradigm come from three types of published data: (1) **abscopal**, or “out-of field,” effects, where radiation treatment to one local area of the body results in an antitumor effect distant to the radiation site; (2) detection of plasma factors in vivo (clastogenic [or capable of chromosome damage] factors) that can affect the survival and function of irradiated cells; and (3) effects in nonirradiated cells that are in the vicinity of irradiated cells (bystander effects) or in the descendants of irradiated cells several generations after the initial radiation exposure (genomic instability). These nontargeted effects are different than the targeted effects that arise in cells upon immediate deposition of energy at the time of radiation exposure. The nontargeted effects arise as a result of intracellular
signaling and appear to represent a genotype-dependent balance (and various epigenetic influences) of toxic factors and cellular responses that may involve both oxidative stress and inflammatory type processes (see Figure 11-15).

Acute, Latent, and Microenvironmental Effects

IR causes acute and persistent short- and long-term effects. Acute exposure to IR can cause damage to several organ systems, especially those with highly proliferative cells such as the hematopoietic system, the skin, and the gastrointestinal system (see Chapter 4). Investigators have postulated that radiation's carcinogenic potential persists because of nontargeted radiation effects that alter cell and tissue signaling and change the microenvironment. Investigators report the brain's innate immune system is very vulnerable to cranial irradiation, altering the microenvironment and causing the recruitment and infiltration of macrophages. With improvement in cancer survival, the long-term risks of a second cancer developing from treatment become more important.

Radiation-induced cancer in humans has latent periods, usually 5 to 10 years, but can be decades. British investigators reported the following results: for solid cancers, radiation-related excess risk starts to appear about 5 years after exposure in therapeutically irradiated groups; and for leukemia, it starts to appear within 5 years of exposure. Using U.S. Surveillance Epidemiology and End Results (SEER) data, the estimated excess of second cancers that could be related to radiotherapy is about 8%; data from the United Kingdom, which included diagnostic procedures and excluded therapeutic irradiation, yielded an estimation of 15%. 

**Low Dose and Dose Rate**

Recent events, including the 2011 Fukushima nuclear accident, terrorist attacks, and exposure to radiation from medical procedures, have increased the need to understand the human health effects of exposure to low-level ionizing radiation.\(^{141}\) Risk estimates for human exposure at low-dose, low-LET ionizing radiation (0 to 100 millisieverts \([\text{mSv}]\), or less than 0.1 gray \([\text{Gy}]\)) are constantly debated. Although investigators have reported that accurate measurements of risks from low doses of radiation are statistically difficult because they require such large populations, researchers have developed an in silico simulation model of a population-based cohort study for conducting future epidemiologic studies of excess cancer risks in CT-exposed individuals.\(^{142}\) Simulation models may provide reasonable approximations and theoretic models are still used to estimate response curves (Box 11-2).

---

**Box 11-2**

**Theoretical Models to Understand Low-Dose Radiation**

Several models include the linear no-threshold (LNT) relationship, in which any dose, including very low doses, has the potential to cause mutations (see A). Another model, the linear-quadratic relationship, proposes there is a risk mathematical term that is directly proportional to the dose (linear term) and another term proportional to the square of the dose (quadratic term) (see B). The threshold model proposes a threshold dose below which radiation may not cause cancer in humans (see C). Proponents of this model argue that such thresholds are derived, for example, from the ability to repair damage caused by lower doses of radiation. There is some evidence that low doses may actually produce a higher level of risk per unit of dose, which is called the supralinear hypothesis (see D). E, Stochastic or random probability is a major model for understanding low-dose radiation. Currently, the shape of the response curve for the low-dose region is really unknown.
Theoretic Models for Estimating Risk of Low-Dose Ionizing Radiation. Collective population dose is expressed as a person-rem (roentgen equivalent, man). Estimating a collective dose then enables an application of a “constant risk factor” to obtain a statistical estimate of the number of additional cancers (above background radiation) from that exposure. These computations apply to low doses–low dose rates only (A). Many propose the best fit is the linear no-threshold (LNT) model (B). The most common alternative to the LNT model is the linear-quadratic model. The quadratic term is the square of the dose. The linear term is equal to zero (C). The threshold model is a threshold below which there is no increase in cancer risk. Proponents of this model argue that because some toxic chemicals/materials exhibit such thresholds, radiation must also have a threshold. Their arguments are related to repair of the radiation damage caused by lower doses of radiation (D). Some evidence exists that low levels of radiation produce a higher level of risk per unit dose, which is called the supralinear model. The stochastic model describes effects that are random and the events cannot be predicted (E). (Adapted from Makhijani et al: Science for the vulnerable: setting radiation and multiple exposure environmental health standards to protect those at most risk, Takoma Park, Md, 2006, Institute for Energy and Environmental Research.)

Ultraviolet Radiation

Ultraviolet radiation, called **UV radiation**, comes from sunlight. Other sources of UV radiation include electric lights, black lights, and tanning lamps. UV radiation is divided into three major wavelengths: UVA, UVB, and UVC radiation. Most of the UV radiation received on earth is UVA and some UVB. UV radiation is weaker than UVB, but UVA penetrates deeper into the skin and is more constant throughout the year despite the weather. UVB affects the outer layer of the skin and UVC radiation does not increase health risks as much as UVB. UV radiation also can be important to health and produces vitamin D that helps in the absorption of calcium and phosphorus from food, which are all important for bone development. The WHO recommends 5 to 15 minutes of sun exposure two to three times a week; however, overexposure can result in acute and chronic health effects on the skin, eye, and immune system. There are three main types of skin cancer: cancer that forms in melanocytes (pigment cells) called **melanoma**, cancer in the lower part of the epidermis or outer layer of the skin called **basal cell carcinoma (BCC)**, and cancer in the flat cells that form the surface of the skin called **squamous cell carcinoma (SCC)** (see Chapter 41). Melanoma, the most lethal form of skin cancer, can occur on any skin surface; however, in men it is often found on the skin on the head, the neck, between the shoulders, and the hips. In women it is more commonly found on the skin on the lower legs, between the shoulders, and the hips. Although rare in people with dark
skin, melanoma is usually found under the fingernails, under the toenails, on the palms of the hands, or on the soles of the feet.\textsuperscript{145} Basal cell carcinoma commonly occurs on the head and neck. Squamous cell carcinoma is found more commonly in men who work outdoors, but can occur in anyone. SCC occurs on sun-exposed areas of the skin including the nose, ears, lower lip, and dorsa of the hand. SCCs are composed of keratinizing cells and are more aggressive than BCC, but the development into invasive SCC is low.\textsuperscript{146} For a more complete discussion about these skin cancers see Chapter 41.

The incidence of basal cell carcinoma and squamous cell carcinoma is strongly correlated with lifetime sunlight exposure (i.e., photocarcinogenesis). Specific patterns of sunlight exposure, intermittent or chronic, confer different host effects, acute or cumulative. Intense intermittent recreational sun exposure has been associated with melanoma and BCC. Chronic occupational sun exposure has been associated with SCC. Tanning bed use also has been associated with an increased risk of BCC. The risk was higher in females and with higher use of indoor tanning facilities.\textsuperscript{147} For other occupational factors linked to skin cancers, see Chapter 41. Depending on the time of day and a person's skin type, acute sun exposure may result in sunburn.\textsuperscript{145} From epidemiologic studies, a sunburn is defined as a burn or pain and/or blistering that lasts for 2 or more days.\textsuperscript{145} Cumulative sun exposure is the additive effects of intermittent sun exposure, chronic sun exposure, or both. Other skin cancer risk factors include ionizing radiation, chronic arsenic ingestion, immunosuppression, and genetic factors. These skin cancers have a higher incidence among people with a light or fair skin tone, but they can occur in anyone and in those who do not burn from sunlight.\textsuperscript{148}

UV radiation is known to cause specific gene mutations; for example, squamous cell carcinoma involves mutation in the \textit{TP53} gene, basal cell carcinoma in the patched 1 tumor-suppressor gene (\textit{PTCH1}), and melanoma in the \textit{p16} gene.\textsuperscript{149} The patched/hedgehog intracellular signaling pathway plays a central role in both sporadic BCCs and nevoid BCC syndrome (Gorlin syndrome) tumor growth.\textsuperscript{150} Investigators are identifying aberrant DNA methylation and histone modifications in tumor tissues and cell lines for skin cancers.\textsuperscript{151-153} In addition, UV light induces the release of tumor necrosis factor-alpha (TNF-\(\alpha\)) in the epidermis, which may reduce immune surveillance against skin cancer.\textsuperscript{154} The identification of transcription factors and chemokine receptors suggests a critical role of inflammation in skin carcinogenesis.\textsuperscript{155}

Skin exposure to UVR and ionizing radiation, as well as chemical (xenobiotic) agents/drugs, produces ROS in large quantities.\textsuperscript{156} Uncontrolled release of ROS is an important contributor to skin carcinogenesis.\textsuperscript{156} Imbalances in ROS and antioxidants can lead to oxidative stress, tissue injury, and direct DNA damage
(Figure 11-16). ROS can induce a number of transcription factors (e.g., activator protein-1 [AP-1] and NF-κB) and increase regulating genes that induce inflammation. Inflammation is a critical component of tumor progression.

The incidence of melanoma has been increasing annually at rates of 2% to 7% for white populations. The increasing incidence is worldwide and in the United States the incidence has been increasing for about 30 years. From 2007 to 2011 incidence rates were stable in men and women younger than 50 years but increased by 2.6% per year in women aged 50 years and older. Mortality rates decreased by 2.6% in people younger than 50 years but increased in those aged 50 years and older. Although pediatric melanoma is rare, most studies have indicated that incidence has been increasing. A new study has found that the incidence of pediatric melanoma in the United States actually has decreased from 2004 to 2010, but only in those children (with melanoma) with good prognostic indicators. Therefore, health programs need to continue to encourage sun protective behavior (protective
clothing, sunscreen use, decreased time spent outside, decreased indoor tanning) to reduce melanoma incidence. Because death rates from melanoma have not risen as rapidly as incidence rates, controversy still exists about whether some of the incidence is a result of overdiagnosis. Melanomas can appear suddenly without warning and can arise from or near a mole (melanocytic nevus) and freckles. Complex interactions between UV exposure profiles and genotype combinations determine nevus numbers and size, as well as facial freckling. When detected in the early stages, melanoma is highly curable. Early stage melanoma is classified as radial growth phase (RGP). Later stage melanoma, called vertical growth phase (VGP), is characterized by invasion into the dermal layer and is frequently metastatic. Much research is ongoing to understand the mechanisms that promote progression from less invasive RGP melanoma to aggressive VGP melanoma. Recent progress in understanding the molecular alterations in melanoma will likely advance its diagnosis, prognosis, and treatment.

The pathogenesis of melanoma is very complex, involving genetic and environmental factors. The genetic factors can be inherited, for example, in high-susceptibility genes (i.e., cyclin-dependent kinase inhibitor 2A [CDKN2A]) or in low-susceptibility genes (i.e., melanocortin-1). About 10% to 15% of melanomas are inherited as an autosomal dominant trait with variable penetrance. The majority of melanomas are sporadic and seem to involve ultraviolet radiation (UVR) damage. UVR is correlated with DNA damage. Epidemiologic and case-control studies suggest that UVR exposure is the most significant factor for the development of melanoma (episodes of intense, intermittent exposure [measured as history of sunburn]). Other evidence, however, reports rates of melanoma are uncommon in persons with outdoor occupations. Furthermore, because melanomas sometimes occur in dark-skinned individuals, other environmental factors may be important. Recent analyses in Iceland and Italy and a previous large prospective study in Norway and Sweden suggest sunbed use as a reason for increased melanoma, especially in women. Indoor tanning (sunbed use) is a risk factor for melanoma (i.e., frequent indoor tanning increases melanoma risk). Certain skin conditions also are treated with UVA and UVB light therapy. Family history (i.e., genetic factors), skin type, and the density of moles are important in determining the risk of developing melanoma. Traits associated with a high risk of melanoma are light-colored hair, eyes, and skin; an inability to tan; and a tendency to freckle, sunburn, and develop nevi.

The emerging molecular changes associated with melanoma emphasize that melanoma, like many other cancers, is not a single disease but a diverse group of disorders. The most frequent driver mutations in melanoma involve cell cycle control, pro-growth pathways, and telomerase. Although other genes may be
involved, melanoma progression is often associated with a mutation in the \textit{BRAF} oncogene. The most common mutation in \textit{BRAF}^{V600E} promotes the progression of melanoma through activation of the mitogen-activated protein kinase (MAPK) signaling cascade. Investigators report disease progression may involve factors secreted by the melanoma cells that activate extracellular matrix enzymes (matrix metalloproteinase-1 [MMP-1]) and adjacent stromal fibroblasts in the tumor microenvironment.

Although avoiding sunlight by keeping in the shade and covering up is very important for protection, more data are needed to understand if sunscreen prevents melanoma. A significant benefit from regular sunscreen use has not yet demonstrated primary prevention for basal cell carcinoma and melanoma. Increased knowledge of the intricate cellular interactions in melanoma will increase understanding of melanoma etiology and pathogenesis. This knowledge is essential for early detection and treatment.

**Electromagnetic Radiation**

Health risks associated with \textbf{radiofrequency electromagnetic radiation (RF-EMR)} are very controversial. RF-EMR is in the frequency range of 30 kHz to 300 GHz. Electromagnetic fields (EMFs) generated by RF sources couple with the body and result in induced electric and magnetic fields with associated currents inside tissue. Exposure to electric and magnetic fields is widespread. Microwaves, radar, mobile and cell phones, mobile phone base stations, power frequency radiation associated with electricity and radio waves, fluorescent lights, computers, and other electric equipment create EMRs of varying strength. Despite the breadth of literature on microwaves (MW), the impact of EMR on human health has not been fully assessed. Scientific evidence is accumulating although it has been hampered by the scarcity of methods to accurately measure exposure, the lack of a clear dose-response relationship, and the difficulty in reproducing effects. In addition, with competing priorities such as convenience, financial interest, and health necessity, a consensus of the risk/benefit ratio of EMR exposure may be difficult to achieve, and safety standards vary significantly, up to 1000 times among countries. The National Institute of Environmental Health Sciences Electric and Magnetic Fields Working Group recommended that low-frequency electromagnetic fields (EMFs) be classified as possible carcinogens. Overall, there is limited evidence that magnetic fields cause childhood leukemia and insufficient evidence for other cancers in children. A recent large census-cohort study from Switzerland did not suggest an association between predicted RF-EMF exposure from broadcast transmitters and childhood leukemia. Studies of magnetic field exposure from
power lines and electric blankets in adults reveal little evidence of an association with leukemia, brain tumors, or breast cancer.\textsuperscript{177}

The most extensively studied exposure is from use of wireless telephones (mobile and cordless); other exposures include occupational settings and sources from the general environment.\textsuperscript{173} One cohort study and five case-control studies did not show an increased rate of brain tumors after the increase in mobile phone use. However, these studies had limitations because most of the analyses examined trends only in the early 2000s.\textsuperscript{173} The INTERPHONE study,\textsuperscript{182} a multicenter case-control study, is the largest study so far that studies the relationship between mobile phone use and brain tumors—glioma, acoustic neuroma, and meningioma. Results for cordless phones are lacking in the INTERPHONE study.\textsuperscript{183} The pooled analyses included 2708 glioma cases and 2972 controls. The odds ratios (ORs) in terms of time spent on the phone showed that the highest time spent on the phone (>1640 hours of use) was related to glioma risk (OR 1.40; 95% confidence interval [CI] 1.03-1.89). There was a suggestion of increased risk of tumors on the same side of the head as the phone use (ipsilateral exposure) in the temporal lobe, where radiofrequency (RF) EMF exposure is highest.\textsuperscript{173} The OR for glioma increased with increasing RF dose for exposure 7 years or more before diagnosis, and there was no association with estimated dose for exposure less than 7 years before diagnosis.\textsuperscript{173} A Swedish investigative group performed a pooled analysis of two similar studies between the relationship of glioma, acoustic neuroma, and meningioma manifestation and mobile and cordless phone use.\textsuperscript{184} Study participants who used a mobile phone for more than 1 year had an OR for glioma of 1.3 (95% CI 1.1-1.6). The OR increased with increasing time since first use and with total call time, 3.2 (2.0-5.1) for more than 2000 hours of use.\textsuperscript{173} Ipsilateral use of the phone was associated with higher risk.\textsuperscript{173} Similar findings were reported for cordless phones.\textsuperscript{173} Although the INTERPHONE and Swedish studies were judged susceptible to bias, the Working Group concluded that the findings could not be dismissed because of bias alone and a causal relationship between phones and glioma is possible.\textsuperscript{173} The Working Group concluded that there is “limited evidence in humans” for the carcinogenicity of RF-EMF based on associations between glioma and acoustic neuroma and exposure to RF-EMF from wireless phones.\textsuperscript{173}

The Working Group reviewed numerous mechanisms of carcinogenicity from RF-EMF.\textsuperscript{173} The mechanisms included genotoxicity, effects on immune function, gene and protein expression, cell signaling, oxidative stress, apoptosis, and the blood-brain barrier. Other suggested mechanisms may include altered DNA repair mechanisms and epigenetic changes to DNA.\textsuperscript{183} The Working Group classified RF-EMF as “possibly carcinogenic to humans” (Group 2B).

EMR from a cell phone can penetrate the skull and deposit energy 4 to 6 cm into
Investigators found a 50-minute cell phone exposure was associated with increased brain glucose metabolism in the region closest to the antenna. Children have a smaller head and thinner skull bone than adults, and investigators have reported higher conductivity and higher absorption from RF-EMF than for adults. Concern is for children in whom the effects may be compounded because of increased vulnerability to radiation and their longer use of cell phones into adulthood. Advice about reducing exposures through simple precautions is increasing; for example, don't hold a cell phone directly to your head, pregnant women should keep cell phones away from their abdomen, and don't allow children to play with or use your cell phone. Mobile phone manufacturers themselves are issuing advice on reducing exposures. Ongoing unbiased research is desperately needed. Absolute proof of causation may be hindered because of the ethical questions of exposing individuals to potentially harmful interventions.

Quick Check 11-3

1. What are the cancers associated with cigarette smoking?

2. How are dietary components related to cancer?

3. What are the possible pathophysiologic mechanisms of obesity-associated cancer risk?

4. How does ionizing radiation contribute to carcinogenesis? UV radiation?

5. Discuss the difficulty in determining cancer risks with electromagnetic radiation.
Infection, Sexual and Reproductive Behavior

Infection is an important contributor to cancer worldwide. Of cancers diagnosed in 2008, about 2 million new cases were caused by infections.\textsuperscript{191} Infection and cancer rates vary widely by region: with a 7.4\% rate for more developed regions and a 22.9\% rate for less developed regions.\textsuperscript{191} The highest rate, 32.7\%, is found in sub-Saharan Africa.\textsuperscript{191} Cancer-causing agents classified by the IARC were used in this report because the strength of published evidence is controversial. The four top notable infections and new cancer cases include human papillomavirus (HPV), \textit{Helicobacter pylori} (\textit{H. pylori}), hepatitis B virus (HBV), and hepatitis C virus (HCV) (Table 11-7). According to investigators, these results are probably conservative and underestimate the true burden of infection-associated cancers.\textsuperscript{191} Hepatitis B and hepatitis C can infect the liver and together account for the large majority of liver cancer cases (see Chapter 36). It has been estimated that \textit{H. pylori} accounted for about 75\% of all stomach cancers;\textsuperscript{192} however, updated estimates using both enzyme-linked immunosorbent assay (ELISA) and Western blot for detection of anti–\textit{H. pylori} antibodies include an additional 120,000 cases of gastric cancer for a total percentage of 89.0\%.\textsuperscript{193} Epstein-Barr virus (EBV) is linked to cancers of the nasopharynx, Hodgkin disease, and non-Hodgkin lymphoma. Human herpesvirus type 8 is linked to Kaposi sarcoma, and human T-cell lymphotropic virus type 1 is linked to leukemia and lymphoma. The following discussion will concern human papillomavirus (HPV).

*Numbers are rounded to two significant digits.
†Data are number of new cancer cases attributed to a particular infectious agent (proportion of the total number of new cases attributed to infection that is due to a specific agent).

Human papillomavirus (HPV) is the most common sexually transmitted virus in the United States. At least 50% of sexually active people will have genital HPV at some time in their lives.\(^{194}\) HPVs are a group of more than 150 related viruses. More than 40 of these viruses can easily spread from direct skin contact or through vaginal, rectal, or oral sex.\(^{195}\) *Low-risk* HPVs do not cause cancer but can cause skin warts, called condylomata acuminata. *High-risk*, or oncogenic, HPVs can cause cancer. Even though about a dozen HPVs are identified, HPV types 16 and 18 are responsible for the majority of cancers.\(^{195}\) However, most high-risk HPV infections may cause cytologic abnormalities or abnormal cell changes that disappear unexpectedly. According to the National Cancer Institute, most infections will be suppressed by the immune system.\(^{196}\) Persistence of infection with high-risk HPV is a prerequisite for the development of cervical intraepithelial neoplasia (CIN) (see Figure 33-19), lesions, and invasive cervical cancers.\(^{12,196,197}\) HPV infection has been identified as a definite carcinogen for six types of cancer: cervix, penis, vulva, anus, and some oropharynx (including the base of the tongue and tonsils).\(^{196,197}\) The incidence of HPV-associated oropharyngeal cancer has increased during the past 20 years, especially among men. Factors that may increase the risk of developing cancer following a high-risk HPV infection include smoking, decreased immunity, having many children (for increased risk of cervical cancer), long-term oral contraceptive use (for increased risk of cervical cancer), poor oral hygiene (for increased risk of oropharyngeal cancer), and chronic inflammation.\(^{198}\) Although the main mode of HPV transmission occurs through sexual contact, HPV has been found in virginal women before first intercourse.\(^{199}\) Consensus is that newborn babies can be exposed to cervical HPV infection from the mother.\(^{199}\) The possible
modes of transmission in children, however, are controversial. The Health Alert: Rising Incidence of HPV-Associated Oropharyngeal Cancers contains information on the rising incidence of HPV-associated oropharyngeal cancers.

**Health Alert**

**Rising Incidence of HPV-Associated Oropharyngeal Cancers**

The incidence of head and neck cancers has fallen with a decrease in smoking in the United States; however, the incidence of HPV-associated oropharyngeal cancers (tonsil and tongue base) appears to be rising—especially in young white men. The two classes of oropharyngeal squamous cell carcinoma seem to have different causes: HPV-positive oral cancers are possibly associated with sex-related risk factors, whereas HPV-negative cancers are associated with tobacco and alcohol consumption. Epidemiologic studies support little interaction between the two sets of risk factors, suggesting that HPV-positive cancer and HPV-negative cancer have distinct pathogenesis. Tobacco use and alcohol use are known etiologic factors in head and neck cancers; it is surprising that most cases of oropharyngeal cancers in non-smokers are HPV-related. Not yet known is whether this increase is attributed to changes in sexual norms (from past generations), with more oral sex partners or oral sex at an earlier age. Smoking, however, has an adverse effect on both HPV-positive and HPV-negative oral cancers. In Sweden the incidence of oropharyngeal cancers caused by HPV increased from 23% in the 1970s to 57% in the 1990s to 93% in 2007. Emerging data indicate that HPV is now the primary cause of tonsillar cancer in North America and Europe. The mechanism of HPV-oropharyngeal cancer is different than that related to tobacco use: $P53$ degradation occurs (i.e., $P53$ helps direct genetic repair and cell death [see Chapter 10]), the retinoblastoma $RB$ pathway is inactivated (cell signaling pathway), and the risk of HPV-16 (i.e., $P16$) is increased. Tobacco-related oropharyngeal cancers are characterized by $TP53$ mutation and a decrease in the $CDKN2A$ mutation (cell cycle gene), and thus a decrease in $P16$. Individuals with $P16$-positive tumors have a better prognosis than those with $P16$-negative tumors.

Current guidelines recommend that women should have a Papanicolaou smear (Pap test) every 3 years beginning at age 21. Guidelines also specify that women
ages 30 to 65 should have HPV and Pap co-testing every 5 years or a Pap test alone every 3 years. Women with certain risk factors may need more frequent screening or to continue screening beyond age 65. Women who have received the HPV vaccine still need regular cervical screening\textsuperscript{196,201} (see Chapter 33 for a discussion on the HPV vaccine). HPV vaccines protect males and females against diseases, including cancers, when given in the recommended age groups. HPV vaccines are given in three shots over 6 months.\textsuperscript{202}

**Other Viruses and Microorganisms**

A discussion of the relationship between viruses, bacteria, and cancer is contained in Chapter 10 and appropriate chapters in Unit II. Other microorganisms involved in carcinogenesis include parasites such as *Opisthorchis viverrini* (bile duct cancer) and *Schistosoma haematobium* (bladder cancer). Their specific roles in carcinogenesis are reported to be related to cofactors or carcinogens, or both.

**Air Pollution**

Outdoor air pollution is a complex mixture of many known carcinogens and its relationship to lung cancer has been studied for more than 50 years.\textsuperscript{203} Past reviews of outdoor and household air pollution indicated that both were associated with increased rates of lung cancer, most particularly with exposures to increased levels of particles called particulate matter (PM). Particulate matter, also known as particle pollution, is a mixture of extremely small particles and liquid droplets. Particle pollution consists of a complex mix of acids (such as nitrates and sulfates), organic chemicals, metals, and soil or dust particles. The International Agency for Research on Cancer (IARC) recently concluded that exposure to outdoor air pollution and to particulate matter (PM) in outdoor air is carcinogenic to humans (IARC Group 1) and causes lung cancer.\textsuperscript{204,205} The IARC's evaluation came from long-term epidemiologic studies of residential exposure to air pollution. Specifically, focused reviews of lung cancer risk are with prominent components of PM in outdoor air (PM\textsubscript{2.5} particles with aerodynamic diameter ≤2.5 µm, or fine particles and PM\textsubscript{10} [≤10 µm, or inhalable particles]) (Figure 11-18).
PM$_{2.5}$ includes a higher proportion of mutagenic agents. Importantly, analyses by continent of study (including North America, Europe, and others) yielded consistent, positive associations between PM$_{2.5}$ and lung cancer. Primary particles are emitted directly from a source, for example, construction sites, unpaved roads, fields, smokestacks, or fires. Secondary particles are emitted from power plants, industries, and automobiles. These particles are a complex of chemicals including sulfur dioxide and nitrogen oxides and make up most of the fine particle pollution in the United States. Fine or ultrafine particles are easily absorbed by the lungs and phagocytosed by macrophages and neutrophils that release tissue-damaging inflammatory mediators. Acute exposure to diesel exhaust that contains fine particles is linked to lung, throat, and eye irritations; asthma attacks; and myocardial ischemia (Figure 11-19). Importantly, according to the WHO, diesel exhaust is carcinogenic and causes lung cancer. The central hypothesis, based on rat studies, for the mechanisms related to particle-induced lung carcinogenesis is that insoluble particles cause pulmonary inflammation (e.g., cytokine release, ROS), which leads to oxidative stress and oxidation of DNA, proliferative response, and tissue remodeling progressing toward fibrosis and tumor development.
The Global Burden of Disease collaboration estimated that approximately 3.22 million deaths were caused by exposure to air pollution in 2010, an increase from 2.91 million deaths attributed to air pollution in 1990. From data in 2010, cancers of the trachea, bronchus, or lung represent about 7% of total mortality attributable to PM$_{2.5}$. So far, data have not allowed the clear relationships of air pollution on lung cancer risk between former heavy smokers versus light smokers.

Living close to certain industries is a recognized cancer risk factor. Overall, fine particle pollution also is linked to other health problems and includes (1) premature death in people with heart or lung disease, (2) nonfatal heart attacks, (3) irregular heartbeat, (4) aggravated asthma, (5) decreased lung function, and (6) respiratory symptoms, including irritation of the airways, coughing, and shortness of breath. Additionally, other effects of particle pollution include reduced visibility (haze); environmental damage in lakes and streams, coastal waters, and river basins; depletion of nutrients in soil; and damage to forests and food crops.

Indoor pollution is generally considered worse than outdoor pollution, partly because of cigarette smoke. Environmental tobacco smoke (ETS; passive smoking) can cause the formation of reactive oxygen free radicals and thus DNA damage. The IARC has classified ETS as a human carcinogen. Another significant indoor air
pollutant is radon gas. **Radon** is a natural radioactive gas derived from the radioactive decay of uranium that is ubiquitous in rock and soil; it can become trapped in houses and form radioactive decay products known to be carcinogenic to humans. The most hazardous houses can be identified by testing and then be modified to prevent further radon contamination. Exposure levels are greater from underground mines than from houses. Most of the lung cancers associated with radon are bronchogenic; however, small cell carcinoma does occur with greater frequency in underground miners. Radon increases the risk of lung cancer in underground miners in spite of their smoking status.

In China, some regions report very high levels of lung cancer in women who spend much of their time indoors. Exposures from heating and cooking combustion sources (e.g., oil vapors) and asbestos are identified as risk factors for lung cancer.\(^{212}\) In addition, domestic coal use and ETS increase the risk of lung cancer in women and men.\(^{213,214}\)

Inorganic arsenic, found principally in underground water (at levels ranging from 1000 to 4000 mcg/L), is found in many regions of the world. According to the IARC, strong evidence indicates an increased risk of bladder, skin, and lung cancers following consumption of water with high levels of arsenic (generally greater than 200 mcg/L).\(^ {215}\) Evidence for cancers of the liver, colon, and kidney is weaker. Other sources of inorganic arsenic are related to occupational exposures (see Table 11-1).

### Chemical and Occupational Hazards as Carcinogens

An estimated 100,000 synthetic chemicals are used in the United States.\(^ {216}\) Of those, only about 7% have been tested for their health effects;\(^ {217}\) another 1000 chemicals are added each year.\(^ {216}\) Exposure to chemicals occurs every day—they are present in air, soil, food, water, household products, toys, personal care products, workplaces, and homes. The number of known carcinogens in experimental animals is large. It is suspected that most of these chemical carcinogens are potentially carcinogenic in humans but documentation is lacking. Table 11-1 (pp. 268-271) provides a summary of the chemicals according to sufficient or limited evidence in humans by cancer site. Known and probable carcinogenic agents are updated by the International Agency for Research on Cancer (IARC).

Chemical carcinogenesis involves the classic genotoxic mechanisms, and exposure to genotoxic carcinogens also might involve a variety of nongenotoxic effects in cells.\(^ {218}\) A number of studies reported that the carcinogenic effects induced by several chemicals, including 2-acetylaminofluorene, tamoxifen,
trichloroethylene, aflatoxin B₁, ochratoxin, nickel, and chromium, do not follow a classic genotoxic carcinogenesis model, but rather involve a spectrum of cellular alterations encompassing epigenetic alterations.²¹⁹ These epigenetically reprogrammed cells show an epigenetic profile similar to that frequently observed in cancer cells, including altered histone patterns, hypomethylation of DNA repetitive elements, alterations in proto-oncogenes, and hypermethylation of tumor-suppressor genes. Altered epigenetic status confers genome instability and loss of controlled growth signals, typically observed in cancer cells.²²⁰ According to the director of the National Institute of Environmental Health Sciences, “… exposure to gene-altering substances, particularly in the womb and shortly after birth can lead to increased susceptibility to disease. There is a huge potential impact from these exposures, partly because the changes maybe inherited across generations.”²²¹

A substantial percentage of cancers of the upper respiratory passages, lung, bladder, and peritoneum are attributed to occupational factors; however, fewer studies of nonsmokers exist.²²² One notable occupational factor is asbestos-silicate mineral woven into fabrics, used in fire-resistant, insulating materials, and many other industrial sources. Chrysotile asbestos, more than any other type, accounts for a majority of asbestos in buildings in the United States. Asbestos increases the risk of mesothelioma and lung cancer and possibly other cancers. Benign conditions of asbestos exposures include pleural plaques, diffuse pleural thickening, and pulmonary fibrosis. The asbestos-related disorders (ARDs) are currently of significant occupational and public health concern.²²³ Asbestos was used in homes and buildings built before the 1970s to insulate ceiling tiles, flooring, and pipe covers. In Western Europe, the epidemic of mesothelioma in building workers and other workers born after 1940 did not become apparent until the 1990s because of long latency. Asbestos usage has been banned in most developed countries, but is still used in many developing countries and the incidence of cases of ARDs is rising.²²³ No exposure to asbestos is without risk.

Carcinoma of the bladder has been linked with the manufacture of dyes, rubber, paint, and aromatic amines, especially β-naphthylamine and benzidine. Benzol inhalation is linked to leukemia in shoemakers and in workers in the rubber cement, explosives, and dyeing industries. Other notable occupational hazards include heavy metals (e.g., high-nickel alloy, chromium VI compounds, inorganic arsenic), silica, polycyclic aromatic hydrocarbons, sulfuric acid, and chloromethyl ether. Data from the Nurse's Health Study in the United States showed increased lung cancer associated with particulate matter air pollution exposure.²²⁴ Data from the European Study of Cohorts for Effects report particulate matter contributes to lung cancer incidence in Europe.²²⁵ Studies of occupational exposure to diesel exhaust indicate an increased risk of lung cancer.²²⁶ Other important exposures are included in Table
Disentangling data related to lung cancer, air pollution, and occupational risks is complex, especially in combination with active and passive smoking and the interplay of environmental factors and genetic polymorphisms at multiple loci.

Quick Check 11-4

1. Identify the high-risk types of HPV that are carcinogenic.

2. What components of air pollution are considered most important for carcinogenesis?

3. Why do certain chemicals present a notable challenge to the environment and cancer?
Did You Understand?

1. Cancer arises from a complicated and interacting web of multiple etiologies. Avoiding high-risk behaviors and exposure to individual carcinogens will prevent many types of cancers.

2. Lifestyle behaviors, dietary and environmental factors and occupational exposure contribute to the number of cancer cases and deaths.

3. Cancers are caused by environmental-lifestyle factors and genetic/epigenetic factors. Driven by genetic alterations and epigenetic abnormalities, biologic processes also include variations in detoxifying enzymes or DNA repair genes. Interacting factors are weaker immune systems, differences in hormone levels, and metabolic factors. These factors are influenced by the surrounding microenvironment or stroma.

4. Altogether the biologic environment is modified by metabolic and hormonal factors, inflammation, and disordered glucose and lipid metabolism. Once malignant phenotypes have developed, complex interactions occur between the tumor, the surrounding stroma, and the cells of the immune and inflammatory systems.

Incidence and Mortality Trends

1. Globally cancer is reported to become a major cause of morbidity and mortality in the coming decades.

2. The global cancer burden is shifting from the more developed countries to economically disadvantaged countries.

3. In the United States, cancer incidence rates in all racial and ethnic groups and genders combined were stable from 2000 to 2009. Cancer incidence rates have increased in children 0 to 19 years of age for black (overall lowest rates) and Hispanic children and stable for all other racial and ethnic groups.

4. Overall, cancer death rates have been declining since the early 1990s in both men and women. Death rates for men, however, increased for cancers of the pancreas, liver, and melanoma. Death rates increased for women for cancers of the pancreas, liver, and uterus. For all racial and ethnic groups, for both genders and children for
the time period 2000 to 2009, overall cancer death rates declined.
In Utero and Early Life Conditions

1. Emerging data suggest early life events influence later susceptibility to chronic diseases.

2. Developmental plasticity is the degree to which an organism's development is contingent on its environment. Plasticity refers to the ability of genes to organize physiologically or structurally in response to environmental conditions during fetal development.

3. Early versus late undernutrition in pregnancy indicated that the first trimester of pregnancy is particularly vulnerable to disease outcome in adulthood.

4. Research on DNA methylation marks, in utero environments, and future phenotypes is growing.

Environmental-Lifestyle Factors

Tobacco Use

1. Cigarette smoking is carcinogenic and the most important cause of cancer. Tobacco smoking causes cancer in more than 15 organ sites, and exposure to secondhand smoke and parental smoking causes cancer in daughters and sons and in other nonsmokers. The risk is greatest in those who begin to smoke when young and continue throughout life. Smoking is, however, pandemic affecting all ages.

2. Cigarette smoking causes more than 6 million deaths per year from cancer, chronic lung disease, cardiovascular disease, and stroke.

3. Smoking tobacco is linked to cancers of the lung, upper aerodigestive tract, lower urinary tract, kidney, pancreas, cervix, uterus, and myeloid leukemia. Recently added to the list are liver cancer and colorectal cancer.

4. Secondhand smoke is a cause of stroke; increases the risk of death in people with cancer and cancer survivors as well as those with macular degeneration, tuberculosis, ectopic pregnancy, and diabetes mellitus. Smoking increases inflammation, impairs immunity, and is a cause of rheumatoid arthritis. Smoking causes even more deaths from vascular and respiratory diseases.

5. Cigar or pipe smoking is causally related to cancers of the oral cavity,
oropharynx, hypopharynx, larynx, esophagus, and lung. Pipe smokers have an increased risk of dying from cancers of lung, lip, throat, esophagus, larynx, pancreas, and colon and rectum.

6. Bidi smoking can cause cancers of the respiratory and digestive sites.

**Diet**

1. Understanding diet as a factor for increasing the risk of cancer is difficult and essential. The complexity is because of the variety of foods consumed, the many constituents of foods, the metabolic consequences of eating, and the temporal changes in the patterns of food use.

2. Nutrigenomics is the study of the effects of nutrition on the phenotypic variability of individuals based on genomic differences. Investigators are focused on genes, SNPs, amplifications, and deletions within the DNA sequences as modifiers of the response to foods and drinks.

3. Decades of research on specific nutrients and foods and cancers have been controversial. Less controversial are the implementation of dietary patterns, for example, the Mediterranean dietary pattern, and the promoting of specific dietary recommendations, for example, approaches to lower blood pressure.

4. The importance of diet has been illustrated by data showing changes in cancer risk among migrants in low-risk countries compared with those in high-risk countries. With migration these changes (low risk becomes high risk) are rapid and a plausible determinant of such changes is the adoption of the Western diet.

5. Most relevant to carcinogenesis, because many cellular functions are affected by nutrition (i.e., cell cycle, cell differentiation, proliferation, miRNA expression, self-renewal, DNA repair, hormonal axes), is focusing on dietary patterns and meaningful biomarkers specific to nutritional factors.

6. Carcinogenic substances from diet can develop from the cooking of fat, meat, or protein (e.g., heterocyclic aromatic amines), and from naturally occurring compounds associated with plant foods.

7. Nutrition may directly influence epigenetic factors that silence genes that should be active or activate genes that should be silent.
8. Dietary components can act directly as mutagens or interfere with their elimination.

**Nutrition, Obesity, Alcohol Consumption, and Physical Activity: Impacts on Cancer**

1. Obesity has been increasing in developed countries and in urban areas of developing countries. Obesity in the United States is an epidemic. Studies have significantly improved the understanding of the relationship between overweight/obesity, energy balance and cancer risk, cancer recurrence, and survival.

2. Obesity is a risk factor for cancers of the endometrium, colorectum, kidney, esophagus, breast (postmenopausal), and pancreas. Evidence is evolving for other cancers.

3. The mechanisms of obesity-associated cancer risks are unclear and vary by type of tumor and distribution of body fat. Emerging are three main factors: (1) insulin-insulin-like growth factor (IGF-1) axis, (2) sex hormones, and (3) adipokines.

4. Metabolic changes in adipose tissue from obesity result in several alterations and include insulin resistance, hyperglycemia, dyslipidemia, hypoxia, and chronic inflammation. Tumor growth is regulated by interactions between tumor cells and stromal compartments that are rich in adipose tissue, adipocytes function as endocrine cells and shape the tumor microenvironment.

5. Alcohol plays a contributory role in several common cancers. Strong data link alcohol with cancers of the mouth, pharynx, larynx, esophagus, liver, colorectum, and breast.

6. Evidence does not show any safe limit of alcohol and the health effects are from ethanol regardless of the type of drink.

7. Alcohol-related carcinogenesis involves acetaldehyde, ROS, procarcinogen activation, cellular regeneration, nutritional deficiencies, altered mucosal integrity, and enzyme and metabolic dysfunction. Under investigation are epigenetic alterations and the effects of alcohol metabolism.

8. Physical activity reduces the risk for breast and colon cancers and may reduce the
risk for other cancers.

9. Biologic mechanisms for the protective effects of physical activity include decreasing insulin and IGF levels, decreasing obesity, increasing free radical scavenger systems, altering inflammatory mediators, decreasing levels of circulating sex hormones and metabolic hormones, improving immune function, enhancing cytochrome P-450 activity (thus modifying carcinogen activation), and increasing gut motility.

10. Physical activity helps to prevent type 2 diabetes, which has been associated with cancer of the pancreas and colon. Exercise in children with cancer was associated with improved body composition, flexibility, and cardiorespiratory fitness.

11. Many unanswered questions remain regarding frequency of exercise, intensity, and duration.

12. Recent data encourage 60 minutes of vigorous activity daily for decreasing BMI, body fat, and intra-abdominal fat.

**Ionizing Radiation (IR)**

1. Much of the knowledge of the effects of ionizing radiation on human cancer has come from Hiroshima and Nagasaki atomic bomb exposures, particularly the Life Span Study. Other evidence is from exposure to radiation for medical reasons, underground miners, and other occupational exposures. Human exposure includes emissions from the environment, x-rays, CT scans, radioisotopes, and other radioactive sources.

2. From the exposures in Japan increased frequencies of cancers occurred in thyroid and breast tissue, and lung, stomach, colon, esophageal, urinary tract, and multiple myeloma.

3. Excess relative risks (ERRs) for radiation-induced cancers at a given age are much higher for individuals exposed during childhood. What is at question now is the ERRs of radiation exposure in adulthood.

4. New models of carcinogenesis identify ionizing radiation not only as an initiator of premalignant cell clones but also as a promoter of preexisting-premalignant damage.
5. Other health risks from radiation include cardiovascular effects and somatic mutations that may contribute to other diseases. These effects may manifest years after completion of radiation therapy.

6. A summary point from BEIR VII and the NCRP is concern about the increased IR exposure from medical procedures, particularly CT scans and nuclear medicine procedures.

7. The risks from low-dose radiation are being debated among radiobiologists, geneticists, physicists, and others because of the potential effect on the health of current and future generations.

8. IR is a mutagen and carcinogen; it can penetrate cells and tissues and deposit energy in tissues at random in the form of ionizations.

9. IR affects many cellular processes, including gene expression, mitochondrial function, nucleotide base damage, and single- and double-strand DNA breaks. These changes can lead to carcinogenesis.

10. It is now known that radiation may induce a type of genomic instability to the progeny of the directly irradiated cells over many generations of cell divisions and can affect so-called innocent bystander cells. Investigators are studying genomic instability as it may contribute to secondary cancers.

11. Epigenetic events after radiation include alterations in pathways affecting cell adhesion, extracellular matrix interactions, and cell-to-cell communication.

**Ultraviolet Radiation (UVR)**

1. Ultraviolet (UV) radiation comes from sunlight. Other sources of UV radiation include electric lights, black lights, and tanning lamps. Most of the UV radiation received on earth is UVA and some UVB. UVA radiation is weaker than UVB, but UVA penetrates deeper into the skin and is more constant throughout the year despite the weather.

2. The incidence of basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) is strongly correlated with lifetime sunlight exposure. Intense intermittent recreational sun exposure has been associated with melanoma and BCC. Tanning bed use has been associated with an increased risk of BCC and data suggest sunbed use as a reason for increased melanoma, especially in women. Chronic occupational
sun exposure has been associated with SCC.

3. Cumulative sun exposure is the additive effects of intermittent sun exposure, chronic sun exposure, or both.

4. UV radiation is known to cause specific gene mutations: for example, squamous cell carcinoma involves mutation in the TP53 gene, basal cell carcinoma in the patched gene, and melanoma in the p16 gene. Investigators are identifying epigenetic alterations in tumor tissues and cell lines for skin cancers.

5. Skin exposure to UV radiation produces ROS in large quantities that can overwhelm tissue antioxidants and other oxygen-degrading pathways. Imbalances in ROS can lead to oxidative stress, tissue injury, and direct DNA damage.

6. UV radiation can activate the transcription factor NF-κβ and other free radicals important in regulating genes that induce inflammation. Inflammation is a critical component of tumor progression.

7. Melanoma is the most lethal skin cancer and the incidence of melanoma has been increasing worldwide. The pathogenesis of melanoma is complex, including genetic and environmental factors.

**Electromagnetic Radiation (EMR)**

1. Radiofrequency electromagnetic radiation (RF-EMR) is a type of nonionizing and low-frequency radiation. Health risks associated with RF-EMR are controversial. Exposure to electric and magnetic fields is widespread.

2. RF-EMRs of varying strength include microwaves, radar, power frequency radiation associated with electricity and radio waves, fluorescent lights, computers, electric equipment, cell and cordless phones, and others.

3. Data regarding the effects of RF-EMR have been slow to emerge because of methods to accurately measure exposure, the lack of clear dose-response relationships, reproducing effects, financial interests, and other priorities such as convenience.

4. Overall there is limited evidence that magnetic fields cause childhood leukemia and insufficient evidence for other cancers in children.
5. The Working Group classified RF-EMF as “possibly carcinogenic to humans” (Group 2B).

Infection, Sexual and Reproductive Behavior

1. Infection is an important contributor to cancer worldwide. The four top infections and new cancer cases include HPV, *H. pylori*, HBV, and HCV.

2. HPV is the most common sexually transmitted virus in the United States. Although a dozen HPV types are identified, HPV types 16 and 18 are responsible for the majority of cancers. Persistence of infection with high-risk HPV is a prerequisite for the development of cervical intraepithelial neoplasia (CIN) lesions, and invasive cancer.

3. HPV infection has been identified as a definite carcinogen for 6 types of cancer: cervix, penis, vulva, anus, and some oropharynx (including the base of the tongue and tonsils).

4. The incidence of HPV-associated oropharyngeal cancer has increased during the past 20 years, especially among men.

5. Biologic factors that may interact with HPV infection to increase cancer risk include long-term oral contraceptive use, smoking, decreased immunity, having many children, poor oral hygiene (for increased risk of oropharyngeal cancer), and chronic inflammation.

6. HPV may be transmitted by genital contact (oral, touching, or sexual intercourse). The possible modes of transmission in children are controversial, newborn babies can be exposed to cervical HPV infection from the mother. A second peak of high-risk HPV prevalence occurs in postmenopausal women.

7. The incidence of oropharyngeal cancers caused by HPV is increasing worldwide.

8. HPV vaccination programs have made it possible to eliminate the majority of all invasive cervical cancer worldwide.

Air Pollution

1. Indoor and outdoor air pollution are both associated with increased rates of lung cancer. The IARC concluded that exposure to outdoor air pollution and to
particulate matter (PM) in outdoor air is carcinogenic to humans.

2. PM$_{2.5}$ includes a higher proportion of mutagenic agents. Primary particles are emitted directly from a source, for example, construction sites, unpaved roads, or smokestacks. Secondary particles are emitted from power plants, industries, and automobiles. Diesel exhaust is carcinogenic and causes lung cancer.

3. Acute exposure to diesel exhaust that contains fine particles is linked to lung, throat and eye irritations, asthma attacks, and myocardial ischemia.

4. Fine particle pollution also is linked to premature death in people with heart or lung disease, nonfatal heart attacks, irregular heartbeat, and decreased lung function.

5. Mechanisms related to particle-induced lung carcinogenesis include soluble particles cause pulmonary inflammation, which leads to oxidative stress and oxidation of DNA, proliferative response, tissue remodeling toward fibrosis, and tumor development.

6. Indoor air pollution is generally considered worse than outdoor pollution. Sources of indoor air pollution include tobacco smoke, heating and cooking combustion sources, radon, and coal use.

### Chemicals and Occupational Hazards as Carcinogens

1. The International Agency for Research on Cancer (IARC) has classified carcinogenic agents as known and probable.

2. An estimated 100,000 synthetic chemicals are used in the United States. Only 7% have been fully tested for their impact on health and another 1000 are added each year.

3. Exposure to chemicals occurs from air, soil, food, water, personal care products, toys, household products, medications, workplaces, and homes

4. Chemical carcinogenesis involves genotoxic and epigenetic alterations. Other mechanisms include hormonal disruption, interference with cell signaling mechanisms and other unknown effects.
5. Exposure to gene-altering substances, particularly in the womb and shortly after birth, can lead to increased susceptibility to disease.

6. Asbestos is linked to an epidemic of mesothelioma and asbestos usage has been banned in most developed countries.

7. A substantial percentage of cancers of the upper respiratory passages, lung, bladder, and peritoneum are attributed to occupational factors.

Cancer in children and adolescents is rare; however, it remains the leading cause of death that is attributable to disease for this age group. Survival rates among children and adolescents with cancer have dramatically improved since the 1960s. Among the factors leading to improved cure rates include the use of combination chemotherapy, the incorporation of research data obtained from clinical trials, and the utilization of multimodal treatment for solid tumors.
Incidence, Etiology, and Types of Childhood Cancer

More than 15,500 children and adolescents 19 years of age and younger were estimated to be diagnosed with cancer in the United States in 2014. The overall incidence of childhood and adolescent cancer is 17.2 per 100,000 children (Figure 12-1). This incidence, however, demonstrates a bimodal distribution across age groups with peaks among children less than 5 years of age and adolescents 15 to 19 years of age. Childhood cancer in the United States also is slightly more common in boys than in girls. The male/female ratio for childhood cancers is 1.2 : 1.0.

In 2011, the death rates of children from birth to 14 years of age with cancer were 2.3 per 100,000 for males and 2.1 per 100,000 for females. Death rates for adolescents 15 to 19 years of age were 3.4 per 100,000 for males and 2.5 per 100,000 for females. By comparison, cancer had an overall mortality of 163.2 per 100,000 adults in 2013.
The types of malignancies occurring in children are vastly different from those that affect adults. The most common types of cancer among adults include prostate, breast, lung, and colon. In contrast, children tend to develop leukemias, brain tumors, and sarcomas. Although many adult cancers have associated lifestyle factors that could theoretically be avoided, such as smoking and exposure to sun, very few environmental factors have been linked to pediatric malignancies. More data are emerging that the developing child may be affected by epigenetic modifications resulting from parental exposures before conception, exposures in utero, and nutrition during early life.\textsuperscript{5,6}

Most childhood cancers originate from the \textit{mesodermal germ layer}, which develops into connective tissue, bone, cartilage, muscle, blood, blood vessels, gonads, kidney, and the lymphatic system (\textit{Figure 12-2}). Thus the more common childhood cancers are leukemias, sarcomas, and embryonic tumors.
Embryonic tumors originate during intrauterine life and contain abnormal cells that appear to be immature embryonic tissue unable to mature or differentiate into fully developed functional cells. Embryonic tumors are most often diagnosed early in life (usually by 5 years of age) and are rare in older children, adolescents, and adults. The names of these tumors often include the root term blast (e.g., neuroblastoma, retinoblastoma), which indicates the embryonic stage of development.

Sarcomas, leukemias, and lymphomas are cancers observed in childhood and also may occur in adults. Most adult cancers, however, involve epithelial tissue and are, therefore, carcinomas. Carcinomas rarely occur in children because these cancers most commonly result from environmental carcinogens and require a long
period from exposure to the appearance of the carcinoma. Carcinomas begin to increase in incidence between the ages of 15 and 19 years, becoming the most common cancer tissue type observed after adolescence.³

Childhood cancers are often diagnosed during peak times of physical growth and maturation, accounting for the bimodal distribution in their incidence. In general, they are extremely fast-growing cancers, resulting in a relatively short latency period—that is, the time from the initial exposure to the onset of symptoms. The distribution of cancer types also changes during childhood and adolescence. Leukemias and embryonal tumors have a peak incidence before the child is 5 years of age. Brain tumors, the second leading type of childhood cancer overall, have a peak incidence among children less than 15 years of age. The incidence of specific subtypes of brain tumors does, however, vary across childhood and adolescence. Lymphomas, both Hodgkin and non-Hodgkin, represent the third most common type of childhood cancer. Lymphoma is rare in children less than 5 years of age and occurs with increasing frequency in children and adolescents 10 years of age and older. Rhabdomyosarcoma is the most common soft tissue sarcoma of childhood. Rhabdomyosarcoma has a bimodal age distribution with two thirds of cases occurring in children less than 6 years of age and one third occurring in children and adolescents 10 years of age and older. The two most common types of bone tumors are osteosarcoma and Ewing sarcoma. These cancers are more likely to occur in adolescents ages 15 and older (Table 12-1). Cancer also is more common in white children relative to other racial groups (Table 12-2).

**Etiology**

The causes of cancer in children are largely unknown. A few environmental factors are known to predispose a child to cancer, but causal factors have not been established for most childhood cancers. A number of host factors, many of which are genetic risk factors or congenital conditions, have been implicated in the development of childhood cancer (Table 12-3).

Because of their relatively short latency period, most childhood cancers do not lend themselves to early cancer warning signs. Certainly the American Cancer Society's seven warning signs of cancer do not apply because they describe adult, environmentally caused carcinomas. Likewise, efforts to establish early screening strategies for childhood cancers have not been effective. Although host factors are important in identifying populations of children at risk for cancer, most children who are diagnosed with cancer do not have known predisposing environmental or host factors.

Multiple causation theory provides a useful framework for interpreting the results of epidemiologic studies. For example, laboratory and epidemiologic studies may indicate that exposure to a certain chemical can cause leukemia, but not all children exposed to that chemical will develop leukemia. Additional studies will be needed to determine what other host and environmental factors must interact with chemical exposure to cause the disease.
Genetic and Genomic Factors

Acquired or inherited mutations in individual genes may contribute to the development of cancer in children and adolescents. Mutations in more than 150 oncogenes and tumor-suppressor genes have been associated with the subsequent development of both childhood and adult cancers (Table 12-4). Fanconi anemia and Bloom syndrome are two autosomal recessive conditions that result in impaired DNA repair and are risk factors for the development of acute leukemia. Retinoblastoma, a malignant embryonic tumor of the eye, occurs either as an inherited defect in the \( RB1 \) gene or as an acquired mutation (see Chapter 17).

### TABLE 12-4

Although leukemia is not inherited as a genetic condition, siblings of children with leukemia have a two to four times increased risk for the development of leukemia relative to that of siblings of healthy children. The occurrence of leukemia in monozygous twins is estimated to be as high as 25%.

**Li-Fraumeni syndrome (LFS)** is an autosomal dominant disorder involving the \( TP53 \) tumor-suppressor gene. For individuals with a mutation in the \( TP53 \) gene, the risk of developing cancer as a child or adult is significantly higher than the risk in the unaffected population. Children and adults in families affected by LFS are at risk for soft tissue sarcoma, breast cancer, leukemia, osteosarcoma, melanoma, and cancer of the colon, pancreas, adrenal cortex, and brain. Individuals with LFS also...
are at increased risk for developing multiple primary cancers.\textsuperscript{8}

Chromosomal abnormalities also may contribute to the development of childhood cancer. Chromosome abnormalities include aneuploidy, deletions, amplifications, translocations, and fragility (see Chapter 2). These abnormalities may occur within the affected cancer cells as a consequence of malignant transformation or may be present as the consequence of a congenital syndrome.

A chromosomal translocation results from the rearrangement of two nonhomologous chromosomes. Translocations may result in the creation of a fusion gene in which the two previously separate gene regions unite. Two fusion genes associated with acute lymphocytic leukemia (ALL) in children are the \textit{BCR-ABL} gene, resulting from a translocation between chromosomes 9 and 22, and the \textit{TEL-AML1} gene, resulting from a translocation between chromosomes 12 and 21.\textsuperscript{3,10}

Several syndromes associated with specific congenital malformations are associated with a higher incidence of cancer development. In some cases, these children may be carefully followed and screened for tumor development. One of the more recognized syndromes is trisomy 21 (Down syndrome), which has an increased susceptibility to acute leukemia. The risk of developing leukemia is 10 to 20 times greater among children with Down syndrome than in healthy children. The age distribution for developing ALL among children with Down syndrome is similar to that of children without Down syndrome.\textsuperscript{11,12}

\textbf{Wilms tumor}, a malignant tumor of the kidney, is particularly recognized for its association with a number of congenital anomalies, including genitourinary anomalies, aniridia (congenital absence of the iris), hemihypertrophy (muscular overgrowth of half of the body or face), and intellectual disabilities. Identifiable malformations and congenital predisposition syndromes are present in approximately 17% of children diagnosed with Wilms tumor.\textsuperscript{13}

\section*{Environmental Factors}

Finding the cause of any disease is typically a long, slow process. Epidemiologic studies require many years to determine whether a risk factor is possibly related to the development of childhood cancer. No single factor determines whether an individual will develop cancer, even if a specific environmental exposure explains a high proportion of the occurrence of a specific cancer (Box 12-1).

\section*{Box 12-1}

\textbf{Factors That May Contribute to the}
Development of Childhood and Adolescent Cancer

- Genetic and epigenetic factors
- Diet
- Immune function
- Occupational exposure
- Ionizing radiation
- Hormonal variations
- Viral illnesses
- Individual characteristics, such as the biologic, social, and physical environment

Prenatal Exposure

Prenatal exposure to some drugs and to ionizing radiation has been linked to childhood cancers. The most well-described drug is diethylstilbestrol (DES), which was prescribed by physicians to prevent spontaneous miscarriage (in women with previous miscarriage). In 1971 DES was identified as a transplacental chemical carcinogen because a small percentage of the daughters of women who took DES developed adenocarcinomas of the vagina. Since then, other studies have attempted to identify other drugs taken by pregnant women that may cause cancer in their offspring, but no other drugs have been found. Current evidence suggests an increased risk of childhood leukemia is associated with low levels of exposure to antenatal x-rays. An association between antenatal x-ray exposure and childhood brain tumors has not been identified. Other current areas of research include exploring epigenetic modifications resulting from prenatal exposures and their role in future cancer development.

Childhood Exposure

Childhood exposure to ionizing radiation, drugs, electromagnetic fields, or viruses has been associated with the risk of developing cancer. Retrospective research has shown a significant correlation between radiation-induced malignancies and either
radiotherapy (cancer treatment) or radiation exposure from diagnostic imaging\textsuperscript{16} (see Health Alert: Radiation Risks and PediatricComputed Tomography [CT]: Data from the National Cancer Institute). In addition to the drug and environmental agents that are known to cause cancer in adults and therefore also are risks for exposure during childhood, a few drugs may particularly increase cancer risk during childhood (Table 12-5).

\textbf{Health Alert}

\textbf{Radiation Risks and Pediatric Computed Tomography (CT): Data from the National Cancer Institute}

Emerging is the concern of radiation risks in children because the use of pediatric CT has been increasing rapidly. Pediatric CT is now a public health concern. Children are more sensitive to radiation than adults as demonstrated in epidemiologic studies. Children have a longer life expectancy than adults, increasing the window of opportunity to express radiation damage, and children may receive higher radiation dose than necessary if CT is not adjusted for their smaller size. Although CT scans comprise up to about 12\% of diagnostic radiologic procedures in large U.S. hospitals, it is estimated that they account for approximately 49\% of the U.S. population's collective radiation dose from all medical x-ray examinations. CT is the largest contributor to medical radiation exposure among the U.S. population. It is important to stress that the absolute cancer risks associated with CT scans are small. The lifetime risks of cancer because of CT scans, which have been estimated in the literature using projection models based on atomic bomb survivors, are about 1 case of cancer for every 1000 people who are scanned, with a maximal incidence of about 1 case of cancer for every 500 people who are scanned. The benefits of properly performed and clinically justified CT examinations should always outweigh the risks for an individual child; unnecessary exposure is associated with unnecessary risk. Minimizing radiation exposure from pediatric CT, whenever possible, will reduce the projected number of CT-related cancers.

The relationship between childhood cancer and other environmental factors (e.g., electromagnetic fields, small appliances, radon) has been the focus of many epidemiologic studies. Although associations between some environmental exposures and acute leukemia have been demonstrated, no conclusive causal evidence has been reported\(^\text{17-19}\) (see *Health Alert: Magnetic Fields and Development of Pediatric Cancer*).

**Health Alert**

**Magnetic Fields and Development of Pediatric Cancer**

Several recent reports have suggested an association between environmental sources and the development of cancer in children. The presence of low-frequency magnetic fields has been a concern for many years as causing leukemia in children. The World Health Organization (WHO) research agenda identified the importance of such an analysis as a high research priority in 2007. A recent meta-analysis evaluated 9 case-control studies, representing 8 different countries, conducted between 1997 and 2013 and involving 11,699 cases of children with leukemia and 13,194 controls. This meta-analysis identified an increased risk of childhood leukemia associated with high levels of magnetic field exposure (≥0.4 µT). For additional perspective, the WHO estimates that only about 1% to 4% of children worldwide live in conditions that exceed this level of exposure. Ongoing research needs to be done in this area because environmental factors may require many years of exposure to cause disease. Additionally, an association between an environmental factor and childhood cancer does not establish causality. Ongoing research is needed to better understand the relationships between environmental factors and other factors associated with the childhood cancer, as well as potential underlying mechanisms by which environmental factors may contribute to the development of childhood cancer.

The strongest association between viruses and the development of cancer in children has been the Epstein-Barr virus (EBV), which is linked to Burkitt lymphoma, nasopharyngeal carcinoma, and Hodgkin disease. Children with acquired immunodeficiency syndrome (AIDS), caused by human immunodeficiency virus (HIV), have an increased risk of developing non-Hodgkin lymphoma and Kaposi sarcoma. However, with the use of highly active antiretroviral therapy in the developed world, the incidence of AIDS-related malignancies has declined dramatically.
Prognosis

More than 70% of children diagnosed with cancer are cured. Some of the factors leading to improved cure rates in pediatric oncology include the use of combination chemotherapy or multimodal treatment for solid childhood tumors and improvements in nursing and supportive care. The development of research centers for comprehensive childhood cancer treatment and cooperative study groups also have facilitated refinements in treatment protocols and data sharing, leading to improved survival rates.

Survival rates for children younger than 15 years of age have increased at a rate of 1.5% per year, which is similar to increases in survival for adults older than 50 years of age. Adolescents and young adults between 15 and 24 years of age, however, have experienced increases in survival of less than 0.5% per year. A partial explanation for the relative lack of progress in curing the adolescent population at the same rate as that realized in the younger pediatric population is the lack of participation in clinical trials. Between 1997 and 2003, the percentage of 15- to 19-year-olds with cancer participating in clinical trials was estimated at 10% to 15%. This value is approximately one fourth the clinical trial participation rate of children younger than 15 years and is likely due to the fact that fewer trials are available for young adolescents. The National Cancer Institute (NCI) and pediatric and adult cooperative groups sponsored by the NCI have launched a national initiative to increase the numbers of adolescents and young adults in clinical trials.

Survivors of childhood cancer are at increased risk of developing a second malignancy later in life. This risk may be associated with a variety of factors, including previous chemotherapy or radiotherapy, genetic factors, and type of primary cancer (e.g., soft tissue sarcoma, neuroblastoma).

Because childhood cancer should be viewed as a chronic disease instead of a fatal illness, treatment includes attention to quality of life and symptom management. Even those cancers that cannot be cured generally can be treated, resulting in significantly improved quality of life. Children and adolescents whose cancers are regarded as cured still face residual and late effects of their treatment. These late effects are more significant in children than in adults because treatment given during childhood occurs in a physically immature, growing individual. Late effects that need further study include physical impairments, reproductive dysfunction, soft tissue and bone atrophy, learning disabilities, secondary cancers, and psychologic sequelae. More must be learned about the genetic factors associated with childhood malignancies and about the genetic consequences of treatment. A referral to genetic services is appropriate for families of children whose cancer is known to be transmitted genetically (e.g., retinoblastoma, Li-Fraumeni syndrome).
Quick Check 12-1

1. What are the most common childhood cancers, and how do they differ from adult cancers?

2. Why are children less likely to develop carcinomas?

3. Compare and contrast different etiologic factors associated with the development of childhood cancer.
Did You Understand?

Incidences and Types of Childhood Cancers

1. Childhood cancer is a rare disease, but it remains the second leading cause of death in children.

2. The most common type of childhood cancer is leukemia, and the second most common type of pediatric malignancy is a tumor involving the brain or central nervous system.

Etiology

1. Because most carcinomas are caused by environmental exposure, these cancers are extremely rare in children because they have not lived long enough to be exposed to carcinogens.

2. Children with immunodeficiencies are at increased risk for developing cancer because of an ineffective immune system.

3. Children with Down syndrome are at increased risk for developing leukemia.

4. Risk factors that may be associated with the development of childhood cancer include inherited and acquired genetic and genomic changes, nutrition and diet, immune function, occupational exposure, hormonal variations, and viral illnesses, as well as other individual characteristics such as biologic, social, or physical environments.

Prognosis

1. Survivors of childhood cancer are at increased risk for developing a second cancer during their lifetime, compared with the general population.

2. Improved survival for children and adolescents with cancer has been facilitated, in part, by research aimed at identifying less toxic treatments that minimize residual effects.

The human nervous system is a remarkable structure responsible for decision making, for the body's ability to interact with the environment, and for the regulation and control of activities involving our internal organs. It is a network composed of complex structures that transmit electrical and chemical signals between the brain and the body's many organs and tissues. Aging changes occur throughout life and vary among individuals (see *Geriatric Considerations: Aging & the Nervous System*). This chapter provides a basic overview of the structure and function of the nervous system and supports the understanding of nervous system pathophysiology in the following chapters.
Overview and Organization of the Nervous System

Although the nervous system functions as a unified whole, structures and functions have been divided here to facilitate understanding. Structurally, the nervous system is divided into the central nervous system and the peripheral nervous system. The central nervous system (CNS) consists of the brain and spinal cord, enclosed within the protective cranial vault and vertebrae, respectively. The peripheral nervous system (PNS) is composed of the cranial nerves and the spinal nerves and their ganglia. Peripheral nerve pathways are differentiated into afferent pathways (ascending pathways), which carry sensory impulses toward the CNS, and efferent pathways (descending pathways), which innervate skeletal muscle or effector organs by transmitting motor impulses away from the CNS.

Functionally, the PNS can be divided into the somatic nervous system and the autonomic nervous system. The somatic nervous system consists of pathways that regulate voluntary motor control (e.g., skeletal muscle). The autonomic nervous system (ANS) is involved with regulation of the body's internal environment (viscera) through involuntary control of organ systems. The ANS is further divided into sympathetic and parasympathetic divisions. Organs innervated by specific components of the nervous system are called effector organs.
Cells of the Nervous System

Two basic types of cells constitute nervous tissue: neurons and supporting nonneuronal cells. The **neuron** is the primary cell of the nervous system. It is an electrically excitable cell and transmits information. Cells, such as **neuroglial cells** (astrocytes, microglia, and oligodendrocytes in the CNS) and **Schwann (neurilemma)** and **satellite cells** (in the PNS), provide structural support, protection, and nutrition for the neurons.

The Neuron

Working alone or in units, neurons detect environmental changes and initiate body responses to maintain a dynamic steady state. Neuronal size and structure vary markedly, so that each neuron is adapted to perform specialized functions. The fuel source for the neuron is predominantly glucose; insulin, however, is not required for cellular glucose uptake in the CNS. The cellular constituents of neurons include **microtubules** (transport substances within the cell), **neurofibrils** (very thin supportive fibers that extend throughout the neuron), **microfilaments** (thought to be involved in transport of cellular products), and **Nissl substances** (endoplasmic reticulum and ribosomes) involved in protein synthesis.

A neuron (Figure 13-1) has three components: a cell body (soma), the dendrites (thin branching fibers of the cell), and the axons. Most cell bodies are located within the CNS; those in the PNS usually are found in groups called ganglia (or plexuses—a group of relay nerves). The **dendrites** are extensions that carry nerve impulses toward the cell body. **Axons** are long, conductive projections that carry nerve impulses away from the cell body. The **axon hillock** is the cone-shaped process where the axon leaves the cell body. The first part of the axon hillock has the lowest threshold for stimulation, so action potentials begin there. A typical neuron has only one axon, which may be wrapped with a segmented layer of lipid material called **myelin**, an insulating substance that speeds impulse propagation. This entire membrane is referred to as the **myelin sheath** (see Figures 13-2 and 13-25, B). The myelin sheaths are interrupted at regular intervals by the **nodes of Ranvier**. Axons can branch at the nodes of Ranvier. In the CNS myelin is produced by oligodendrocytes. In the PNS myelin is produced by Schwann cells. Telodendria form presynaptic vesicles for neurotransmission.
FIGURE 13-1  Neuron with Composite Parts. Multipolar neuron: PNS neuron with multiple extensions from the cell body. PNS, Peripheral nervous system.  (Modified from Patton KT, Thibodeau GA, Douglas MM: Essentials of anatomy & physiology, St Louis, 2012, Mosby.)
FIGURE 13-2 Neuronal Transmission and Synaptic Cleft. Electrical impulse travels along axon of first neuron (presynaptic cell) to synapse. Chemical transmitter is secreted into synaptic space to depolarize membrane (dendrite or cell body) of next neuron (postsynaptic cell) in pathway. Cell A represents pseudounipolar cell; cell B represents multipolar cell.

The principle of divergence refers to the ability of axonal branches to influence many different neurons. Convergence applies when branches of various numbers of neurons “converge” on and influence a single neuron. Nutrient exchange is not possible through the myelin sheath, although it can occur at the nodes of Ranvier where the axon is not insulated. Where there is myelin, the velocity of nerve
impulses increases. Myelin acts as an insulator that allows an action potential to leap between segments rather than flow along the entire length of the membrane, yielding the increased velocity. This mechanism is referred to as **saltatory conduction**. Disorders of the myelin sheath (demyelinating diseases), such as multiple sclerosis and Guillain-Barré syndrome, demonstrate the important role myelin plays in nerve conduction (see Chapter 16). Conduction velocities depend not only on the myelin coating but also on the diameter of the axon. Larger axons transmit impulses at a faster rate.

Neurons are structurally classified on the basis of the number of processes (projections) extending from the cell body. There are four basic types of cell configuration: (1) unipolar, (2) pseudounipolar, (3) bipolar, and (4) multipolar. **Unipolar neurons** have one process that branches shortly after leaving the cell body. One example is found in the retina. **Pseudounipolar neurons** (some authors call them unipolar) also have one process; the dendritic portion of each of these neurons extends away from the CNS and the axon portion projects into the CNS (Figure 13-2). This configuration is typical of sensory neurons in both cranial and spinal nerves. **Bipolar neurons** have two distinct processes arising from the cell body. This type of neuron connects the rod and cone cells of the retina. **Multipolar neurons** are the most common and have multiple processes capable of extensive branching. A motor neuron is typically multipolar (see Figure 13-2).

Functionally, there are three types of neurons (their direction of transmission and typical configuration are noted in parentheses): (1) sensory (afferent, mostly pseudounipolar), (2) associational (interneurons, multipolar), and (3) motor (efferent, multipolar). **Sensory neurons** carry impulses from peripheral sensory receptors to the CNS. **Associational neurons (interneurons)** transmit impulses from neuron to neuron—that is, sensory to motor neurons. They are located solely within the CNS. Motor neurons transmit impulses away from the CNS to an effector (i.e., skeletal muscle or organs). In skeletal muscle the end processes form a **neuromuscular (myoneural) junction** (see Figure 13-15).

**Neuroglia and Schwann Cells**

**Neuroglia** (“nerve glue”) are the general classification of nonneuronal cells that support the neurons of the CNS. They comprise approximately half of the total brain and spinal cord volume and are 5 to 10 times more numerous than neurons. Different types of neuroglia serve different functions. **Astrocytes**, for example, surround blood vessels, fill the spaces between neurons, and contribute to synaptic function in the CNS.1 **Oligodendroglia (oligodendrocytes)** form myelin sheaths within the CNS. **Ependymal cells** line the cerebrospinal fluid (CSF)-filled cavities of
the CNS. **Microglia** remove debris (phagocytosis) in the CNS. **Schwann cells** form the myelin sheath around axons and direct axonal regrowth and functional recovery in the PNS.² **Nonmyelinating Schwann cells** provide metabolic support. (Characteristics of neuroglia and Schwann cells are summarized in Figure 13-3 and Table 13-1.)

CNS, Central nervous system; PNS, peripheral nervous system.

Nerve Injury and Regeneration

Mature nerve cells do not divide, and injury can cause permanent loss of function. When an axon is severed, Wallerian degeneration occurs in the distal axon: (1) a characteristic swelling appears within the portion of the axon distal to the cut; (2) the neurofilaments hypertrophy; (3) the myelin sheath shrinks and disintegrates; and (4) the axon degenerates and disappears. The myelin sheaths re-form into Schwann cells that align in a column between the severed part of the axon and the effector organ.

At the proximal end of the injured axon, similar changes occur but only back to the next node of Ranvier. The cell body responds to trauma by swelling and dying by chromatolysis (dispersing the Nissl substance) or apoptosis. During the repair process, the cell increases protein synthesis and mitochondrial activity. Approximately 7 to 14 days after the injury, new terminal sprouts project from the proximal segment and may enter the remaining Schwann cell pathway. (Figure 13-4 contains a more detailed representation of these events.) This process, however, is limited to myelinated fibers and generally occurs only in the PNS. The regeneration of axonal constituents in the CNS is limited by an increased incidence of scar
Nerve regeneration depends on many factors, such as location of the injury, the type of injury, the presence of inflammatory responses, and the process of scarring. The closer to the cell body of the nerve, the greater the chances that the nerve cell will die and not regenerate. A crushing injury allows recovery more fully than does a cut injury. Crushed nerves sometimes recover fully, whereas cut nerves form connective tissue scars that block or slow regenerating axonal branches. Peripheral nerves injured close to the spinal cord recover poorly and slowly because of the long distance between the cell body and the peripheral termination of the axon.\(^3\)
The Nerve Impulse

Neurons generate and conduct electrical and chemical impulses by selectively changing the electrical potential of the plasma membrane and influencing other nearby neurons by releasing chemicals (neurotransmitters). An unexcited neuron maintains a resting membrane potential. When the membrane potential is sufficiently raised, an action potential is generated and the nerve impulse then flows to all parts of the neuron. The action potential response occurs only when the stimulus is strong enough; if it is too weak, the membrane remains unexcited. This property is termed the all-or-none response (see Chapter 1 for a discussion of electrical impulse conduction).

Quick Check 13-1

1. How do the functions of the somatic and autonomic nervous systems differ?

2. What are the three components of a neuron?

3. How does myelin affect nerve impulses?

4. Name the process through which injured axons are repaired, and describe the process.

Synapses

Neurons are not physically continuous with one another. The region between adjacent neurons is called a synapse (see Figure 13-2). Impulses are transmitted across the synapse by chemical and electrical conduction (see Figure 13-2); only chemical conduction is discussed here. Chapter 1 contains information on electrical conduction (see Figure 1-29). The neurons that conduct a nerve impulse are named according to whether they relay impulses toward (presynaptic neurons) or away from (postsynaptic neurons) the synapse. When an impulse originates in a presynaptic neuron, the impulse reaches the vesicles, where chemicals (neurotransmitters) are stored in the synaptic bouton. Once released from the vesicles, the neurotransmitters diffuse across the synaptic cleft (the space between the neurons) and bind to specific neurotransmitter (protein) receptor sites on the plasma membrane of the postsynaptic neuron, relaying the impulse (see Figure 13-2). Brain synapses can change in strength and number throughout life and this is known as synaptic plasticity or neuroplasticity (see Health Alert: Neuroplasticity).
Neuroplasticity

Neuroplasticity is the lifelong ability of the brain to adapt to new conditions by reorganizing neural pathways and forming new synapses, resulting in development, learning, and memory or recovery from injury. The process is complex and the underlying mechanisms include environmental influences, genetics, neurochemical alterations, functional changes in excitatory and inhibitory synapses, and axonal and dendritic sprouting and turnover. Research is currently in progress to identify the sequence of molecular and structural processes involved, and ways of delivering agents and therapies to promote neurorestoration and enhance brain or spinal cord reorganization of motor and sensory function following injury or disease. The new clinical area of neuro-optometry provides an example of neuroplasticity within the brain. The utilization of external prisms and computerized vision programs for visual rehabilitation can modify the visual processing system in children and adults to significantly improve visual performance.

Neurotransmitters

Neurotransmitters are chemicals synthesized in the neuron and localized in the presynaptic terminal (synaptic bouton). Neurotransmitters are then released into the synaptic cleft and bind to a receptor site (binding site) on the postsynaptic membrane of another neuron or effector, where they affect ion channels (see Figure 13-2). Each neurotransmitter is removed by a specific mechanism from its site of action. Many substances are neurotransmitters, including norepinephrine, acetylcholine, dopamine, histamine, and serotonin. Many of these transmitters have more than one function. Neurotransmitter and neuromodulator substances are summarized in Table 13-2.

*Increase the release and block the reuptake of norepinephrine.

ANS, Autonomic nervous system; CNS, central nervous system; GI, gastrointestinal; PNS, peripheral nervous system.

Because the neurotransmitter is normally stored on one side of the synaptic cleft and the receptor sites are on the other side, chemical synapses operate in one direction. Therefore action potentials are transmitted along a multineuronal pathway in one direction. The binding of the neurotransmitter at the receptor site changes the permeability of the postsynaptic neuron and, consequently, its membrane potential. Two possible scenarios can then follow: (1) the postsynaptic neuron may be excited (depolarized; **excitatory postsynaptic potentials [EPSPs]**) or (2) the postsynaptic neuron's plasma membrane may be inhibited (hyperpolarized; **inhibitory postsynaptic potentials [IPSPs]**). Cannabinoid transmitters have been discovered that are released from postsynaptic neurons and modulate neurotransmitter release from the presynaptic neurons (retrograde transmission).⁵,⁶ (Chapter 1 reviews electrical impulses and membrane potentials.)

Usually a single EPSP cannot induce a neuron's action potential and the
propagation of the nerve impulse. Whether this occurs depends on the number and frequency of potentials the postsynaptic neuron receives—a concept known as **summation**. **Temporal summation** (time relationship) refers to the effects of successive, rapid impulses received from a single neuron at the same synapse. **Spatial summation** (spacing effect) is the combined effects of impulses from a number of neurons onto a single neuron at the same time. **Facilitation** refers to the effect of EPSP on the plasma membrane potential. The plasma membrane is facilitated when summation brings the membrane closer to the threshold potential and decreases the stimulus required to induce an action potential. The effect that a chemical neurotransmitter has on the plasma membrane potential depends on the balance of these effects. The mechanisms of **convergence** (many neurons firing and converging on one neuron), **divergence** (one neuron firing and diverging on many neurons), summation, and facilitation allow for the integrative processes of the nervous system.

**Quick Check 13-2**

1. Explain the process of the chemical conduction of impulses.

2. What are neurotransmitters? Give two examples.

3. Compare summation and facilitation.
The Central Nervous System

The Brain

The brain is a functionally integrated circuit of millions of neurons with different genomes, structures, molecular composition, networks, and connections. It weighs approximately 3 pounds and receives 15% to 20% of the total cardiac output. The brain enables a person to reason, function intellectually, express personality and mood, and perceive and interact with the environment.

The three major structural divisions of the brain are (1) the forebrain (prosencephalon), which includes the telencephalon and diencephalon; (2) the midbrain (mesencephalon), which connects the pons to the diencephalon; and (3) the hindbrain (rhombencephalon), which includes the cerebellum, pons, and medulla (Table 13-3 and Figure 13-5). The midbrain, medulla, and pons comprise the brainstem, which connects the hemispheres of the brain, cerebellum, and spinal cord. A collection of nerve cell bodies (nuclei) within the brainstem makes up the reticular formation (Figure 13-6). The reticular formation is a large network of diffuse nuclei that connect the brainstem to the cortex and control vital reflexes, such as cardiovascular function and respiration. It is essential for maintaining wakefulness and attention and, therefore, is referred to as the reticular activating system (see Figure 13-6). Some nuclei within the reticular formation cause specific motor movements, such as balance and posture.⁴

FIGURE 13-6  Reticular Activating System (RAS). The RAS consists of nuclei in the brainstem reticular formation plus fibers that conduct sensory information to the nuclei and fibers that conduct from the nuclei to widespread areas of the cerebral cortex. Functioning of the reticular activating system is essential for consciousness.

Divisions of the brain are associated with different functions, but attributing specific functions to definite regions of the brain is not entirely accurate. However, for clinical considerations functional specificity is very useful for localizing pathologic conditions in various nervous system regions. A neuropsychiatrist (Brodmann) is credited with postulating that various activities are correlated to many regions of the cerebral cortex.\(^7\) (Figure 13-7, C illustrates these regions and describes some of the areas). The mapping of brain networks is also helpful in discovering how varying parts of the brain are interconnected when performing a specific function\(^8,9\) (Box 13-1).
Box 13-1

**Brain Networks**

The architecture and integrated function of neural nodes, networks, and interconnected pathways within the brain are being mapped in the advancing field of human connectomics. Imaging techniques include positron emission tomography (PET, measures pairs of gamma rays emitted by an introduced positron-emitting radionuclide), tracer diffusion tensor magnetic resonance imaging (MRI, measures diffusion of water in tissue), functional MRI (measures changes in blood flow), magnetoencephalography (MEG, measures magnetic fields produced by electric currents generated by neurons), and electroencephalography
(EEG, measures voltage changes in brain neurons), which are combined with mathematical and computational models.

The figure below provides an illustration of brain connectivity showing interconnecting cortical pathways using diffusion tensor imaging tracking technology. Such mapping of the brain contributes to an understanding of the commonalities and individual differences of the normally functioning brain and changes associated with aging and disease (i.e., degenerative brain disease, epilepsy, schizophrenia, and brain tumors).

(From Filippi M et al: Lancet Neurol 12[12]:1189-1199, 2013.)

**Forebrain**

**Telencephalon.**

The telencephalon (cerebral hemispheres) consists of the cerebral cortex (the largest portion of the brain) and the basal ganglia (composed of several nuclei). The surface of the cerebral cortex is covered with convolutions called gyri (see Figure 13-7), which greatly increase the cortical surface area and the number of neurons. Grooves between adjacent gyrus are termed sulci; deeper grooves are fissures. The cerebral cortex contains an outer layer of cell bodies of neurons (gray matter). White matter lies beneath the cerebral cortex and is composed of myelinated nerve fibers.
The two cerebral hemispheres are separated by a deep groove known as the **longitudinal fissure**. The surface of each hemisphere is divided into lobes named after the region of the skull under which each lobe lies. The posterior margin of the **frontal lobe** is on the **central sulcus (fissure of Rolando)**, and it borders inferiorly on the **lateral sulcus (sylvian fissure, lateral fissure)** (see Figure 13-7). The **prefrontal area** is responsible for goal-oriented behavior (e.g., ability to concentrate), short-term or recall memory, the elaboration of thought, and inhibition of the limbic areas of the CNS. The **premotor area (Brodmann area 6)** (see Figure 13-7, C) is involved in programming motor movements. This area contains the cell bodies that form part of the **basal ganglia system (extrapyramidal system)**—efferent pathways outside the pyramids of the medulla oblongata. The frontal eye fields (the lower portion of Brodmann area 8), which are involved in controlling eye movements, are located on the middle frontal gyrus.

The **primary motor area (Brodmann area 4)** is located along the **precentral gyrus** forming the **primary voluntary motor area**, which has a somatotopic organization that is often referred to as a **homunculus** (little man) (Figure 13-8). Electrical stimulation of specific areas of this cortex causes specific muscles of the body to move. For example, stimulation of Brodmann area 4 in the medial longitudinal fissure affects the lower limb and foot, whereas stimulation of the superior lateral surface of the precentral gyrus affects the torso and arm, the middle third of the hand, and the lower third of the face and mouth/throat. The axons traveling from the cell bodies in and on either side of this gyrus project fibers (axons) that form the **pyramidal system**. This system includes the **corticobulbar tract** that synapses in the brainstem and provides voluntary control of muscles in the head and neck, and the **corticospinal tracts (pyramidal system)** that descend into the spinal cord and provide voluntary control of muscles throughout the body. Cerebral impulses control function on the opposite side of the body, a phenomenon called **contralateral control** (Figure 13-9, A). The **Broca speech area (Brodmann areas 44, 45)** is rostral on the inferior frontal gyrus. It is usually on the left hemisphere and is responsible for the motor aspects of speech. Damage to this area, commonly as a result of a cerebrovascular accident (stroke), results in the inability to form words or at least some difficulty in forming words (expressive aphasia or dysphasia) (see Chapter 15).
FIGURE 13-8  Primary Somatic Sensory (A) and Motor (B) Areas of the Cortex. A, The motor homunculus shows proportional somatotopical representation in the main motor area. B, The sensory homunculus shows proportional somatotopical representation in the somaesthetic cortex. (From Standring S, et al. (eds): Gray’s Anatomy, ed 40, Edinburgh, Churchill Livingstone, 2008.)
The parietal lobe lies within the borders of the central, parietooccipital, and lateral sulci. This lobe contains the major area for somatic sensory input, located primarily along the postcentral gyrus (Brodmann areas 3, 1, 2) (see Figure 13-7), which is adjacent to the primary motor area. Communication between the motor and sensory areas (and among other regions in the cortex) is provided by association fibers. Much of this region is involved in sensory association (storage, analysis, and
interpretation of stimuli). (shows the distribution of functions associated with both the primary motor area and the primary sensory area of the cerebral cortex.)

The **occipital lobe** lies caudal to the parietooccipital sulcus and is superior to the cerebellum. The primary visual cortex (Brodmann area 17) is located in this region and receives input from the retinas. Much of the remainder of this lobe is involved in visual association (Brodmann areas 18, 19). The **temporal lobe** lies inferior to the lateral fissure and is composed of the superior, middle, and inferior temporal gyri. The primary auditory cortex (Brodmann area 41) and its related association area (Brodmann area 42) lie deep within the lateral sulcus on the superior temporal gyrus. The **Wernicke area**, along with adjacent portions of the parietal lobe, constitutes a *sensory speech area*. This area is responsible for reception and interpretation of speech, and dysfunction may result in receptive aphasia or dysphasia. The temporal lobe also is involved in memory consolidation and smell.

Another lobe, the **insula (insular lobe)**, lies hidden from view in the lateral sulci between the temporal and frontal lobes of each hemisphere. The insula processes sensory and emotional information and routes the information to other areas of the brain. Lying directly beneath the longitudinal fissure is a mass of white matter pathways called the **corpus callosum (transverse or commissural fibers)**. This structure connects the two cerebral hemispheres through sensory and motor contralateral projection of axons and is essential in coordinating activities between hemispheres (see Figure 13-7).

Inside the cerebrum are numerous tracts (white matter) and nuclei (gray matter). The major **cerebral nuclei** are called the **basal ganglia (basal nuclei)** system. The basal ganglia system is a group of nuclei that includes the caudate nucleus, putamen, and globus pallidus. The **putamen** and **globus pallidus** together are called the **lentiform nucleus**. The **caudate nucleus** and **putamen** together are called the **striatum** (Figure 13-10). Other structures in the basal ganglia include the **substantia nigra**, the **nucleus accumbens**, and the **subthalamic nucleus**. The nuclei of the basal ganglia are important for voluntary movement and cognitive and emotional functions.
The internal capsule is a thick layer of white matter in which axons of afferent (sensory) and efferent (motor) pathways pass to and from the cerebral cortex through the center of the cerebral hemispheres and between the caudate and lentiform nuclei (see Figure 13-10, B).

The basal ganglia plus their direct and indirect interconnections with the thalamus, premotor cortex, red nucleus, reticular formation, and spinal cord have been considered part of the extrapyramidal system. The extrapyramidal system is a part of the motor control system that causes involuntary reflexes and movement and has a stabilizing effect on motor control. Parkinson disease (substantia nigra) and Huntington disease (striatum) are characterized by various involuntary or exaggerated motor movements (see Chapter 15).

The limbic system is a group of interconnected structures located between the telencephalon and diencephalon and surrounding the corpus callosum. It is composed of the amygdala, hippocampus, fornix, hypothalamus, and related autonomic nuclei (see Figure 13-10). It is an extension or modification of the
olfactory system and influences the autonomic and endocrine systems. The limbic system mediates emotion and long-term memory through connections in the prefrontal cortex (limbic cortex). Its principal effects are involved in primitive behavioral responses, visceral reaction to emotion, motivation, mood, feeding behaviors, biologic rhythms, and the sense of smell.

**Diencephalon.**

The diencephalon (interbrain), surrounded by the cerebrum and sitting on top of the brainstem, has four divisions: epithalamus, thalamus, hypothalamus, and subthalamus (see Table 13-3 and Figure 13-7). The epithalamus forms the roof of the third ventricle (a brain cavity) and composes the most superior portion of the diencephalon. The diencephalon controls vital functions and visceral activities and is closely associated with those of the limbic system.

The thalamus borders and surrounds the third ventricle. It is a major integrating center for afferent impulses to the cerebral cortex. Various sensations are perceived at this level, but cortical processing is required for interpretation. The thalamus serves also as a relay center for information from the basal ganglia and cerebellum to the appropriate motor area.

The hypothalamus forms the base of the diencephalon. The hypothalamus functions to (1) maintain a constant internal environment and (2) implement behavioral patterns. Integrative centers control autonomic nervous system (ANS) function, regulate body temperature and endocrine function, and adjust emotional expression. The hypothalamus exerts its influence through the endocrine system, as well as through neural pathways (Box 13-2). The subthalamus flanks the hypothalamus laterally. It serves as an important basal ganglia center for motor activities.

**Box 13-2**

**Functions of the Hypothalamus**

- Visceral and somatic responses
- Affectual responses
- Hormone synthesis
- Sympathetic and parasympathetic activity
- Temperature regulation
- Fluid balance
- Appetite and feeding responses
- Physical expression of emotions
- Sexual behavior
- Pleasure-punishment centers
- Level of arousal or wakefulness

**Midbrain**

**Mesencephalon.**

The midbrain (mesencephalon) is composed of three structures: the corpora quadrigemina (located on the tectum, the ceiling of the midbrain), which is composed of the two pairs of superior colliculi and two pairs of inferior colliculi; the tegmentum (the floor of the midbrain), which is composed of the red nucleus, substantia nigra, and the basis pedunculi. The tegmentum and basis pedunculi are collectively called the cerebral peduncles.

The superior colliculi are involved with voluntary and involuntary visual motor movements (e.g., the ability of the eyes to track moving objects in the visual field). The inferior colliculi accomplish similar motor activities but involve movements affecting the auditory system (e.g., positioning the head to improve hearing). The red nucleus receives ascending sensory information from the cerebellum and projects a minor motor pathway, the rubrospinal tract, to the cervical spinal cord. The last portion of the basal ganglia is the substantia nigra, which synthesizes dopamine, a neurotransmitter and precursor of norepinephrine. Its dysfunction is associated with Parkinson disease and schizophrenia. The basis pedunculi are made up of efferent fibers of the corticospinal, corticobulbar, and corticopontocerebellar tracts.

Other notable structures of this region are the nuclei of the third and fourth cranial nerves. The cerebral aqueduct (aqueduct of Sylvius), which carries cerebrospinal fluid, also traverses this structure. Obstruction of this aqueduct is often the cause of hydrocephalus.
Hindbrain

Metencephalon.
The major structures of the metencephalon are the cerebellum and the pons. The cerebellum (see Figure 13-7) is composed of gray and white matter, and its cortical surface is convoluted like the surface of the cerebrum. It also is divided by a central fissure into two lobes connected by the vermis.

The cerebellum is responsible for reflexive, involuntary fine-tuning of motor control and for maintaining balance and posture through extensive neural connections with the medulla (through the inferior cerebellar peduncle) and with the midbrain (through the superior cerebellar peduncle). The two hemispheres are connected to the pons by the middle cerebellar peduncles. These connections allow extensive sampling of visual, vestibular, and proprioceptive data from other regions of the CNS and periphery.

The pons (bridge) is easily recognized by its bulging appearance below the midbrain and above the medulla. Primarily it transmits information from the cerebellum to the brainstem and between the two cerebellar hemispheres. The nuclei of the fifth through eighth cranial nerves are located in this structure.

Myelencephalon.
The myelencephalon usually is called the medulla oblongata and forms the lowest portion of the brainstem. Reflex activities, such as heart rate, respiration, blood pressure, coughing, sneezing, swallowing, and vomiting, are controlled in this area. The nuclei of cranial nerves IX through XII are located in this region.

A major portion of the descending motor pathways (i.e., corticospinal tracts) cross to the other side, or decussate, at the medulla (see Figure 13-9). These pathways, together with other areas of decussation in the CNS, are the basis for the phenomenon of contralateral control. Sleep-wake rhythms also are processed by neural influences from lower brain centers and are associated with a complex group of diffuse structures and functions (see Chapter 14), including the reticular activating system (cells that receive collateral signals from the afferent sensory pathways and project the signals to the higher brain centers, thus controlling CNS activity) (see Figure 13-6).

Quick Check 13-3

1. Name the three major divisions of the brain and their component parts.
2. Describe the limbic system's functions.

3. What are the two major functions of the hypothalamus?

**The Spinal Cord**

The **spinal cord** is the portion of the CNS that lies within the vertebral canal and is surrounded and protected by the **vertebral column**. The spinal cord has many functions, which include a long nerve cable that connects the brain and body, somatic and autonomic reflexes, motor pattern control centers, and sensory and motor modulation. It originates in the medulla oblongata and ends at the level of the first or second lumbar vertebra in adults (Figure 13-11). The end of the spinal cord, the **conus medullaris**, is cone shaped. Spinal nerves continue from the end of the spinal cord and form a nerve bundle called the **cauda equina**. The filament anchor from the conus medullaris to the coccyx is the **filum terminale** (see Figure 13-11). The coverings of the spinal cord are illustrated in Figure 13-12.
Grossly, the spinal cord is divided into vertebral sections (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal) that correspond to paired nerves (see Figure 13-11). A cross section of the spinal cord (Figure 13-13) is characterized by a butterfly-shaped inner core of gray matter (containing nerve cell bodies). The central canal lies in the center of this region and extends through the spinal cord from its origin in the fourth ventricle. The gray matter of the spinal cord is divided into three regions and displays specific functional characteristics. These regions include the posterior horn, or dorsal horn (composed primarily of interneurons and axons from sensory neurons whose cell bodies lie in the dorsal root ganglion). At the tip of the posterior horn is the substantia gelatinosa, a structure involved in pain transmission (see Chapter 14). The lateral horn contains cell bodies involved
with the ANS. The **anterior horn**, or **ventral horn**, contains the nerve cell bodies for efferent pathways that leave the spinal cord by way of spinal nerves.

Surrounding the gray matter is white matter that forms ascending and descending pathways called **spinal tracts**. Spinal tracts are named to denote their beginning and ending points. For example, the **spinothalamic tract** (see Figure 13-9, B, and Figure 13-13) carries nerve impulses from the spinal cord to the thalamus in the diencephalon. Numerous spinal tracts are grouped into columns according to their location within the white matter. These include the **anterior columns**, **lateral columns**, and posterior (dorsal) columns (see Figure 13-13).

Neural circuits in the spinal cord, when activated, display specific sets of motor responses. **Reflex arcs** form basic units that respond to stimuli and provide protective circuitry for motor output. Structures needed for a reflex arc are a receptor, an **afferent (sensory) neuron**, an **efferent (motor) neuron**, and an effector muscle or gland. A simple reflex arc may contain only two neurons (Figure 13-14). Interneurons are usually present and provide a link between sensory and motor neurons. The motor effects of reflex arcs generally occur before the event is
perceived in the brain's higher centers. Much internal environmental regulation is mediated by reflex activity involving the ANS.

Afferent pathways transmit information from peripheral receptors and eventually it terminates in the cerebral or cerebellar cortex, or both. Efferent pathways primarily relay information from the cerebrum to the brainstem or spinal cord. **Upper motor neurons** are completely contained within the CNS. Their primary roles are controlling fine motor movement and influencing/modifying spinal reflex arcs and circuits. Generally, upper motor neurons form synapses with interneurons, which then form synapses with lower motor neurons that project into the periphery. **Lower motor neurons** directly influence muscles. Their cell bodies lie in the gray matter of the brainstem and spinal cord, but their processes extend out of the CNS and into the PNS. Destruction of upper motor neurons usually results in initial paralysis followed within days or weeks by partial recovery, whereas destruction of the **lower motor neurons** leads to paralysis unless peripheral nerve damage is
followed by nerve regeneration and recovery (see Figure 13-4).

Muscle activity (i.e., stimulation and contraction) is regulated by nerve impulses. Motor neurons innervate one or more muscle cells, forming motor units, which consist of a neuron and the skeletal muscles it stimulates. The junction between the axon of the motor neuron and the plasma membrane of the muscle cell is called the neuromuscular (myoneural) junction (Figure 13-15). (Injury to motor neurons is discussed in Chapter 16.)

**FIGURE 13-15 Normal Neuromuscular Junction.** This figure shows how the distal end of a motor neuron fiber forms a synapse, or “chemical junction,” with an adjacent muscle fiber. Neurotransmitters (specifically, acetylcholine) are released from the neuron’s synaptic vesicles and diffuse across the synaptic cleft. There, they stimulate receptors in the motor end-plate region of the sarcolemma. (From Damjanov I: Pathology for the health professions, ed 4, St Louis, 2012, Saunders.)

**Motor Pathways**

Clinically relevant motor pathways are the lateral corticospinal and corticobulbar pyramidal tracts; and the extrapyramidal reticulospinal, vestibulospinal, and
rubrospinal tracts. The corticospinal and corticobulbar pathways are essentially the same tract and consist of a two-neuron chain. The cell bodies (upper motor neurons) originate in and around the precentral gyrus; pass through the corona radiata of the cerebrum, the internal capsule, middle three fifths of the cerebral pedunculus, pons, and pyramid; and decussate (cross contralaterally) in the medulla oblongata and form the lateral corticospinal tract of the spinal cord (see Figures 13-9A and 13-13) and thus control the opposite side of the body. The corticobulbar tract axons synapse on motor cranial nuclei within the brainstem that control muscles of the face, head, and neck. The lateral corticospinal tract axons leave the tract to go to specific interneurons or motor neurons in the anterior horn. The lateral corticospinal tract has the same somatotopic organization as the body (see Figures 13-8 and 13-9, A). These lower motor neurons project through nerves to specific muscles. These tracts are involved in precise motor movements. The reticulospinal tract (see Figure 13-13) modulates motor movement by inhibiting and exciting spinal activity. The vestibulospinal tract arises from a vestibular nucleus in the pons and causes the extensor muscles of the body to rapidly contract, most dramatically witnessed when a person starts to fall backward. The rubrospinal tract originates in the red nucleus, decussates, and terminates in the cervical spinal cord. It is important for muscle movement and fine muscle control in the upper extremities.

Sensory Pathways

The three clinically important spinal afferent pathways are the posterior column, anterior spinothalamic tract, and lateral spinothalamic tract (see Figures 13-8, B, 13-9, B, and 13-13). The posterior (dorsal) column (fasciculus gracilis and fasciculus cuneatus) carries fine-touch sensation, two-point discrimination, and proprioceptive information (i.e., epicritic information). The posterior column is formed by a three-neuron chain. The first neuron of the chain is the primary afferent neuron. It also is the sensory neuron of the reflex arc. After entering the spinal cord it sends its axon ipsilaterally up the spinal cord to a specific part of the posterior column and synapses in the three posterior column nuclei in the medulla oblongata. A basketball playing center has primary afferent neurons that could be more than 6 feet long, running from the great toe up to the medulla oblongata. The axon of the second-order neuron crosses contralaterally at the medial lemniscus and ascends and synapses with a specific nucleus of the thalamus. The third-order neuron, originating in the thalamus, continues the tract into the internal capsule, corona radiata, and postcentral gyrus (Brodmann areas 3, 1, 2) (see Figures 13-7, 13-8, A, and 13-9, B).
The anterior and lateral spinothalamic tracts are responsible for vague touch sensation and for pain and temperature perception, respectively (see Figure 13-9, B). These modalities are referred to as protopathic. These tracts also form a three-neuron chain. However, their primary afferent neurons synapse in the posterior horn of the spinal cord, not just at the level they enter the intervertebral foramen but in a number of spinal segments above and below their point of entry. This is an example of divergence. The axons of the second-order neurons in the posterior horn cross to the contralateral side in the spinal cord in the lateral column, ascend to the same thalamic nucleus as the posterior column pathway, and continue with the posterior column pathway to the postcentral gyrus.

Protective Structures of the Central Nervous System

Cranium

The cranium is composed of eight bones. The cranial vault encloses and protects the brain and its associated structures. The galea aponeurotica, which is a thick, fibrous band of tissue overlying the cranium between the frontal and occipital muscles, affords added protection to the skull. The subgaleal space has venous connections with the dural sinuses, and with increased intracranial pressure, blood can be shunted to the space, thus reducing pressure in the intracranial cavity. The subgaleal space is also a common site for wound drains after intracranial surgery.

The floor of the cranial vault is irregular and contains many foramina (openings) for cranial nerves, blood vessels, and the spinal cord to exit. The cranial floor is divided into three fossae (depressions). The frontal lobes lie in the anterior fossa, the temporal lobes and base of the diencephalon lie in the middle fossa (temporal fossa), and the cerebellum lies in the posterior fossa. These terms are commonly used anatomic landmarks to describe the location of intracranial lesions.

Meninges

Surrounding the brain and spinal cord are three protective membranes: the dura mater, the arachnoid, and the pia mater. Collectively they are called the meninges (Figure 13-16, C). The dura mater (meaning literally “hard mother”) is composed of two layers, with the venous sinuses formed between them. The outermost layer forms the periosteum (endosteal layer) of the skull. The inner dura (meningeal layer) is responsible for forming rigid membranes that support and separate various brain structures.
One of these membranes, the **falx cerebri**, dips between the two cerebral hemispheres along the longitudinal fissure. The falx cerebri is anchored anteriorly to the base of the brain at the crista galli of the ethmoid bone. The **tentorium cerebelli**, a common landmark, is a membrane that separates the cerebellum below from the cerebral structures above. Internal to the dura mater is the location of the **arachnoid**, a spongy, weblike structure that loosely follows the contours of the cerebral structures.

The **subdural space** lies between the dura and arachnoid. Many small bridging veins that have little support traverse the subdural space. Their disruption results in a subdural hematoma (see Chapter 16). The **subarachnoid space** lies between the...
arachnoid and the pia mater and contains cerebrospinal fluid (CSF) (see Figure 13-16, A and C). Unlike the dura mater and arachnoid, the delicate pia mater adheres to the contours of the brain and spinal cord. It provides support for blood vessels serving brain tissue. The choroid plexuses, structures that produce CSF, arise from the pial membrane (see Figure 13-16, B). The spinal cord is anchored to the vertebrae by extension of the meninges. The meninges continue beyond the end of the spinal cord (at vertebrae levels L1 and L2) to the lower portion of the sacrum. CSF contained within the subarachnoid space also circulates inferiorly to about the second sacral vertebra.

The meninges form potential and real spaces important to understanding functional and pathologic mechanisms. For example, between the dura mater and skull lies a potential space termed the epidural space (see Figure 13-16, C). The arterial supply to the meninges consists of blood vessels that lie within grooves in the skull. A skull fracture can sever one of these vessels and produce an epidural hematoma.

**Cerebrospinal Fluid and the Ventricular System**

Cerebrospinal fluid (CSF) is a clear, colorless fluid similar to blood plasma and interstitial fluid. The intracranial and spinal cord structures float in CSF and are thereby partially protected from jolts and blows. The buoyant properties of the CSF also prevent the brain from tugging on meninges, nerve roots, and blood vessels. ( Constituents of CSF are listed in Table 13-4.) Between 125 and 150 ml of CSF is circulating within the ventricles (small cavities) and subarachnoid space at any given time. Approximately 600 ml of CSF is produced daily.

</table>

The choroid plexuses in the lateral, third, and fourth ventricles produce the major
portion of CSF. (Ventricles are illustrated in Figure 13-16.) These plexuses are characterized by a rich network of blood vessels, supplied by the pia mater, that lie close to the ependymal cells of the ventricles. The tight junctions of the choroid blood vessel provide a limiting barrier between the CSF and blood that functions similarly to the blood-brain barrier (see p. 324).

The CSF exerts pressure within the brain and spinal cord. When a person is supine, CSF pressure is about 80 to 180 mm of water pressure, or approximately 5 to 14 mm of mercury pressure, but doubles when the person moves to an upright position. CSF flow results from the pressure gradient between the arterial system and the CSF-filled cavities. Beginning in the lateral ventricles, the CSF flows through the **interventricular foramen (foramen of Monro)** into the third ventricle and then passes through the cerebral aqueduct (aqueduct of Sylvius) into the fourth ventricle. From the fourth ventricle the CSF may pass through either the paired **lateral apertures (foramen of Luschka)** or the **median aperture (foramen of Magendie)** before communicating with the subarachnoid spaces of the brain and spinal cord. The CSF does not, however, accumulate. Instead, it is reabsorbed into the venous circulation through the arachnoid villi. The **arachnoid villi** protrude from the arachnoid space, through the dura mater, and lie within the blood flow of the venous sinuses (see Figure 13-16, B). CSF is reabsorbed through a pressure gradient between the arachnoid villi and the cerebral venous sinuses. The villi function as one-way valves directing CSF outflow into the blood but preventing blood flow into the subarachnoid space. Thus CSF is formed from the blood, and after circulating throughout the CNS, it returns to the blood.

**Vertebral Column**

The vertebral column (Figure 13-17) is composed of 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 4 fused coccygeal. Between each interspace (except for the fused sacral and coccygeal vertebrae) is an **intervertebral disk** (Figure 13-18). At the center of the intervertebral disk is the **nucleus pulposus**, a pulpy mass of elastic fibers. The intervertebral disk absorbs shocks, preventing damage to the vertebrae. The intervertebral disk is also a common source of back problems. If too much stress is applied to the vertebral column, the disk contents may rupture and protrude into the spinal canal, causing compression of the spinal cord or nerve roots.

---

**Quick Check 13-4**

1. What information is conveyed in the ascending and descending spinal tracts?
2. Contrast the functions of upper and lower motor neurons.

3. Name the protective structures of the central nervous system, and briefly describe each one.

**FIGURE 13-17** Vertebral Column. A, The normal curves and regions of the vertebral column. The vertebrae in each region are numbered. B, Lateral view of several vertebrae showing how they articulate. (From Solomon E: Introduction to human anatomy and physiology, ed 4, St Louis, 2016, Saunders.)
Blood Supply of the Central Nervous System

Blood Supply to the Brain

The brain receives approximately 20% of the cardiac output, or 800 to 1000 ml of blood flow per minute. Carbon dioxide is a primary regulator for blood flow within the CNS. It is a potent vasodilator, and its effects ensure an adequate blood supply.

The brain derives its arterial supply from two systems: the internal carotid arteries and the vertebral arteries (Figure 13-19). The internal carotid arteries supply a proportionately greater amount of blood flow. They originate at the common carotid arteries, enter the cranium through the base of the skull, and pass through the cavernous sinus. After forming some small branches, these arteries divide into the anterior and middle cerebral arteries. The vertebral arteries originate at the subclavian arteries and pass through the transverse foramina of the cervical vertebrae, entering the cranium through the foramen magnum. They join at the junction of the pons and medulla to form the basilar artery (Figure 13-20). The basilar artery divides at the level of the midbrain to form paired posterior cerebral arteries.
The circle of Willis (see Figure 13-20) provides an alternative route for blood flow when one of the contributing arteries is obstructed (collateral blood flow). The circle of Willis is formed by the posterior cerebral arteries, posterior communicating arteries, internal carotid arteries, anterior cerebral arteries, and anterior communicating artery. The anterior cerebral, middle cerebral, and posterior cerebral arteries leave the circle of Willis and extend to various brain structures. The border zone is the area between the major arterial territories (Table 13-5 and Figure 13-21 illustrate structures served, functional relationships, and pathologic considerations related to occlusion of cerebral arteries).

</table>
Cerebral venous drainage does not parallel its arterial supply, whereas the venous drainage of the brainstem and cerebellum does parallel the arterial supply of these structures. The cerebral veins are classified as superficial and deep veins. The veins drain into venous plexuses and dural sinuses (formed between the dural layers) and eventually join the internal jugular veins at the base of the skull (Figure 13-22). Adequacy of venous outflow can significantly affect intracranial pressure. For example, head-injured individuals who turn or let their heads fall to the side partially occlude venous return, and the intracranial pressure can increase then because of decreased flow through the jugular veins.

Blood-Brain Barrier
The blood-brain barrier (BBB) describes cellular structures that selectively inhibit certain potentially harmful substances in the blood from entering the interstitial spaces of the brain or CSF allowing neurons to function normally. Endothelial cells in brain capillaries with their intracellular tight junctions are the site of the BBB. Supporting cells include astrocytes, pericytes, and microglia\(^\text{10}\) (Figure 13-23 and see Chapter 1). The exact nature of this mechanism is controversial, but it appears
that certain metabolites, electrolytes, and chemicals can cross into and out of the brain to varying degrees. This has substantial implications for drug therapy because certain types of antibiotics and chemotherapeutic drugs show a greater propensity than others for crossing this barrier. Breakdown of the BBB can contribute to neuroinflammation and neurodegeneration.
**Blood Supply to the Spinal Cord**

The spinal cord derives its blood supply from branches off the vertebral arteries and from branches from various regions of the aorta (Figure 13-24). The anterior
spinal artery and the paired posterior spinal arteries branch from the vertebral artery at the base of the cranium and descend alongside the spinal cord. Arterial branches from vessels exterior to the spinal cord follow the spinal nerve through the intervertebral foramina, pass through the dura, and divide into the anterior and posterior radicular arteries.

The radicular arteries eventually connect to the spinal arteries. Branches from the radicular and spinal arteries form plexuses whose branches penetrate the spinal cord, supplying the deeper tissues. Venous drainage parallels the arterial supply closely and drains into venous sinuses located between the dura and periosteum of the vertebrae.
The Peripheral Nervous System

The cranial and spinal nerves, including their branches and ganglia, constitute the peripheral nervous system (PNS). A peripheral nerve (cranial or spinal) is composed of individual axons wrapped in a myelin sheath. These individual fibers are arranged in bundles called *fascicles* (Figure 13-25, *B*).

![Image of cranial and peripheral nerves and skin dermatomes](attachment://image.png)

The 31 pairs of spinal nerves derive their names from the vertebral level from which they exit. There are 8 cervical, 12 thoracic, 5 lumbar, 5 sacral pair of spinal nerves, and 1 coccygeal. The first cervical nerve exits above the first cervical vertebra, and the rest of the spinal nerves exit below their corresponding vertebrae. From the thoracic region (and inferiorly), nerves correspond to the vertebral level
Spinal nerves contain both sensory and motor neurons and are called **mixed nerves**. They arise as rootlets lateral to anterior and posterior horns of the spinal cord. These two spinal nerve roots converge in the region of the intervertebral foramen to form the spinal nerve trunk. Shortly after converging, the spinal nerve divides into anterior and posterior rami (branches). The anterior rami (except the thoracic) initially form **plexuses** (networks of nerve fibers), which then branch into the peripheral nerves. Instead of forming plexuses, the thoracic nerves pass through the intercostal spaces and innervate regions of the thorax.

The main spinal nerve plexuses innervate the skin and the underlying muscles of the limbs. The **brachial plexus**, for example, is formed by the last four cervical nerves (C5 to C8) and the first thoracic nerve (T1) (see Figure 13-11). The brachial plexus innervates the nerves of the arm, wrist, and hand. The **lumbar plexus** (L1 to L4) and **sacral plexus** (L5 to S5) contain nerves that innervate the anterior and posterior portions of the lower body, respectively.

The posterior rami of each spinal nerve, with their many processes, are distributed to a specific area in the body. Sensory signals thus arise from specific sites associated with a specific spinal cord segment. Specific areas of cutaneous innervation at these spinal cord segments are called **dermatomes** (Figure 13-25, C).

Like spinal nerves, cranial nerves are categorized as peripheral nerves. Most of these are mixed nerves (like the spinal nerves), although some are purely sensory or purely motor. Cranial nerves (see Figure 13-25, A) connect to nuclei in the brain and brainstem. **Table 13-6** describes structural and functional characteristics of the cranial nerves.

**Quick Check 13-5**

1. Describe the circle of Willis and explain its role in supplying blood to the brain.

2. What is the source of the spinal cord's blood supply?

3. What are the plexuses? Give two examples in the PNS.

4. What are the cranial nerves? Give three examples.

5. Describe the anatomy and function of the PNS.
### TABLE 13-6
The Cranial Nerves

</thead>
<tbody>
<tr>
<td>I. Olfactory</td>
<td>Fibers arise from nasal olfactory epithelium and form synapses with olfactory bulbs, which transmit impulses to temporal lobe</td>
<td>Purely sensory; carries impulses for sense of smell</td>
<td>Person is asked to sniff aromatic substances, such as oil of cloves and vanilla, and to identify them</td>
</tr>
<tr>
<td>II. Optic</td>
<td>Fibers arise from retina of eye to form optic nerve, which passes through sphenoid bone; two optic nerves then form optic chiasma (with partial crossover of fibers) and eventually end in occipital cortex</td>
<td>Purely sensory; carries impulses for vision</td>
<td>Vision and visual field tested with an eye chart and by testing point at which person first sees an object (finger) moving into visual field; inside of eye is viewed with ophthalmoscope to observe blood vessels of eye interior</td>
</tr>
<tr>
<td>III. Oculomotor</td>
<td>Fibers emerge from midbrain and exit from skull to run to eye</td>
<td>Contains motor fibers to inferior oblique and to superior, inferior, and medial rectus extraocular muscles that direct eyeball; levator muscles of eyelid; smooth muscles of iris and ciliary body; and proprioceptor (sensory) to brain from extraocular muscles</td>
<td>Pupils examined for size, shape, and equality; pupillary reflex tested with a penlight (pupils should constrict when illuminated); ability to follow moving objects</td>
</tr>
<tr>
<td>IV. Trochlear</td>
<td>Fibers emerge from posterior midbrain and exit from skull to run to eye</td>
<td>Proprioceptor and motor fibers for superior oblique muscle of eye (extraocular muscle)</td>
<td>Tested in common with cranial nerve III relative to ability to follow moving objects</td>
</tr>
<tr>
<td>V. Trigeminal</td>
<td>Fibers emerge frompons and form three divisions that exit from skull and run to face and cranial dura mater</td>
<td>Both motor and sensory for face; conducts sensory impulses from mouth, nose, surface of eye, and dura mater; also contains motor fibers that stimulate chewing muscles</td>
<td>Sensations of pain, touch, and temperature tested with safety pin and hot and cold objects; corneal reflex tested with a wisp of cotton; motor branch tested by asking subject to clench teeth, open mouth against resistance, and move jaw from side to side</td>
</tr>
<tr>
<td>VI. Abducens</td>
<td>Fibers leave inferior pons and exit from skull to run to eye</td>
<td>Contains motor fibers to lateral rectus muscle and proprioceptor fibers from same muscle to brain</td>
<td>Tested in common with cranial nerve III relative to ability to move each eye laterally</td>
</tr>
<tr>
<td>VII. Facial</td>
<td>Fibers leave pons and travel through temporal bone to reach face</td>
<td>Mixed: (1) supplies motor fibers to muscles of facial expression and to lacrimal and salivary glands and (2) carries sensory fibers from taste buds of anterior part of tongue</td>
<td>Anterior two thirds of tongue tested for ability to taste sweet (sugar), salty, sour (vinegar), and bitter (quinine) substances; symmetry of face checked; subject asked to close eyes, smile, whistle, and so on; tearing tested with ammonia fumes</td>
</tr>
<tr>
<td>VIII. Vestibulocochlear (acoustic)</td>
<td>Fibers run from inner ear (hearing and equilibrium receptors in temporal bone) to enter brainstem just below pons</td>
<td>Purely sensory; vestibular branch transmits impulses for sense of equilibrium; cochlear branch transmits impulses for sense of hearing</td>
<td>Hearing checked by air and bone conduction by use of a tuning fork; vestibular tests: Bárány and caloric tests</td>
</tr>
<tr>
<td>IX. Glossopharyngeal</td>
<td>Fibers emerge from medulla and leave skull to run to throat</td>
<td>Mixed: (1) motor fibers serve pharynx (throat) and salivary glands, and (2) sensory fibers carry impulses from pharynx, posterior tongue (taste buds), and pressure receptors of carotid artery</td>
<td>Gag and swallow reflexes checked; subject asked to speak and cough; posterior one third of tongue may be tested for taste</td>
</tr>
<tr>
<td>X. Vagus</td>
<td>Fibers emerge from medulla, pass through skull, and descend through neck region into thorax and abdominal region</td>
<td>Fibers carry sensory and motor impulses for pharynx; a large part of this nerve is parasympathetic motor fibers, which supply smooth muscles of abdominal organs; receives sensory impulses from viscera</td>
<td>Same as for cranial nerve IX (IX and X are tested in common) because they both serve muscles of throat</td>
</tr>
<tr>
<td>XI. Spinal accessory</td>
<td>Fibers arise from medulla and superior spinal cord and travel to muscles of neck and back</td>
<td>Provides sensory and motor fibers for sternocleidomastoid and trapezius muscles and muscles of soft palate, pharynx, and larynx</td>
<td>Sternoideomastoid and trapezius muscles checked for strength by asking subject to rotate head and shrug shoulders against resistance</td>
</tr>
<tr>
<td>XII. Hypoglossal</td>
<td>Fibers arise from medulla and exit from skull to travel to tongue</td>
<td>Carries motor fibers to muscles of tongue and sensory impulses from tongue to brain</td>
<td>Subject asked to stick out tongue, and any position abnormalities are noted</td>
</tr>
</tbody>
</table>
The structure and function of the autonomic nervous system (ANS) are complex and still not well understood. Components of the ANS are located in both the CNS and the PNS; however, the ANS is considered to be part of the efferent division of the PNS, even though visceral afferent neurons are certainly an important part of this system. Many neurons of the ANS travel in the spinal nerves and certain cranial nerves. The widespread activity of this system indicates that its components are distributed all over the body. The peripheral autonomic nerves carry mainly efferent fibers. The motor component of the ANS is a two-neuron system consisting of preganglionic neurons (myelinated) and postganglionic neurons (unmyelinated) (Figure 13-26). This arrangement contrasts with the somatic nervous system, where a single motor neuron travels from the CNS to the innervated structure. Visceral afferent neurons have their cell bodies in some sensory and cranial ganglia and their fiber processes traveling in peripheral nerves.

The CNS has autonomic areas in the intermediolateral horns of the spinal cord, the cardiovascular and respiratory centers in the reticular formation, and both sympathetic and parasympathetic areas in the hypothalamus. CNS pathways interconnect all these areas.

The ANS coordinates and maintains a steady state among visceral (internal) organs, such as regulation of cardiac muscle, smooth muscle, and the glands of the body. This system is considered an involuntary system because one generally cannot will these functions to happen. The ANS is separated both structurally and functionally into two divisions: (1) the sympathetic nervous system and (2) the
parasympathetic nervous system (Figure 13-27).
Anatomy of the Sympathetic Nervous System

The sympathetic nervous system mobilizes energy stores in times of need (e.g., in the “fight or flight” or stress response) (see Figure 9-3; see also Chapter 9). The sympathetic division is innervated by cell bodies located from the first thoracic (T1) through the second lumbar (L2) regions of the spinal cord and therefore is called the thoracolumbar division. The preganglionic axons of the sympathetic division form synapses shortly after leaving the spinal cord in the sympathetic (paravertebral) ganglia. These preganglionic axons travel several different ways: (1) directly synapsing with postganglionic neurons in the sympathetic chain ganglion at their level; (2) up or down the sympathetic chain ganglion before forming synapses with a higher or lower postganglionic neuron; or (3) through the sympathetic chain ganglion, postganglionic neurons within collateral ganglia (see Figure 13-27). Some preganglionic axons form pathways called splanchnic nerves, which lead to collateral ganglia on the front of the aorta. The collateral ganglia are named according to the branches of the aorta nearest them, namely, the celiac, superior mesenteric, and inferior mesenteric. The preganglionic neurons synapse with postganglionic neurons within the collateral ganglia. These postganglionic neurons leave the collateral ganglia and innervate the viscera below the diaphragm.

Preganglionic sympathetic neurons that innervate the adrenal medulla also travel in the splanchnic nerves and do not synapse before reaching the gland. The secretory cells in the adrenal medulla are considered modified postganglionic neurons. Because preganglionic sympathetic fibers are all myelinated, travel to the adrenal medulla is quick, and innervation causes the rapid release of epinephrine and norepinephrine. Epinephrine and norepinephrine are mediators of the fight or flight response (see Chapter 9).

Anatomy of the Parasympathetic Nervous System

The parasympathetic nervous system conserves and restores energy. The nerve cell bodies of this division are located in the cranial nerve nuclei and in the sacral
region of the spinal cord and therefore constitute the craniosacral division. Unlike the sympathetic branch, the preganglionic fibers in the parasympathetic division travel close to the organs they innervate before forming synapses with the relatively short postganglionic neurons (see Figure 13-27). Parasympathetic nerves arising from nuclei in the brainstem travel to the viscera of the head, thorax, and abdomen within cranial nerves—including the oculomotor (III), facial (VII), glossopharyngeal (IX), and vagus (X) nerves.

Preganglionic parasympathetic nerves that originate from the sacral region of the spinal cord run either separately or together with some spinal nerves. The preganglionic axons unite to form the pelvic nerve, which innervates the viscera of the pelvic cavity. These preganglionic axons synapse with postganglionic neurons in terminal ganglia located close to the organs they innervate.

**Neurotransmitters and Neuroreceptors**

Sympathetic preganglionic fibers and parasympathetic preganglionic and postganglionic fibers release acetylcholine—the same neurotransmitter released by somatic efferent neurons (see Figure 13-26). These fibers are characterized by cholinergic transmission. Most postganglionic sympathetic fibers release norepinephrine (adrenaline) and thus are considered to function by adrenergic transmission. A few postganglionic sympathetic fibers, such as those that innervate the sweat glands, release acetylcholine.

The action of catecholamines varies with the type of neuroreceptor stimulated. It should be remembered that catecholamines also are released by the adrenal medulla gland that physiologically and biochemically resembles the sympathetic nervous system. Two types of adrenergic receptors exist, α and β. Cells of the effector organs may have only one or both types of adrenergic receptors. The α-adrenergic receptors have been further subdivided according to the action produced. α₁-Adrenergic activity is associated mostly with excitation or stimulation; α₂-adrenergic activity is associated with relaxation or inhibition. Most of the α-adrenergic receptors on effector organs belong to the α₁ class. The β-adrenergic receptors are classified as β₁-adrenergic receptors (which facilitate increased heart rate and contractility and cause the release of renin from the kidney) and β₂-adrenergic receptors (which facilitate all remaining effects attributed to β receptors).¹¹ Norepinephrine stimulates all α₁ and β₁ receptors and only certain β₂ receptors. The primary response from norepinephrine, however, is stimulation of the α₁-adrenergic receptors that cause vasoconstriction. Epinephrine strongly stimulates all four types of receptors and induces general vasodilation because of
the predominance of β receptors in muscle vasculatures. (Table 13-7 summarizes
the effects of neuroreceptors on their effector organs.)

Muscarnic receptors respond to circulating muscarinic antagonists.

### Functions of the Autonomic Nervous System

Many body organs are innervated by both the sympathetic and parasympathetic nervous systems. The two divisions often cause opposite responses; for example, sympathetic stimulation of the stomach causes decreased peristalsis, whereas parasympathetic stimulation of the intestine increases peristalsis. In general, sympathetic stimulation promotes responses for the protection of the individual. For example, sympathetic activity increases blood glucose levels and temperature and raises the blood pressure. In emergency situations, a generalized and widespread discharge of the sympathetic system occurs and is known as the “fight or flight” reflex or acute stress response (see Chapter 9). This is accomplished by an increased firing frequency of sympathetic fibers and by activation of sympathetic fibers normally silent and at rest (fibers to the sweat glands, pilomotor muscles, and the adrenal medulla, as well as vasodilator fibers to muscle). Regulation of vasomotor tone is considered the single most important function of the sympathetic nervous system. (Figure 13-28 illustrates some of the most important functions of the sympathetic nervous system.)
Increased parasympathetic activity promotes rest and tranquility and is characterized by reduced heart rate and enhanced visceral functions concerned with digestion. Stimulation of the vagus nerve (cranial nerve X) in the gastrointestinal
tract increases peristalsis and secretion, as well as the relaxation of sphincters. Activation of parasympathetic fibers in the head, provided by cranial nerves III, VII, and IX, causes constriction of the pupil, tear secretion, and increased salivary secretion. Stimulation of the sacral division of the parasympathetic system contracts the urinary bladder and facilitates the process of genital erection.

The parasympathetic system lacks the generalized and widespread response of the sympathetic system. Specific parasympathetic fibers are activated to regulate particular functions. Although the actions of the parasympathetic and sympathetic systems are usually antagonistic, there are exceptions. Peripheral vascular resistance, for example, is increased dramatically by sympathetic activation but is not altered appreciably by activity of the parasympathetic system. Most blood vessels involved in the control of blood pressure are innervated by sympathetic nerves. To decrease blood pressure, therefore, it is more important to block or paralyze the continuous (tonic) discharge of the sympathetic system than to promote parasympathetic activity.

Quick Check 13-6

1. What are the structural and functional divisions of the ANS?

2. Compare cholinergic and adrenergic transmission.

3. What are the functions of the ANS?

Geriatric Considerations

Aging & the Nervous System

Structural Changes with Aging

Decreased brain weight and size, particularly frontal regions

Increase in ventricular volume

Fibrosis and thickening of the meninges

Narrowing of gyri and widening of sulci

Increase in size of ventricles
**Cellular Changes with Aging**

Decrease in number of neurons not consistently related to changes in mental function

Decreased myelin

Lipofuscin deposition (a pigment resulting from cellular autodigestion)

Decreased number of dendritic processes and synaptic connections

Intracellular neurofibrillary tangles; significant accumulation in cortex associated with Alzheimer dementia

Imbalance in amount and distribution of neurotransmitters

Decrease in glucose metabolism

**Cerebrovascular Changes with Aging**

Arterial atherosclerosis (may cause infarcts and scars)

Increased permeability of blood-brain barrier

Decreased vascular density

**Functional Changes with Aging**

Decreased tendon reflexes

Progressive deficit in taste and smell

Decreased vibratory sense

Decrease in accommodation and color vision

Decrease in neuromuscular control with change in gait and posture

Sleep disturbances

Memory impairments
Cognitive alterations associated with chronic disease

Functional changes and nervous system aging have significant individual variation

Did You Understand?

Overview and Organization of the Nervous System

1. The divisions of the nervous system have been categorized as either structural (central nervous system [CNS] and peripheral nervous system [PNS]) or functional (somatic nervous system and autonomic nervous system [ANS]).

2. The CNS is contained within the brain and spinal cord.

3. The PNS is composed of cranial and spinal nerves, which carry impulses toward the CNS (afferent—sensory) and away from the CNS (efferent—motor) to and from target organs or skeletal muscle.

Cells of the Nervous System

1. The neuron and neuroglial cells (nonnerve cells) constitute nervous tissue. The neuron is specialized to transmit and receive electrical and chemical impulses, whereas the neuroglial cell provides supportive and maintenance functions. The neuron is further divided into unipolar, pseudounipolar, bipolar, and multipolar categories, according to its structure and particular mechanics of impulse transmission.

2. The neuron is composed of a cell body, dendrite(s), and an axon. A myelin sheath around selected axons forms insulation that allows faster nerve impulse conduction.

The Nerve Impulse

1. The region between the neurons is the synapse, and the region between the neuron and muscle is the myoneural junction.

2. Neurotransmitters are responsible for chemical conduction across the synapse, and the myoneural junction nerve impulse is regulated predominantly by a balance of inhibitory postsynaptic potentials (IPSPs) and excitatory postsynaptic potentials (EPSPs), temporal and spatial summation, and convergence and divergence.

The Central Nervous System
1. The brain is contained within the cranial vault and is divided into three distinct regions: (1) forebrain, (2) hindbrain, and (3) midbrain.

2. The forebrain comprises the two cerebral hemispheres and allows conscious perception of internal and external stimuli, thought and memory processes, and voluntary control of skeletal muscles. The deep portion of the forebrain is termed the **diencephalon** and processes incoming sensory data. The center for voluntary control of skeletal muscle movements is located along the precentral gyrus in the frontal lobe, whereas the center for perception is along the postcentral gyrus in the parietal lobe. The Broca area (inferior frontal gyrus) and the Wernicke area (superior temporal gyrus) are major speech centers.

3. The hindbrain allows sampling and comparison of sensory data, which are received from the periphery and motor impulses of the cerebral hemispheres, for the purpose of coordination and refinement of skeletal muscle movement.

4. The midbrain is primarily a relay center for motor and sensory tracts, as well as a center for auditory and visual reflexes.

5. The spinal cord contains most of the nerve fibers that connect the brain with the periphery. The corticospinal tracts are descending pyramidal (motor) pathways from the motor cortex. The rubrospinal and reticulospinal tracts are descending extrapyramidal tracts that coordinate movement. The anterior, posterior, and lateral spinothalamic tracts carry sensory information to the brainstem and thalamus, where information is relayed to the sensory cortex. Reflex arcs are sensory and motor circuits completed in the spinal cord and influenced by the higher centers in the brain.

6. The CNS is protected by the scalp, bony cranium, meninges (dura mater, arachnoid, membrane, and pia mater), vertebral column, and cerebrospinal fluid (CSF). CSF is formed from blood components in the choroid plexuses of the ventricles and is reabsorbed in the arachnoid villi (located in the dural venous sinuses) after circulating through the brain and subarachnoid space.

7. The paired carotid and vertebral arteries supply blood to the brain and connect to form the circle of Willis. The major branches projecting from the circle of Willis are the anterior, middle, and posterior cerebral arteries. Drainage of blood from the brain is accomplished through the venous sinuses and jugular veins.

8. The blood-brain barrier is provided by tight junctions between the cells of brain
capillary endothelial cells and surrounding supporting cells.

9. Blood supply to the spinal cord originates from the vertebral arteries and branches arising from the aorta.

The Peripheral Nervous System

1. The cranial and spinal nerves constitute the PNS. The PNS relays information from the CNS to muscle and effector organs through cranial and spinal nerve tracts arranged in fascicles (multiple fascicles bound together form the peripheral nerve).

The Autonomic Nervous System

1. The ANS is responsible for maintaining a steady state in the internal environment. Two opposing systems make up the ANS: (1) the sympathetic nervous system (thoracolumbar division) responds to stress by mobilizing energy stores and prepares the body to defend itself, and (2) the parasympathetic nervous system (craniosacral division) conserves energy and the body's resources. Both systems function, more or less, at the same time.
Key Terms

Acetylcholine, 329
α-Adrenergic receptor, 329
β-Adrenergic receptor, 329
Adrenergic transmission, 329
Afferent (sensory) neuron, 319
Afferent pathway (ascending pathway), 307
Anterior column, 319
Anterior fossa, 321
Anterior horn (ventral horn), 319
Anterior spinal artery, 325
Anterior spinothalamic tract, 321
Arachnoid, 321
Arachnoid villi, 322
Association fiber, 314
Associational neuron (interneuron), 308
Astrocyte, 308
Autonomic nervous system (ANS), 307
Axon, 308
Axon hillock, 308
Basal ganglia (basal nuclei), 315
Basal ganglia system (extrapyramidal system), 313
Basilar artery, 323
Basis pedunculi, 317
Bipolar neuron, 308
Blood-brain barrier (BBB), 324
Brachial plexus, 326
Brain network, 313
Brainstem, 311
Broca speech area (Brodmann areas 44, 45), 314
Cauda equina, 318
Caudate nucleus, 315
Cavernous sinus, 323
Celiac, 329
Central canal, 319
Central nervous system (CNS), 307
Central sulcus (fissure of Rolando), 313
Cerebellum, 317
Cerebral aqueduct (aqueduct of Sylvius), 317
Cerebral cortex, 313
Cerebral nuclei, 315
Cerebral peduncle, 317
Cerebrospinal fluid (CSF), 321
Cholinergic transmission, 329
Choroid plexus, 321
Circle of Willis, 323
Collateral ganglia, 329
Contralateral control, 314
Conus medullaris, 318
Convergence, 311
Corpora quadrigemina, 316
Corpus callosum (transverse fibers or commissural fibers), 315
Corticobulbar tract, 314
Corticobulbar tract axon, 320
Corticospinal tract (pyramidal system), 314
Cranial nerve, 307
Craniosacral division, 329
Dendrite, 308
Dermatome, 326
Diencephalon (interbrain), 315
Divergence, 311
Dopamine, 317
Dorsal root ganglion, 319
Dura mater, 321
Efferent (motor) neuron, 319
Effector organ, 307
Efferent pathway (descending pathway), 307
Ependymal cell, 308
Epicritic information, 320
Epidural space, 321
Epithalamus, 315
Excitatory postsynaptic potential (EPSP), 311
Extrapyramidal system, 313
Facilitation, 311
Falx cerebri, 321
Fascicle, 325
Filum terminale, 318
Frontal lobe, 313
Galea aponeurotica, 321
Ganglia (plexus), 308
Globus pallidus, 315
Gray matter, 313
Hypothalamus, 315
Inferior colliculi, 317
Inferior mesenteric, 329
Inhibitory postsynaptic potential (IPSP), 311
Inner dura (meningeal layer), 321
Insula (insular lobe), 315
Internal capsule, 315
Internal carotid artery, 323
Interventricular foramen (foramen of Monro), 321
Intervertebral disk, 322
Lateral aperture (foramen of Luschka), 322
Lateral column, 319
Lateral corticospinal tract, 320
Lateral horn, 319
Lateral spinothalamic tract, 321
Lateral sulcus (sylvian fissure, lateral fissure), 313
Lentiform nucleus, 315

- Olfaction and Taste, 353
Somatosensory Function, 353
Alterations in sensory function may involve dysfunctions of the general or the special senses. Dysfunctions of the general senses include chronic pain, abnormal temperature regulation, and tactile or proprioceptive dysfunction. Pain is an unpleasant but protective phenomenon that is uniquely experienced by each individual, and it cannot be adequately defined, identified, or measured by an observer. Like pain, variations in temperature can signal disease. Fever is a common manifestation of dysfunction and is often the first symptom observed in an infectious or inflammatory condition.

Sleep is a normal cyclic process that restores the body's energy and maintains normal functioning. Sleep is so essential to both physiologic and psychologic function that sleep deprivation causes a wide range of clinical manifestations. The special senses of vision, hearing, touch, smell, and taste are the means by which individuals perceive stimuli that are essential in interacting with the environment. Dysfunctions of the special senses include visual, auditory, vestibular, olfactory, and gustatory (taste) disorders.
Pain

Pain is a complex experience. It is comprised of dynamic interactions between physical, cognitive, spiritual, emotional, and environmental factors and cannot be characterized as only a response to injury. McCaffery defined pain as “whatever the experiencing person says it is, existing whenever he says it does.” The International Association for the Study of Pain and the American Pain Society defined pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.” Acute pain is protective and promotes withdrawal from painful stimuli, allows the injured part to heal, and teaches avoidance of painful stimuli.

Neuroanatomy of Pain

Three portions of the nervous system are responsible for the sensation, perception, and response to pain:

1. The afferent pathways, which begin in the peripheral nervous system (PNS), travel to the spinal gate in the dorsal horn and then ascend to higher centers in the central nervous system (CNS)

2. The interpretive centers located in the brain stem, midbrain, diencephalon, and cerebral cortex

3. The efferent pathways that descend from the CNS back to the dorsal horn of the spinal cord

The processing of potentially harmful (noxious) stimuli through a normally functioning nervous system is called nociception. Nociceptors, or pain receptors, are free nerve endings in the afferent peripheral nervous system. When they are stimulated they cause nociceptive pain. The cell bodies of nociceptors are located in the dorsal root ganglia (DRG) for the body and in the trigeminal ganglion for the face. Nociceptors have a peripheral and central axonal branch that innervates their target organ and the spinal cord, respectively. Nociceptors are unevenly distributed throughout the body so the relative sensitivity to pain differs according to their location (Table 14-1). Nociceptors respond to different types of noxious stimuli: mechanical (pressure or mechanical distortion), thermal (extreme temperatures), or chemical (acids or chemicals of inflammation such as bradykinin, histamine, leukotrienes, or prostaglandins). Nociception involves four phases: transduction, transmission, perception, and modulation.

Pain transduction begins when nociceptors are activated by a noxious stimulus, causing ion channels (sodium, potassium, calcium) on nociceptors to open, creating electrical impulses that travel through axons of two primary types of nociceptors that are transmitted to the spinal cord, brainstem, thalamus, and cortex (see Figure 13-9). There are two primary types of nociceptors: A-delta (Aδ) fibers and C fibers. Aδ fibers are larger myelinated fibers that rapidly transmit sharp, well-localized “fast” pain sensations such as a burn or pinprick to the skin. Activation of these fibers causes a spinal reflex withdrawal of the affected body part from the stimulus, before a pain sensation is perceived. C fibers are the most numerous, are smaller and unmyelinated, and are located in muscle, tendons, body organs, and in the skin. They slowly transmit dull, aching, or burning sensations that are poorly localized and often constant.

Pain transmission is the conduction of pain impulses along the Aδ and C fibers (primary order neurons) into the dorsal horn of the spinal cord (Figure 14-1). Here they form synapses with excitatory or inhibitory interneurons (second order neurons) in the substantia gelatinosa of the dorsal horn. The impulses then synapse with projection neurons (third order neurons), cross the midline of the spinal cord, and ascend to the brain through two lateral spinothalamic tracts. The neospinothalamic tract (anterior spinal thalamic tract) carries fast impulses for acute sharp pain. The paleospinothalamic tract (lateral spinothalamic tract) carries slow impulses for dull or chronic pain. The fast sharp pain is perceived first, followed by dull, throbbing pain. These tracts connect to the reticular formation, hypothalamus, thalamus (the major relay station of sensory information), and limbic system. The impulses are then projected to the somatosensory cortex for interpretation of location and intensity of pain (see Figure 14-1), and to other areas of the brain for an integrated response to pain.
Pain perception is the conscious awareness of pain, which occurs primarily in the reticular and limbic systems and the cerebral cortex. Interpretation of pain is influenced by many factors including genetics, cultural preferences, gender roles, and life experience, including past pain experiences and level of health. Three systems interact to produce the perception of pain. The sensory-discriminative system is mediated by the somatosensory cortex and is responsible for identifying the presence, character, location, and intensity of pain. The affective-motivational system determines an individual's conditioned avoidance behaviors and emotional responses to pain. It is mediated through the reticular formation, limbic system, and brainstem. The cognitive-evaluative system overlies the individual's learned behavior concerning the experience of pain and therefore can modulate perception of pain. It is mediated through the cerebral cortex. The integration of these three systems is referred to as the “pain matrix.” Pain threshold and tolerance are subjective phenomena that influence an
individual's perception of pain. They can be influenced by genetics, gender, cultural perceptions, expectations, role socialization, physical and mental health, and age\textsuperscript{11,12} (Table 14-2).

**Pain threshold** is defined as the lowest intensity of pain that a person can recognize.\textsuperscript{2} Intense pain at one location may increase the threshold in another location. For example, a person with severe pain in one knee is more likely to experience less intense chronic back pain (this is called **perceptual dominance**). Because of perceptual dominance, pain at one site may mask other painful areas. Stress, excessive physical exertion, acupuncture, sexual activity, and other factors can increase the levels of circulating neuromodulators, thereby raising the pain threshold.

**Pain tolerance** is defined as the greatest intensity of pain that a person can endure.\textsuperscript{2} It varies greatly among people and in the same person over time because of the body's ability to respond differently to noxious stimuli (see Table 14-2). Pain tolerance generally **decreases** with repeated exposure to pain, fatigue, anger, boredom, apprehension, and sleep deprivation and may **increase** with alcohol consumption, persistent use of opioid medications, hypnosis, distracting activities, and strong beliefs or faith.

**Pain Modulation**

**Pain modulation** involves many different mechanisms that increase or decrease the transmission of pain signals throughout the nervous system. Depending on the mechanism, modulation can occur before, during, or after pain is perceived.\textsuperscript{7}
Neurotransmitters of Pain Modulation

A wide variety of neurotransmitters act to modulate control over transmission of pain impulses in the periphery, spinal cord, and brain.\textsuperscript{13,14} The peripheral triggering mechanisms that initiate release of \textbf{excitatory neurotransmitters} include tissue injury (prostaglandins, histamine, bradykinin) and chronic inflammatory lesions (lymphokines). Glutamate, aspartate, substance P, and calcitonin are common excitatory neurotransmitters in the brain and spinal cord. These substances sensitize nociceptors by reducing the activation threshold, leading to increased responsiveness of nociceptors.\textsuperscript{15}

\textbf{Inhibitory neurotransmitters} in the spinal cord include gamma-aminobutyric acid (GABA) and glycine. Norepinephrine and 5-hydroxytryptamine (serotonin) contribute to pain inhibition in the medulla and pons, but can excite peripheral nerves.\textsuperscript{4}

\textbf{Endogenous opioids} are a family of morphine-like neuropeptides that inhibit transmission of pain impulses in the periphery, spinal cord, and brain by binding with specific opioid receptors (mu [\(\mu\)], kappa [\(\kappa\)], and delta [\(\delta\)]) on neurons. They inhibit ion channels, preventing the release of excitatory neurotransmitters, such as substance P and glutamate, in the dorsal horn. In the midbrain they influence descending inhibitory pathways\textsuperscript{16} (Figure 14-2). In peripheral inflamed tissue, opioids are produced and released from immune cells and activate opioid receptors on sensory nerve terminals.\textsuperscript{17} Opioid receptors are widely distributed throughout the body and are responsible for general sensations of well-being and modulation of many physiologic processes including control of respiratory and cardiovascular functions, stress and immune responses, gastrointestinal function, reproduction, and neuroendocrine control.\textsuperscript{18,19}
Enkephalins are the most prevalent of the natural opioids and bind to δ opioid receptors. Endorphins (endogenous morphine) are produced in the brain. The best studied endorphin is β-endorphin, which binds to µ receptors and is purported to produce the greatest sense of exhilaration as well as substantial natural pain relief. Dynorphins are the most potent of the endogenous opioids, binding strongly with κ receptors to impede pain signals. Paradoxically, they play a role in neuropathic pain and in mood disorders and drug addiction. Endomorphins bind with µ receptors and have potent analgesic effects. Nociceptin/orphanin FQ is an opioid that induces pain or hyperalgesia but does not interact with opioid receptors. The nociceptin receptor is widely distributed throughout the peripheral and central nervous system and is also associated with inflammation, immune regulation, mood, and emotion.

Synthetic and natural opiates have pharmacologic actions similar to morphine and bind as direct agonists to the opioid receptors. Morphine has a 50 times higher affinity for µ receptors in comparison with other opioids. Naloxone is the only
clinically used opioid receptor antagonist, with a higher affinity for the µ receptors than for the other receptors.\textsuperscript{23}

**Endocannabinoids** are synthesized from phospholipids and are classified as eicosanoids. They activate cannabinoid CB\textsubscript{1} (primarily in the central nervous system [CNS]) and CB\textsubscript{2} receptors (primarily in immune tissue [e.g., the spleen]) to modulate pain and other functions including memory, appetite, immune function, sleep, stress response, thermoregulation, and addiction. CB\textsubscript{1} receptors decrease pain transmission by inhibiting release of excitatory neurotransmitters in the spinal dorsal horn, periaqueductal gray, thalamus, rostral ventromedial medulla, and amygdala. **Cannabis** (marijuana) produces a resin containing cannabinoids. **Cannabinoids** are analgesic in humans, but their use is limited by their psychoactive and addictive properties. Work is in progress to develop cannabinoid receptor agonists that do not have addictive side effects.\textsuperscript{24-26}

**Pathways of Modulation**

**Descending inhibitory** and **facilitatory pathways** and nuclei inhibit or facilitate pain. Afferent stimulation of particularly the ventromedial medulla and periaqueductal gray (PAG) (gray matter surrounding the cerebral aqueduct) in the midbrain stimulates efferent pathways, which inhibit afferent pain signals at the dorsal horn.\textsuperscript{27} The rostroventromedial medulla (RVM) stimulates efferent pathways that facilitate or inhibit pain in the dorsal horn.\textsuperscript{28} Inhibitory pathways can activate opioid receptors and inhibit release of excitatory neurotransmitters, facilitate release of inhibitory neurotransmitters, or stimulate inhibitory interneurons.

**Segmental pain inhibition** occurs when **A-beta (A\textbeta) fibers** (large myelinated fibers that transmit touch and vibration sensations) are stimulated and the impulses arrive at the same spinal level as impulses from Aδ or C fibers. They stimulate an inhibitory interneuron and decrease pain transmission. An example is rubbing an area that has been injured to relieve pain.\textsuperscript{7}

**Diffuse noxious inhibitory control (DNIC)** is an inhibitory pain system that involves a spinal-medullary-spinal pathway. Pain is relieved when two noxious stimuli occur at the same time from different sites (pain inhibiting pain). This also is known as **heterosegmental pain inhibition** and is the basis for pain relief with acupuncture, deep massage, or intense cold or heat.\textsuperscript{29}

**Expectancy-related cortical activation** (placebo effect [beneficial expectations] or nocibo effect [adverse expectations]) can exert control over analgesic systems to attenuate or intensify pain.\textsuperscript{30} In other words, cognitive expectations can cause real, measurable physiologic effects that share some of the same descending pain pathways as the pain modulatory systems.
Clinical Descriptions of Pain

Pain can be described in a variety of ways. Because of the complex nature of pain, however, many terms overlap and more than one description is often used. The broad categories of pain are summarized in Box 14-1. Some of the most common clinical pain presentations are summarized below.

Box 14-1

Categories of Pain

I Neurophysiologic Pain

A. Nociceptive pain

1. Somatic (e.g., skin, muscle, bone)

2. Visceral (e.g., intestine, liver, stomach)

3. Referred

B. Neuropathic (non-nociceptive)

1. Central pain (lesion in brain or spinal cord)

2. Peripheral pain (lesion in PNS)

II Neurogenic Pain

A. Neuralgia (pain in the distribution of a nerve)

B. Constant

1. Sympathetically independent
2. Sympathetically dependent

**III Temporal Pain (time related, duration)**

A. **Acute pain**

1. Somatic
2. Visceral
3. Referred

B. **Chronic**

**IV Pain Location**

A. **Abdominal pain**
B. **Chest pain**
C. **Headache**
D. **Low back pain**
E. **Orofacial pain**
F. **Pelvic pain**

**V Etiologic Pain**

A. **Cancer pain**
B. **Dental pain**
C. **Inflammatory pain**
D. **Ischemic pain**
E. Vascular pain

**Acute pain** (nociceptive pain) is a normal protective mechanism that alerts the individual to a condition or experience that is immediately harmful to the body and mobilizes the individual to take prompt action to relieve it. Acute pain is transient, usually lasting seconds to days, sometimes up to 3 months. It begins suddenly and is relieved after the chemical mediators that stimulate pain receptors are removed. Stimulation of the autonomic nervous system results in physical manifestations including increased heart rate, hypertension, diaphoresis, and dilated pupils. Anxiety related to the pain experience, including its cause, treatment, and prognosis, is common as is the hope of recovery and expectation of limited duration.

Acute pain arises from cutaneous, deep somatic, or visceral structures and can be classified as (1) somatic, (2) visceral, or (3) referred. **Somatic pain** arises from the skin, joints, and muscles. It is either sharp and well localized (especially fast pain carried by A\(\delta\) fibers) or dull, aching, throbbing, and poorly localized as seen in polymodal C fiber transmissions. **Visceral pain** is transmitted by C fibers and refers to pain in internal organs and the lining of body cavities; it tends to be poorly localized with an aching, gnawing, throbbing, or intermittent cramping quality. It is carried by sympathetic fibers and is associated with nausea and vomiting, hypotension, and, in some cases, shock. Visceral pain often radiates (spreads away from the actual site of the pain) or is referred. **Referred pain** is felt in an area removed or distant from its point of origin—the area of referred pain is supplied by the same spinal segment as the actual site of pain. Referred pain can be acute or chronic. Impulses from many cutaneous and visceral neurons converge on the same ascending neuron, and the brain cannot distinguish between the different sources of pain. Because the skin has more receptors, the painful sensation is experienced at the referred site instead of at the site of origin. Referred pain can be acute or chronic. **Figure 14-3** illustrates common areas of referred pain and their associated sites of origin.
Chronic or persistent pain has been defined as lasting for more than 3 to 6 months and is pain lasting well beyond the expected normal healing time. It varies with type of injury.\textsuperscript{34} Chronic or persistent pain serves no purpose and is poorly understood and causes suffering. It often appears to be out of proportion to any observable tissue injury. It may be ongoing (e.g., low back pain) or intermittent (e.g., migraine headaches). Changes in the peripheral and central nervous systems that cause dysregulation of nociception and pain modulation processes (peripheral and central sensitization) are thought to lead to chronic pain\textsuperscript{35,36} (see neuropathic pain, described later in this section).

Neuroimaging studies have demonstrated brain changes in individuals with chronic pain, which may lead to cognitive deficits and decreased ability to cope with pain.\textsuperscript{37} These negative manifestations of chronic pain are thought to be due, in part, to the stress of coping with continuous pain and may be reversible when pain is controlled.\textsuperscript{38-40} Because it is not yet possible to predict when acute pain will develop into chronic pain, early treatment of acute pain is encouraged.\textsuperscript{41}

Physiologic responses to intermittent chronic pain are similar to those for acute pain, whereas persistent pain allows for physiologic adaptation, producing normal heart rate and blood pressure. This leads many to mistakenly conclude that people with chronic pain are malingering because they do not appear to be in pain. As chronic pain progresses, certain behavioral and psychologic changes often emerge, including depression, difficulty eating and sleeping, preoccupation with the pain, and avoidance of pain-provoking stimuli.\textsuperscript{42} The desire to relieve pain and the need
to hide it become conflicting drives for those with chronic pain, who fear being labeled complainers. Chronic pain is perceived as meaningless and is often associated with a sense of hopelessness as more time elapses and no cure seems possible. Some of the chronic pain syndromes are listed in Table 14-3. Comparison of acute and chronic pain is summarized in Table 14-4. Chronic pain associated with specific organ systems is discussed in later chapters. Neuropathic pain is presented next.

**Neuropathic pain** is chronic pain initiated or caused by a primary lesion or dysfunction in the nervous system and leads to long-term changes in pain pathway structures (neuroplasticity) and abnormal processing of sensory information. There is amplification of pain without stimulation by injury or inflammation. Neuropathic pain is often described as burning, shooting, shocklike, or tingling. It is characterized by increased sensitivity to painful or nonpainful stimuli with hyperalgesia, **allodynia** (the induction of pain by normally nonpainful stimuli), and the development of spontaneous pain. Neuropathic pain is classified as either peripheral or central and is associated with central and peripheral sensitization.

**Peripheral neuropathic pain** is caused by peripheral nerve lesions and an increase in the sensitivity and excitability of primary sensory neurons and cells in the dorsal root ganglion (**peripheral sensitization**). Examples include nerve entrapment, diabetic neuropathy, or chronic pancreatitis.

**Central neuropathic pain** is caused by a lesion or dysfunction in the brain or spinal cord. A progressive repeated stimulation of group C neurons (wind-up) in the dorsal horn leads to increased sensitivity of central pain signaling neurons (**central sensitization**). This results in pathologic changes in the CNS that cause chronic pain. Examples include brain or spinal cord trauma, tumors, vascular lesions, multiple sclerosis, Parkinson disease, postherpetic neuralgia, and phantom limb pain.

The following mechanisms have been implicated in the cause of neuropathic pain:
- Changes in sensitivity of neurons—lower threshold with peripheral and central sensitization
• Spontaneous impulses from regenerating peripheral nerves
• Alterations in the dorsal root ganglion and spinothalamic tract in response to peripheral nerve injury (i.e., deafferentation pain—loss of pain-related afferent information to the brain)
• Loss of pain inhibition and stimulation of pain facilitation by excitatory neurotransmitters in the dorsal horn (e.g., release of glutamate by stimulation of N-methyl-D-aspartate [NMDA] receptors)
• Loss of descending inhibitory pain modulation
• Hyperexcitable spinal interneurons stimulated by Aβ fibers (nonpainful stimulation of pain)
• Release of nociceptive inflammatory cytokines, chemokines, and growth factors by activated glial cells
• Structural and functional alterations in brain processing neural networks

Because of the complexity of the causes of neuropathic pain syndromes, they are difficult to treat. Multimodal therapy is often needed including nondrug treatment.50

Quick Check 14-1

1. What is the difference between A-delta and C fibers?

2. Give two examples of pain excitatory and inhibitory neurotransmitters.

3. How do A-beta fibers inhibit pain and cause pain?

4. What are two differences between nociceptive pain and neuropathic pain?
Temperature Regulation

Human **thermoregulation** is achieved through precise balancing of heat production, heat conservation, and heat loss. The normal range of body temperature is considered to be 36.2° to 37.7° C (96.2° to 99.4° F) overall, but a person's individual body parts will vary in temperature. Body temperature rarely exceeds 41° C. The extremities are generally cooler than the trunk and the temperature at the core of the body (as measured by rectal temperature) is generally 0.5° C higher than the surface temperature (as measured by oral temperature). Internal temperature varies in response to activity, environmental temperature, and daily fluctuation (circadian rhythm). Oral temperatures fluctuate within 0.2° to 0.5° C during a 24-hour period. Women tend to have wider fluctuations that follow the menstrual cycle, with a sharp rise in temperature just before ovulation. The daily fluctuating temperature in both genders peaks around 6 PM and is at its lowest during sleep. Maintenance of body temperature within the normal range is necessary for life.

Control of Body Temperature

**Temperature regulation (thermoregulation)** is mediated primarily by the hypothalamus and endocrine system. Peripheral thermoreceptors in the skin and abdominal organs (unmyelinated C fibers and thinly myelinated A-delta fibers) and central thermoreceptors in the hypothalamus, spinal cord, abdominal organs, and other central locations provide the hypothalamus with information about skin and core temperatures. If these temperatures are low or high, the hypothalamus triggers heat production and heat conservation or heat loss mechanisms.

Body heat is produced by the chemical reactions of metabolism and skeletal muscle tone and contraction. The heat-producing mechanism (chemical or nonshivering thermogenesis) begins with hypothalamic thyrotropin-stimulating hormone-releasing hormone (TSH-RH); it stimulates the anterior pituitary to release thyroid-stimulating hormone (TSH), which acts on the thyroid gland and stimulates the release of thyroxine. Thyroxine then acts on the adrenal medulla, causing the release of epinephrine into the bloodstream. Epinephrine causes vasoconstriction, stimulates glycolysis, and increases metabolic rate, thus increasing body heat. Norepinephrine and thyroxine activate brown fat thermogenesis where energy is released as heat instead of as adenosine triphosphate (ATP). Heat is distributed by the circulatory system.¹

The hypothalamus also triggers heat conservation by stimulating the sympathetic nervous system, which stimulates the adrenal cortex and results in increased skeletal muscle tone, initiating the shivering response and producing vasoconstriction. By
constricting peripheral blood vessels, centrally warmed blood is shunted away from the periphery to the core of the body where heat can be retained. This involuntary mechanism takes advantage of the insulating layers of the skin and subcutaneous fat to protect core temperature. The hypothalamus relays information to the cerebral cortex about cold and voluntary responses result. Individuals typically bundle up, keep moving, or curl up in a ball. These types of voluntary physical activities respectively provide insulation, increase skeletal muscle activity, and decrease the amount of skin surface available for heat loss through radiation, convection, and conduction.52

The hypothalamus responds to warmer core and peripheral temperatures by reversing the same mechanisms resulting in heat loss. Heat loss is achieved through (1) radiation, (2) conduction, (3) convection, (4) vasodilation, (5) evaporation (sweating), (6) decreased muscle tone, (7) increased respiration, (8) voluntary measures, and (9) adaptation to warmer climates (i.e., increasing or decreasing the volume of sweat). Table 14-5 summarizes further information about heat production and loss.

Temperature Regulation in Infants and Elderly
Persons

Infants (particularly low birth weight infants) and elderly persons require special attention to maintenance of body temperature. Term infants produce sufficient body heat, primarily through metabolism of brown fat, but cannot conserve heat produced because of their small body size, greater ratio of body surface to body weight, and inability to shiver. Infants also have little subcutaneous fat and thus are not as well insulated as adults.\(^5\) Children also have a greater ratio of body surface to body weight, lower sweating rate, higher peripheral blood flow in the heat, and a greater extent of vasoconstriction in the cold than adults. They can acclimatize to changes in environmental temperatures, but do so at a lower rate than adults.\(^5\)

Elderly persons respond poorly to environmental temperature extremes because of their slowed blood circulation, structural and functional skin changes, overall decreased heat-producing activities, and the presence of disease (i.e., congestive heart failure, chronic lung disease, diabetes mellitus, or peripheral vascular disease). Cold stress in older adults also decreases coronary perfusion.\(^5\) In addition, elderly persons have a decreased shivering response (delayed onset and decreased effectiveness), slowed metabolic rate, decreased vasoconstrictor response, diminished or absent ability to sweat, decreased peripheral sensation, desynchronized circadian rhythm, decreased perception of heat and cold, decreased thirst, decreased nutritional reserves, and decreased brown adipose tissue.\(^5\)

Pathogenesis of Fever

Fever (febrile response) is a temporary resetting of the hypothalamic thermostat to a higher level in response to exogenous or endogenous pyrogens. Exogenous pyrogens (endotoxins produced by pathogens; see Chapter 8) stimulate the release of endogenous pyrogens from phagocytic cells, including tumor necrosis factor-alpha (TNF-\(\alpha\)), interleukin-1 (IL-1), interleukin-6 (IL-6), and interferon (IFN). These pyrogens raise the thermal set point by inducing the hypothalamic synthesis of prostaglandin E\(_2\) (PGE\(_2\)). This produces an integrated response that raises body temperature through an increase in heat production and conservation (Figure 14-4). The individual feels colder, dresses more warmly, decreases body surface area by curling up, and may go to bed in an effort to get warm. Body temperature is maintained at the new level until the fever “breaks,” when the set point begins to return to normal with decreased heat production and increased heat reduction mechanisms. The individual feels very warm, dons cooler clothes, throws off the covers, and stretches out. Once the body has returned to a normal temperature the individual feels more comfortable and the hypothalamus adjusts thermoregulatory
mechanisms to maintain the new temperature.

**Fever of unknown origin (FUO)** is a body temperature of greater than 38.3°C (101°F) for longer than 3 weeks' duration that remains undiagnosed after 3 days of hospital investigation, 3 outpatient visits, or 1 week of ambulatory investigation. The clinical categories of FUO include infectious, rheumatic/inflammatory, neoplastic, HIV-associated, and miscellaneous disorders.57

**Benefits of Fever**
Moderate fever helps the body respond to infectious processes through several mechanisms:\textsuperscript{58,59}:

1. Raising of body temperature kills many microorganisms and adversely affects their growth and replication.

2. Higher body temperatures decrease serum levels of iron, zinc, and copper—minerals needed for bacterial replication.

3. Increased temperature causes lysosomal breakdown and autodestruction of cells, preventing viral replication in infected cells.

5. Phagocytosis is enhanced, and production of antiviral interferon is augmented.

Suppression of fever with antipyrogenic medications can be effective but should be used with caution.\textsuperscript{60,61} Infection and fever responses in elderly persons and children may vary from those in normal adults. Box 14-2 lists the principal features associated with fever at these extremes of age.\textsuperscript{62}

**Box 14-2**

**Effects of Fever at the Extremes of Age**

**Elderly Persons**

Show decreased or no fever response to infection; therefore benefits of fever are reduced.

High morbidity and mortality result from lack of beneficial aspects.

**Children**

Develop higher temperatures than adults for relatively minor infections.

Febrile seizures before age 5 years are not uncommon.

**Disorders of Temperature Regulation**
**Hyperthermia**

Hyperthermia is elevation of the body temperature without an increase in the hypothalamic set point. Hyperthermia can produce nerve damage, coagulation of cell proteins, and death. At 41°C (105.8°F), nerve damage produces convulsions in the adult. Death results at 43°C (109.4°F). Hyperthermia may be therapeutic, accidental, or associated with stroke or head trauma. Prevention of hyperthermia in stroke and head trauma assists in limiting brain injury.63

Therapeutic hyperthermia is a form of local, regional, or whole-body hyperthermia used to destroy pathologic microorganisms or tumor cells by facilitating the host's natural immune process or tumor blood flow.64

The forms of accidental hyperthermia are summarized as follows65:

1. **Heat cramps**—severe, spasmodic cramps in the abdomen and extremities that follow prolonged sweating and associated sodium loss. Usually occur in those not accustomed to heat or those performing strenuous work in very warm climates. Fever, rapid pulse rate, and increased blood pressure accompany the cramps.

2. **Heat exhaustion**—results from prolonged high core or environmental temperatures, which cause profound vasodilation and profuse sweating, leading to dehydration, decreased plasma volumes, hypotension, decreased cardiac output, and tachycardia. Symptoms include weakness, dizziness, confusion, nausea, and fainting.

3. **Heat stroke**—a potentially lethal result of an overstressed thermoregulatory center. Heat stroke can be caused by exertion, by overexposure to environmental heat, or from impaired physiologic mechanisms for heat loss. With very high core temperatures (>40°C; 104°F), the regulatory center ceases to function and the body's heat loss mechanisms fail. Symptoms include high core temperature, absence of sweating, rapid pulse rate, confusion, agitation, and coma. Complications include cerebral edema, degeneration of the CNS, swollen dendrites, renal tubular necrosis, and hepatic failure with delirium, coma, and eventually death if treatment is not undertaken.66

4. **Malignant hyperthermia**—a potentially lethal hypermetabolic complication of a rare inherited muscle disorder that may be triggered by inhaled anesthetics and depolarizing muscle relaxants.67 The syndrome involves altered calcium function in muscle cells with hypermetabolism, uncoordinated muscle contractions, increased muscle work, increased oxygen consumption, and a raised level of lactic acid production. Acidosis develops, and body temperature rises, with resulting tachycardia and cardiac dysrhythmias, hypotension, decreased cardiac output, and
cardiac arrest. Signs resemble those of coma—unconsciousness, absent reflexes, fixed pupils, apnea, and occasionally a flat electroencephalogram. Oliguria and anuria are common. It is most common in children and adolescents.

**Hypothermia**

Hypothermia (core body temperature less than 35°C [95°F]) produces depression of the central nervous and respiratory systems, vasoconstriction, alterations in microcirculation and coagulation, and ischemic tissue damage. Hypothermia may be accidental or therapeutic (Box 14-3). Most tissues can tolerate low temperatures in controlled situations, such as surgery. However, in severe hypothermia, ice crystals form on the inside of the cell, causing cells to rupture and die. Tissue hypothermia slows cell metabolism, increases the blood viscosity, slows microcirculatory blood flow, facilitates blood coagulation, and stimulates profound vasoconstriction (also see Frostbite, Chapter 41).

**Box 14-3**

**Defining Characteristics of Hypothermia**

**Accidental Hypothermia**

The unintentional decrease in core temperature to less than 35°C (95°F) results from sudden immersion in cold water, prolonged exposure to cold environments, diseases that diminish the ability to generate heat, or altered thermoregulatory mechanisms. It is most common among young and elderly persons.

**Factors That Increase Risk**

1. Hypothyroidism
2. Hypopituitarism
3. Malnutrition
4. Parkinson disease
5. Rheumatoid arthritis
6. Chronic increased vasodilation
7. Failure of thermoregulatory control resulting from cerebral injury, ketoacidosis,
uremia, sepsis, and drug overdose

**Response Mechanisms**

1. Peripheral vasoconstriction—shunts blood away from cooler skin to core to decrease heat loss and produces peripheral tissue ischemia

2. Intermittent reperfusion of extremities (Lewis phenomenon) helps preserve peripheral oxygenation until core temperature drops dramatically

3. Hypothalamic center induces shivering; thinking becomes sluggish, and coordination is depressed

4. Stupor; heart rate and respiratory rate decline; cardiac output diminishes; metabolic rate falls; acidosis; eventual ventricular fibrillation and asystole occur at 30° C (86° F) and lower

**Treatment**

1. Most changes are reversible with rewarming

2. Core temperature greater than 30° C (86° F)—active rewarming (external)

3. Core temperature less than 30° C (86° F) or with severe cardiovascular problems—active core rewarming (internal)

**Therapeutic Hypothermia**

Used to slow metabolism and preserve ischemic tissue during surgery (e.g., limb reimplantation), after cardiac arrest, or following neurologic injury

**Effects and Cautions**

1. Stresses the heart, leading to ventricular fibrillation and cardiac arrest (may be desired outcome in open heart surgery when heart must be stopped)

2. Exhusts liver glycogen stores by prolonged shivering

3. Surface cooling may cause burns, frostbite, and fat necrosis

4. Immunosuppression with increased infection risk
5. Slows drug metabolism

**Trauma and Temperature**

Major body trauma can affect temperature regulation through various mechanisms. Damage to the CNS, inflammation, increased intracranial pressure, or intracranial bleeding typically produces a body temperature of greater than 39° C (102.2° F). This sustained noninfectious fever, often referred to as a “central fever,” appears with or without bradycardia. A central fever does not induce sweating and is very resistant to antipyretic therapy. Other traumatic mechanisms that produce temperature alterations include accidental injuries, hemorrhagic shock, major surgery, and thermal burns. The severity and type of alteration (hyperthermia or hypothermia) vary with the severity of the cause and the body system affected.

✅ **Quick Check 14-2**

1. Why is temperature regulation important?
2. What are the principal heat production methods? Heat loss methods?
3. How does the hypothalamus alter its set point to change body temperature?
4. Compare and contrast hyperthermia and hypothermia and their effects on the body.
Sleep

Sleep is an active multiphase process that provides restorative functions and promotes memory consolidation. Complex neural circuits, interacting hormones, and neurotransmitters involving the hypothalamus, thalamus, brainstem, and cortex control the timing of the sleep-wake cycle and coordinate this cycle with circadian rhythms (24-hour rhythm cycles).

Normal sleep has two phases that can be documented by electroencephalogram (EEG): rapid eye movement (REM) sleep (20% to 25% of sleep time) and slow-wave (non-REM) sleep. Non-REM sleep is further divided into three stages (N1, N2, N3) from light to deep sleep followed by REM sleep. Four to six cycles of REM and non-REM sleep occur each night in an adult.

The hypothalamus is a major sleep center and the hypocretins (orexins), acetylcholine, and glutamate are neuropeptides secreted by the hypothalamus that promote wakefulness. Prostaglandin D₂, adenosine, melatonin, serotonin, L-tryptophan, gamma-aminobutyric acid (GABA), and growth factors promote sleep. The pontine reticular formation is primarily responsible for generating REM sleep, and projections from the thalamocortical network produce non-REM sleep.

REM (rapid eye movement) sleep is initiated by REM-on and REM-off neurons in the pons and mesencephalon. REM sleep occurs about every 90 minutes beginning 1 to 2 hours after non-REM sleep begins. This sleep is known as paradoxical sleep because the EEG pattern is similar to that of the normal awake pattern and the brain is very active with dreaming. REM and non-REM sleep alternate throughout the night, with lengthening intervals of REM sleep and fewer intervals of deeper stages of non-REM sleep toward morning. The changes associated with REM sleep include increased parasympathetic activity and variable sympathetic activity associated with rapid eye movement; muscle relaxation; loss of temperature regulation; altered heart rate, blood pressure, and respiration; penile erection in men and clitoral engorgement in women; release of steroids; and many memorable dreams. Respiratory control appears largely independent of metabolic requirements and oxygen variation. Loss of normal voluntary muscle control in the tongue and upper pharynx may produce some respiratory obstruction. Cerebral blood flow increases.

Non-REM sleep (NREM) accounts for 75% to 80% of sleep time in adults and is initiated when inhibitory signals are released from the hypothalamus. Sympathetic tone is decreased and parasympathetic activity is increased during NREM sleep, creating a state of reduced activity. The basal metabolic rate falls by 10% to 15%; temperature decreases 0.5° to 1.0° C (0.9° to 1.8° F); heart rate, respiration, blood pressure, and muscle tone decrease; and knee jerk reflexes are absent. Pupils are constricted. During the various stages, cerebral blood flow to the brain decreases...
and growth hormone is released, with corticosteroid and catecholamine levels depressed. **Box 14-4** summarizes sleep characteristics in infants and elderly persons.

### Box 14-4

**Sleep Characteristics of Infants and Elderly Persons**

#### Infants

- Sleep 10 to 16 hours per day: 50% REM (active) sleep, 25% non-REM (inactive) sleep.

- Infant sleep cycles are 50 to 60 minutes in length; 10 to 45 minutes of REM sleep accompanied by movement of the arms, legs, and facial muscles followed by about 20 minutes of non-REM sleep.

- At 1 year, REM and non-REM sleep cycles are about equal in length and infants sleep through the night with about two naps per day.

#### Elderly Persons

- Total sleep time is decreased with a longer time to fall asleep and poorer quality sleep.

- Total time in slow-wave and final phase of non-REM sleep decreases by 15% to 30%.

- Increases in stage 1 and 2 non-REM sleep, attributable to an increased number of spontaneous arousals.

- Elderly individuals tend to go to sleep earlier in the evening and wake earlier in the morning because of a phase advance in their normal circadian sleep cycle.

- Alterations in sleep patterns occur about 10 years later in women than in men.

- Sleep disorders more likely in elderly and increase risk of morbidity and mortality.

**Sleep Disorders**

Because classification of sleep disorders is complex, a system has been established by the American Academy of Sleep Medicine and includes six classifications: (1) insomnia, (2) sleep related breathing disorders, (3) central disorders of hypersomnolence, (4) circadian rhythm sleep-wake disorders, (5) parasomnias, (6) sleep related movement disorders.\(^72\) The most common disorders are summarized here.

**Common Dyssomnias**

**Insomnia** is the inability to fall or stay asleep; it is accompanied by fatigue during wakefulness and may be mild, moderate, or severe. It may be transient, lasting a few days or months (primary insomnia), and related to travel across time zones or caused by acute stress.\(^73\) Chronic insomnia can be idiopathic, start at an early age, and be associated with drug or alcohol abuse, chronic pain disorders, chronic depression, the use of certain drugs, obesity, aging, genetics, and environmental factors that result in hyperarousal.\(^74\)

**Obstructive sleep apnea syndrome (OSAS)** is the most commonly diagnosed sleep disorder. An estimated 1% to 5% of children, 9% of women, and 24% of men younger than 65 years of age in the United States have diagnosable sleep-disordered breathing. The incidence increases in those older than 65 years. Major risk factors include obesity, male gender, older age, and postmenopausal status (not on hormone therapy) in women.\(^75\) A lack of daytime sleepiness often lessens awareness of a potential sleep disorder and many persons are never properly diagnosed and treated.\(^76\) OSAS results from partial or total upper airway collapse with obstruction to airflow recurring during sleep with excessive loud snoring, gasping, and multiple apneic episodes that last 10 seconds or longer. The periodic breathing eventually produces arousal, which interrupts the sleep cycle, reducing total sleep time and producing sleep and REM deprivation. Associated conditions include decreased sensitivity to carbon dioxide and oxygen tensions, upper airway obstruction, a small airway, and decreased airway dilator muscle activation. **Obesity hypoventilation syndrome** may be related to leptin resistance because leptin also is a respiratory stimulant. Sleep apnea produces hypercapnia and low oxygen saturation and eventually leads to polycythemia, pulmonary hypertension, systemic hypertension, stroke, right-sided congestive heart failure, dysrhythmias, liver congestion, cyanosis, and peripheral edema.\(^77\) **Hypersomnia** (excessive daytime sleepiness) is associated with OSAS. Individuals may fall asleep while driving a car,
working, or even while conversing, with significant safety concerns.\textsuperscript{78} Sleep deprivation also can result in impaired mood and cognitive function characterized by impairments of attention, episodic memory, working memory, and executive functions.\textsuperscript{79}

Polysomnography is needed to diagnose OSAS in addition to the history and physical examination. Treatments include use of nasal continuous positive airway pressure and dental devices, surgery of the upper airway and jaw in selected individuals, and management of obesity.\textsuperscript{90} Adenotonsillar hypertrophy is the major cause of obstructive sleep apnea in children and obesity increases risk. Adenotonsillectomy is the treatment of choice.\textsuperscript{81,82}

Narcolepsy is a primary hypersomnia characterized by hallucinations, sleep paralysis, and, rarely, cataplexy (brief spells of muscle weakness). Narcolepsy is usually sporadic or can occur in families. Narcolepsy without cataplexy is associated with immune-mediated destruction of hypocretin (orexin)-secreting cells in the hypothalamus. Orexins stimulate wakefulness.\textsuperscript{83}

Circadian rhythm sleep disorders are common disorders of the 24-hour sleep-wake schedule (circadian rhythm sleep disorders). They can result from having rapid time-zone changes (or jet-lag syndrome), alternating the sleep schedule (rotating work shifts) involving 3 hours or more in sleep time, changing the total sleep time from day to day, or being diagnosed either with advanced sleep phase disorder (early morning waking–early evening sleeping), resulting in sleep loss if social requirements are for late sleeping, or with delayed sleep phase disorder (late morning waking–late night to early morning sleeping), with loss of sleep because of required early morning rising (common in adolescents). These changes desynchronize the circadian rhythm, which can depress the degree of vigilance, performance of psychomotor tasks, and arousal.\textsuperscript{84,85} A circadian rhythm sleep disorder known as shift work sleep disorder affects many shift workers who rotate or swing long shifts (such as nurses), particularly between the hours of 2200 (10:00 AM) and 0600 (6:00 AM).\textsuperscript{86,87} Our sleep-wake cycle is driven by circadian rhythms and the disruption of this circadian influence may cause problems in the short term, such as cognitive deficits and difficulty concentrating. However, long-term health consequences of shift work sleep disorder may be quite serious and include depression/anxiety, increased risk for cardiovascular disease, and increased all-cause mortality.\textsuperscript{84} Sleep cycle phenotype also has a genetic basis and influences the timing and cycles of sleep and can affect advances or delays in sleep-wake times.\textsuperscript{88,89}

**Common Parasomnias**

Parasomnias are unusual behaviors occurring during NREM stage 3 (slow wave)
These behaviors include sleepwalking, having night terrors, rearranging furniture, eating food, and exhibiting sleep sex or violent behavior, and having restless legs syndrome. REM sleep behavior disorder is manifested by loss of REM paralysis, leading to potentially injurious dream enactment.\textsuperscript{91,92}

Two dysfunctions of sleep (somnambulism and night terrors) are common in children and may be related to central nervous system immaturity. \textit{Somnambulism (sleepwalking)} is a disorder primarily of childhood and appears to resolve within a few years. Sleepwalking is therefore not associated with dreaming, and the child has no memory of the event on awakening. Sleepwalking in adults is often associated with sleep disordered breathing. \textit{Night terrors} are characterized by sudden apparent arousals in which the child expresses intense fear or emotion. However, the child is not awake and can be difficult to arouse. Once awakened, the child has no memory of the night terror event. Night terrors are not associated with dreams. Although this problem occurs most often in children, adults also may experience it with corresponding daytime anxiety.

\section*{Restless Leg Syndrome}

\textit{Restless legs syndrome (RLS)/Willis Ekbom disease} is a common sensorimotor disorder associated with unpleasant sensations (prickling, tingling, crawling) and nonvolitional periodic leg movements that occurs at rest and is worse in the evening or at night. There is a compelling urge to move the legs for relief with a significant effect on sleep and quality of life. The disorder is more common in women, during pregnancy, the elderly, and individuals with iron deficiency. RLS has a familial tendency and is associated with a circadian fluctuation of dopamine in the substantia nigra. Iron is a cofactor in dopamine production and some individuals respond to iron administration as well as dopamine agonists.\textsuperscript{93} Diagnostic and treatment guidelines have been established to assist with disease management.\textsuperscript{94}

\section*{Quick Check 14-3}

2. What is the major difference between the dyssomnias and parasomnias?
The Special Senses

Vision

The eyes are complex sense organs responsible for vision. Within a protective casing, each eye has receptors, a lens system for focusing light on the receptors, and a system of nerves for conducting impulses from the receptors to the brain. Visual dysfunction may be caused by abnormal ocular movements or alterations in visual acuity, refraction, color vision, or accommodation. Visual dysfunction also may be the secondary effect of another neurologic disorder.

The Eye

The wall of the eye consists of three layers: (1) sclera, (2) choroid, and (3) retina (Figure 14-5). The sclera is the thick, white, outermost layer. It becomes transparent at the cornea—the portion of the sclera in the central anterior region that allows light to enter the eye. The choroid is the deeply pigmented middle layer that prevents light from scattering inside the eye. The iris, part of the choroid, has a round opening, the pupil, through which light passes. Smooth muscle fibers control the size of the pupil so that it adjusts to bright light or dim light and to close or distant vision.
The retina is the innermost layer of the eye, and contains millions of rods and cones—special photoreceptors that convert light energy into nerve impulses. Rods mediate peripheral and dim light vision and are densest at the periphery. Cones, densest in the center of the retina, are color and detail receptors. There are no photoreceptors where the optic nerve leaves the eyeball; this creates the optic disc, or blind spot. Lateral to each optic disc is the macula lutea, the area of most distinct vision, and in the center is the fovea centralis, a tiny area that contains only cones and provides the greatest visual acuity (see Figure 14-5).

As shown in Figure 14-8 (p. 350), nerve impulses pass through the optic nerves (second cranial nerve) to the optic chiasm. The nerves from the inner (nasal) halves of the retinas cross to the opposite side and join fibers from the outer (temporal) halves of the retinas to form the optic tracts. The fibers of the optic tracts synapse in the dorsal lateral geniculate nucleus and pass by way of the optic radiation (or geniculocalcarine tract) to the primary visual cortex in the occipital lobe of the brain. Some fibers terminate in the suprachiasmatic nucleus (SCN) (located above the optic chiasm) and are involved in regulating the sleep-wake cycle. Light entering the eye is focused on the retina by the lens—a flexible, biconvex, crystal-like structure. The flexibility of the lens allows a change in curvature with contraction of the ciliary muscles, called accommodation, and allows the eye to focus on objects.
at different distances. The lens divides the anterior chamber into (1) the aqueous chamber and (2) the vitreous chamber. Aqueous humor fills the aqueous chamber and helps maintain pressure inside the eye, as well as provide nutrients to the lens and cornea. Aqueous humor is secreted by the ciliary processes and reabsorbed into the canal of Schlemm. If drainage is blocked, intraocular pressure increases (causing glaucoma). The vitreous chamber is filled with a gel-like substance called vitreous humor. Vitreous humor helps to prevent the eyeball from collapsing inward.

The central retinal artery provides blood to the inner retinal surface, and the choroid supplies nutrients to the outer surface of the retina. Six extrinsic eye muscles allow gross eye movements and permit eyes to follow a moving object (Figure 14-6).

**Visual Dysfunction**

**Alterations in ocular movements.**

Abnormal ocular movements result from oculomotor, trochlear, or abducens cranial nerve dysfunction (see Table 13-6). The three types of eye movement disorders are (1) strabismus, (2) nystagmus, and (3) paralysis of individual extraocular muscles.

In strabismus, one eye deviates from the other when the person is looking at an object. This is caused by a weak or hypertonic muscle in one eye. The deviation may be upward, downward, inward (entropia), or outward (extropia). Strabismus in children requires early intervention to prevent amblyopia (reduced vision in the
affected eye caused by cerebral blockage of the visual stimuli). The primary symptom of strabismus is **diplopia** (double vision). Causes include neuromuscular disorders of the eye muscle, diseases involving the cerebral hemispheres, or thyroid disease.

**Nystagmus** is an involuntary unilateral or bilateral rhythmic movement of the eyes. It may be present at rest or when the eye moves. **Pendular nystagmus** is characterized by a regular back and forth movement of the eyes. In **jerk nystagmus**, one phase of the eye movement is faster than the other. Nystagmus may be caused by imbalanced reflex activity of the inner ear, vestibular nuclei, cerebellum, medial longitudinal fascicle, or nuclei of the oculomotor, trochlear, and abducens cranial nerves (see Table 13-6 and Figure 13-25). Drugs, retinal disease, and diseases involving the cervical cord also may produce nystagmus.

Paralysis of specific extraocular muscles may cause limited abduction, abnormal closure of the eyelid, ptosis (drooping of the eyelid), or diplopia (double vision) as a result of unopposed muscle activity. Trauma or pressure in the area of the cranial nerves or diseases such as diabetes mellitus and myasthenia gravis also paralyze specific extraocular muscles.

**Alterations in visual acuity.**

Visual acuity is the ability to see objects in sharp detail. With advancing age, the lens of the eye becomes less flexible and adjusts slowly, and there is altered refraction of light by the cornea and lens. Thus, visual acuity declines with age. Table 14-6 contains a summary of changes in the eye caused by aging. Specific causes of visual acuity changes are (1) amblyopia, (2) scotoma, (3) cataracts, (4) papilledema, (5) dark adaptation, (6) glaucoma, (7) retinal detachment, and (8) macular degeneration (Table 14-7).

# Causes of Visual Acuity Changes

<table>
<thead>
<tr>
<th>Disorder</th>
<th>Description</th>
</tr>
</thead>
</table>
| Amblyopia    | Reduced or dimmed vision; cause unknown  
Associated with strabismus  
Accompanies such diseases as diabetes mellitus, renal failure, and malaria and use of drugs such as alcohol and tobacco                                                                 |
| Scotoma      | Circumscribed defect of central field of vision  
Often associated with retrobulbar neuritis and multiple sclerosis, compression of optic nerve by tumor, inflammation of optic nerve, pernicious anemia, methyl alcohol poisoning, and use of tobacco                                                                 |
| Cataract     | Cloudy or opaque area in ocular lens  
Incidence increases with age because most commonly a result of degeneration; other causes are congenital                                                                 |
| Papilledema  | Edema and inflammation of optic nerve where it enters eyeball  
Caused by obstruction of venous return from retina by one of three main sources: increased intracranial pressure, retrobulbar neuritis, or changes in retinal blood vessels                                                                 |
| Dark adaptation | With age, eye does not adapt as readily to dark  
Also, changes in quantity and quality of rhodopsin are causative; vitamin A deficiencies can produce this at any age                                                                 |
| Glaucoma     | Increased intraocular pressures (>12-20 mm Hg)  
Loss of acuity results from pressure on optic nerve, which blocks flow of nutrients to optic nerve fibers, leading to their death; sixth leading cause of blindness                                                                 |
| Retinal detachment | Tear or break in retina with accumulation of fluid and separation from underlying tissue; seen as floaters, flashes of light, or a curtain over visual field; risks include extreme myopia, diabetic retinopathy, sickle cell disease |

A cataract is a cloudy or opaque area in the ocular lens and leads to visual loss when located on the visual axis. It is the leading cause of blindness in the world. The incidence of cataracts increases with age as the lens enlarges. Cataracts develop because of alterations of metabolism and transport of nutrients within the lens. Although the most common form of cataract is degenerative, cataracts also may occur congenitally or as a result of infection, radiation, trauma, drugs, or diabetes mellitus. Cataracts cause decreased visual acuity, blurred vision, glare, and decreased color perception. Cataracts are treated by removal of the entire lens and replacement with an intraocular artificial lens.  

Glaucomas are the second leading cause of blindness and are characterized by intraocular pressures greater than 12 to 20 mm Hg with death of retinal ganglion cells and their axons.

There are three primary types of glaucoma.

1. Open angle. This type of glaucoma is characterized by outflow obstruction of aqueous humor at the trabecular meshwork or canal of Schlemm even though there is adequate space for drainage; often this is an inherited disease and is a leading cause of blindness with few preliminary symptoms.

2. Angle closure. In this type of glaucoma there is displacement of the iris toward the cornea with obstruction of the trabecular meshwork and obstruction of outflow of aqueous humor from the anterior chamber; it may occur acutely with a sudden rise in intraocular pressure, causing pain and visual disturbances.
3. **Congenital closure.** This is a rare disease associated with congenital malformations and other genetic anomalies.

Glaucoma is often asymptomatic and diagnosis may not occur until a late stage of disease. Both medical and surgical therapies are available.  

**Age-related macular degeneration (AMD)** is a severe and irreversible loss of vision and a major cause of blindness in older individuals. Hypertension, cigarette smoking, diabetes mellitus, and family history of AMD are risk factors. The degeneration usually occurs after the age of 60 years. There are two forms: atrophic (dry, nonexudative) and neovascular (wet, exudative). The atrophic form is more common and is slowly progressive with inflammation and accumulation of lipofuscin (a lysosomal pigmented residue) and drusen (waste products from photoreceptors) in the retina and may include limited night vision and difficulty reading. The neovascular form includes accumulation of drusen and lipofuscin, abnormal choroidal blood vessel growth, leakage of blood or serum, retinal detachment, fibrovascular scarring, loss of photoreceptors, and more severe and rapid loss of central vision. Treatment includes antivascular endothelial growth factor (anti-VEGF) injection for wet macular degeneration and antioxidant vitamins for dry macular degeneration. Two carotenoids, lutein and zeaxanthin, are antioxidants that selectively accumulate in the retina and may protect the eye from AMD.

**Alterations in accommodation.**

**Accommodation** refers to changes in the thickness of the lens. Accommodation is needed for clear vision and is mediated through the oculomotor nerve. Pressure, inflammation, age, and disease of the oculomotor nerve may alter accommodation, causing diplopia, blurred vision, and headache.

Loss of accommodation with advancing age is termed **presbyopia**, a condition in which the ocular lens becomes larger, firmer, and less elastic. The major symptom is reduced near vision, causing the individual to hold reading material at arm's length. Treatment includes corrective forward, contact, and intraocular lenses or laser refractive surgery for monovision.

**Alterations in refraction.**

Alterations in refraction are the most common visual problem. Causes include irregularities of the corneal curvature, the focusing power of the lens, and the length of the eye. The major symptoms of refraction alterations are blurred vision and headache. Three types of refraction are as follows (**Figure 14-7**):
Myopia—nearsightedness: Light rays are focused in front of the retina when the person is looking at a distant object.

Hyperopia—farsightedness: Light rays are focused behind the retina when a person is looking at a near object.

Astigmatism—unequal curvature of the cornea: Light rays are bent unevenly and do not come to a single focus on the retina. Astigmatism may coexist with myopia, hyperopia, or presbyopia.

Alterations in color vision.

Normal sensitivity to color diminishes with age because of the progressive yellowing of the lens that occurs with aging. All colors become less intense, although color discrimination for blue and green is greatly affected. Color vision deteriorates more rapidly for individuals with diabetes mellitus than for the general population.

Abnormal color vision also may be caused by color blindness and is an X-linked genetic trait. Color blindness affects 6% to 8% of the male population and about 0.5% of the female population. Although many forms of color blindness exist, most
commonly the affected individual cannot distinguish red from green. In the most severe form individuals see only shades of gray, black, and white.

**Neurologic disorders causing visual dysfunction.**

Vision may be disrupted at many points along the visual pathway, causing various defects in the visual field. Visual changes may cause defects or blindness in the entire visual field or in half of a visual field (hemianopia). (Figure 14-8 illustrates the many areas along the visual pathway that may be damaged and the associated visual changes.) Injury to the optic nerve causes same-side blindness. Injury to the optic chiasm (the X-shaped crossing of the optic nerves) can cause various defects, depending on the location of the injury.

![Figure 14-8: Visual Pathways and Defects](Modified from Thompson JM et al: Mosby's clinical nursing, ed 5, St Louis, 2002, Mosby)

**External Eye Structure and Disorders**

Protective external eye structures include the eyelids (palpebrae), conjunctivae, and
The eyelids control the amount of light reaching the eyes, and the conjunctiva lines the eyelids. Tears released from the lacrimal apparatus bathe the surface of the eye and prevent friction, maintain hydration, and wash out foreign bodies and other irritants (Figure 14-9).

Infection and inflammatory responses are the most common conditions affecting the supporting structures of the eyes. Blepharitis is an inflammation of the eyelids caused by Staphylococcus or seborrheic dermatitis. A hordeolum (stye) is an infection (usually staphylococcal) of the sebaceous glands of the eyelids usually centered near an eyelash. A chalazion is a noninfectious lipogranuloma of the meibomian (oil-secreting) gland that often occurs in association with a hordeolum and appears as a deep nodule within the eyelid. These conditions present with redness, swelling, and tenderness and are treated symptomatically. Entropion is a
common eyelid malposition in which the lid margin turns inward against the eyeball. There are both surgical and nonsurgical treatments to reposition the lid margin.

**Conjunctivitis** is an inflammation of the conjunctiva (mucous membrane covering the front part of the eyeball) caused by viruses (most common), bacteria, allergies, or chemical irritants.** Acute bacterial conjunctivitis (pinkeye)** is highly contagious and often caused by *Staphylococcus, Haemophilus, Streptococcus pneumoniae,* and *Moraxella catarrhalis,* although other bacteria may be involved. In children younger than 6 years, *Haemophilus* infection often leads to otitis media (conjunctivitis-otitis syndrome). Preventing the spread of the microorganism with meticulous handwashing and use of separate towels is important. The disease also is treated with antibiotics.

**Viral conjunctivitis** is caused by an adenovirus. Again, it is contagious, with symptoms of watering, redness, and photophobia. **Allergic conjunctivitis** is associated with a variety of antigens, including pollens. **Chronic conjunctivitis** results from any persistent conjunctivitis. **Trachoma** (chlamydial conjunctivitis) is caused by *Chlamydia trachomatis* and often is associated with poor hygiene. It is the leading cause of preventable blindness in the world.

**Keratitis** is an infection of the cornea caused by bacteria or viruses. Bacterial infections can cause corneal ulceration, and type 1 herpes simplex virus can involve both the cornea and the conjunctiva. **Acanthamoeba** keratitis can occur from contact lens wear because of poor hygiene. Severe ulcerations with residual scarring require corneal transplantation.

## Hearing

The external auditory canal is surrounded by the bones of the cranium. The opening (meatus) of the canal is just above the **mastoid process.** The air-filled sinuses, called **mastoid air cells,** of the mastoid process promote conductivity of sound between the external and the middle ear.

### The Normal Ear

The ear is divided into three areas: (1) the external ear, involved only with hearing; (2) the middle ear, involved only with hearing; and (3) the inner ear, involved with both hearing and equilibrium.

The external ear is composed of the **pinna** (auricle), which is the visible portion of the ear, and the **external auditory canal,** a tube that leads to the middle ear (Figure 14-10). The external auditory canal is surrounded by the bones of the cranium. The opening (meatus) of the canal is just above the **mastoid process.** The
air-filled sinuses, called mastoid air cells, of the mastoid process promote conductivity of sound between the external and the middle ear. The **tympanic membrane** separates the external ear from the middle ear. Sound waves entering the external auditory canal hit the tympanic membrane (eardrum) and cause it to vibrate.

The middle ear is composed of the **tympanic cavity**, a small chamber in the temporal bone. Three ossicles (small bones known as the **malleus** [hammer], **incus** [anvil], and **stapes** [stirrup]) transmit the vibration of the tympanic membrane to the inner ear. When the tympanic membrane moves, the malleus moves with it and transfers the vibration to the incus, which passes it on to the stapes. The stapes presses against the **oval window**, a small membrane of the inner ear. The movement of the oval window sets the fluids of the inner ear in motion (*Figure 14-11*).
FIGURE 14-11  The Inner Ear. A, The bony labyrinth (tan) is the hard outer wall of the entire inner ear and includes the semicircular canals, vestibule, and cochlea. Within the bony labyrinth is the membranous labyrinth (purple), which is surrounded by perilymph and filled with endolymph. Each ampulla in the vestibule contains a crista ampullaris that detects changes in head position and sends sensory impulses through the vestibular nerve to the brain. B, Section of the membranous cochlea. Hair cells in the organ of Corti detect sound and send the information through the cochlear nerve. The vestibular and cochlear nerves join to form the eighth cranial nerve. (From Applegate E: The anatomy and physiology learning system, ed 4, St Louis, 2011, Saunders.)
The **eustachian** (pharyngotympanic) **tube** connects the middle ear with the thorax. Normally flat and closed, the eustachian tube opens briefly when a person swallows or yawns, and it equalizes the pressure in the middle ear with atmospheric pressure. Equalized pressure permits the tympanic membrane to vibrate freely. Through the eustachian tube the mucosa of the middle ear is continuous with the mucosal lining of the throat.

The inner ear is a system of osseous labyrinths (bony, mazelike chambers) filled with **perilymph**. The bony labyrinth is divided into the **cochlea**, the **vestibule**, and the **semicircular canals** (see Figure 14-10). Suspended in the perilymph is the endolymph-filled membranous labyrinth that basically follows the shape of the bony labyrinth.

Within the cochlea is the **organ of Corti**, which contains **hair cells** (hearing receptors). Sound waves that reach the cochlea through vibrations of the tympanic membrane, ossicles, and oval window set the cochlear fluids into motion. Receptor cells on the basilar membrane are stimulated when their hairs are bent or pulled by fluid movement. Once stimulated, hair cells transmit impulses along the cochlear nerve (a division of the vestibulocochlear nerve) to the auditory cortex of the temporal lobe in the brain (see Figure 14-11 and view an animation at https://www.youtube.com/watch?v=46aNGGNPm7s). This is where interpretation of the sound occurs.

The semicircular canals and vestibule of the inner ear contain **equilibrium receptors**. In the semicircular canals the dynamic equilibrium receptors respond to changes in direction of movement. Within each semicircular canal is the **crista ampullaris**, a receptor region composed of a tuft of hair cells covered by a gelatinous cupula. When the head is rotated, the endolymph in the canal lags behind and moves in the direction opposite to the head's movement. The hair cells are stimulated, and impulses are transmitted through the vestibular nerve (a division of the vestibulocochlear nerve) to the cerebellum.

The vestibule in the inner ear contains **maculae**—receptors essential to the body's sense of static equilibrium. As the head moves, **otoliths** (small pieces of calcium salts) move in a gel-like material in response to changes in the pull of gravity. The otoliths pull on the gel, which in turn pulls on the hair cells in the maculae. Nerve impulses in the hair cells are triggered and transmitted to the brain (see Figure 14-11). Thus the ear not only permits the hearing of a large range of sounds but also assists with maintaining balance through the sensitive equilibrium receptors (see animation at https://www.youtube.com/watch?v=YMIMvBa8XGs).

**Auditory Dysfunction**
Between 5% and 10% of the general population have impaired hearing, and it is the most common sensory defect. The major categories of auditory dysfunction are conductive hearing loss, sensorineural hearing loss, mixed hearing loss, and functional hearing loss. Hearing loss may range from mild to profound. Auditory changes caused by aging are common and incremental (see the *Geriatric Considerations: Aging & Changes in Hearing* box).

**Conductive hearing loss.**

A **conductive hearing loss** occurs when a change in the outer or middle ear impairs conduction of sound from the outer to the inner ear. Conditions that commonly cause a conductive hearing loss include impacted cerumen, foreign bodies lodged in the ear canal, benign tumors of the middle ear, carcinoma of the external auditory canal or middle ear, eustachian tube dysfunction, *otitis* media, acute viral *otitis* media, chronic supplicative *otitis* media, cholesteroloma (accumulation of keratinized epithelium), and otosclerosis.

Symptoms of conductive hearing loss include diminished hearing and soft speaking voice. The voice is soft because often the individual hears his or her voice, conducted by bone, as loud.

**Sensorineural hearing loss.**

A **sensorineural hearing loss** is caused by impairment of the organ of Corti or its central connections. The loss may occur gradually or suddenly. Conditions causing sensorineural loss include congenital and hereditary factors, noise exposure, aging, Ménière disease, ototoxicity, systemic disease (syphilis, Paget disease, collagen diseases, diabetes mellitus), neoplasms, and autoimmune processes. Congenital and neonatal sensorineural hearing loss may be caused by maternal rubella, ototoxic drugs, prematurity, traumatic delivery, erythroblastosis fetalis, bacterial meningitis, and congenital hereditary malfunction. Diagnosis often is made when delayed speech development is noted. Sudden onset bilateral sensorineural hearing loss is a medical emergency.

**Presbycusis** is the most common form of sensorineural hearing loss in elderly people. Its cause may be atrophy of the basal end of the organ of Corti, loss of auditory receptors, changes in vascularity, or stiffening of the basilar membranes. Drug ototoxicities (drugs that cause destruction of auditory function) have been observed after exposure to various chemicals; for example, antibiotics such as streptomycin, neomycin, gentamicin, and vancomycin; diuretics such as ethacrynic acid and furosemide; and chemicals such as salicylate, quinine, carbon monoxide, nitrogen mustard, arsenic, mercury, gold, tobacco, and alcohol. In most instances,
the drugs and chemicals listed initially cause tinnitus (ringing in the ear), followed by a progressive high-tone sensorineural hearing loss that is permanent.

**Mixed and functional hearing loss.**

A mixed hearing loss is caused by a combination of conductive and sensorineural losses. With functional hearing loss, which is rare, the individual does not respond to voice and appears not to hear. It is thought to be caused by emotional or psychologic factors.

**Ménière disease.**

Ménière disease (endolymphatic hydrops) is an episodic disorder of the middle ear with an unknown etiology that can be unilateral or bilateral. There is excessive endolymph and pressure in the membranous labyrinth that disrupts both vestibular and hearing functions. There are four symptoms: recurring episodes of vertigo (often accompanied by severe nausea and vomiting), hearing loss, ringing in the ears (tinnitus), and a feeling of fullness in the ear. Treatment is symptomatic with medical management or surgical management when medications fail.

**Ear Infections**

**Otitis externa.**

Otitis externa is the most common inflammation of the outer ear and may be acute or chronic, infectious or noninfectious. The most common origins of acute infections are bacterial microorganisms including Pseudomonas, Staphylococcus aureus, and, less commonly, Escherichia coli. Fungal infections are less common. Infection usually follows prolonged exposure to moisture (swimmer's ear). The earliest symptoms are inflammation with pruritus, swelling, and clear drainage progressing to purulent drainage with obstruction of the canal. Tenderness and pain with earlobe retraction accompany inflammation. Acidifying solutions are used for early treatment and topical antimicrobials usually provide effective treatment for later stages of disease. Chronic infections are more often related to allergy or skin disorders.

**Otitis media.**

Otitis media is a common infection of infants and children. Most children have one episode by 3 years of age. The most common pathogens are Streptococcus pneumoniae, Haemophilus influenzae, and Moraxella catarrhalis. Predisposing factors include allergy, sinusitis, submucosal cleft palate, adenoidal hypertrophy,
eustachian tube dysfunction, and immune deficiency. Breast-feeding is a protective factor. Recurrent acute otitis media may be genetically determined.109

Acute otitis media (AOM) is associated with ear pain, fever, irritability, inflamed tympanic membrane, and fluid in the middle ear. The appearance of the tympanic membrane progresses from erythema to opaqueness with bulging as fluid accumulates. There is an increasing prevalence of AOM caused by penicillin-resistant microorganisms. Otitis media with effusion (OME) is the presence of fluid in the middle ear without symptoms of acute infection.

Treatment includes symptom management, particularly of pain, with watchful waiting, antimicrobial therapy for severe illness, and placement of tympanostomy tubes when there is persistent bilateral effusion and significant hearing loss. Complications include mastoiditis, brain abscess, meningitis, and chronic otitis media with hearing loss. Persistent middle ear effusions may affect speech, language, and cognitive abilities. Multivalent vaccines for prevention of otitis media are effective for reducing disease incidence.110,111

Olfaction and Taste

Olfaction (smell) is a function of cranial nerve I and part of cranial nerve V. Taste (gustation) is a function of multiple nerves in the tongue, soft palate, uvula, pharynx, and upper esophagus innervated by cranial nerves VII and IX. Both of these cranial nerves are influenced by hormones within the sensory cells. Dysfunctions of smell and taste may occur separately or jointly. The strong relationship between smell and taste creates the sensation of flavor. If either sensation is impaired, the perception of flavor is altered. Olfactory structures are illustrated in Figure 14-12.
Olfactory cells, located in the olfactory epithelium, are the receptor cells for smell. Seven different primary classes of olfactory stimulants have been identified: (1) camphoraceous, (2) musky, (3) floral, (4) peppermint, (5) ethereal, (6) pungent, and (7) putrid. The primary sensations of taste are (1) sour, (2) salty, (3) sweet, (4) bitter, and (5) umami (savoriness). Taste buds (fungiform, foliate, and circumvallate) sensitive to each of the primary sensations are located in specific areas of the tongue.\(^\text{112}\)

Sensitivity to odors declines steadily with aging. See the *Geriatric Considerations: Aging & Changes in Olfaction and Taste* box for a summary of changes in olfaction and taste with aging.

**Olfactory and Taste Dysfunctions**

Olfactory dysfunctions include the following:

1. **Hyposmia**—impaired sense of smell
2. **Anosmia**—complete loss of sense of smell
3. **Olfactory hallucinations**—smelling odors that are not really present
4. **Parosmia**—abnormal or perverted sense of smell
The sense of taste can be impaired by injury. Altered taste may be attributed to impaired smell associated with injury near the hippocampus.

**Hypogeusia** is a decrease in taste sensation, whereas **ageusia** is an absence of the sense of taste. These disorders result from cranial nerve injuries and can be specific to the area of the tongue innervated. **Dysgeusia** is a perversion of taste in which substances possess an unpleasant flavor (i.e., metallic). Alterations in taste may compromise adequate nutrition or cause anorexia.¹¹³

**Quick Check 14-4**

1. List the major structures of the eye.
2. Visual disorders fall into several categories; name them.
3. How does fluid accumulate in the middle ear during otitis media?
4. What factors are involved in the sensation of flavor?
Somatosensory Function

Touch

The sensation of touch involves four afferent fiber types that mediate tactile sensation and there may be an additional sensory nerve that transmits pleasurable touch. Receptors sensitive to touch are present in the skin with high densities in the fingers and lips. Meissner and pacinian corpuscles are fast adapting receptors and sense movement across the skin and vibration, respectively. The slowly adapting Merkel disks sense sustained light touch, and Ruffini endings respond to deep sustained pressure, stretch, and joint position. Specific sensory input is carried to the higher levels of the CNS by the dorsal column of the spinal cord and the anterior spinothalamic tract.

The cutaneous senses develop before birth, but structural growth continues into early adulthood. Then a gradual decline occurs, with loss in tactile discrimination with advancing age. Abnormal tactile perception may be caused by alterations at any level of the nervous system, from the receptor to the cerebral cortex. Factors that interrupt or impair reception, transmission, perception, or interpretation of touch—including trauma, tumor, infection, metabolic changes, vascular changes, and degenerative diseases—may cause tactile dysfunction. In addition, most tactile sensations evoke affective responses that determine whether the sensation is unpleasant, pleasant, or neutral.

Proprioception

Proprioception is the awareness of the position of the body and its parts. It depends on impulses from the inner ear and from receptors in joints and ligaments. Sensory data are transmitted to higher centers, primarily through the dorsal columns and the spinocerebellar tracts, with some data passing through the medial lemnisci and thalamic radiations to the cortex. These stimuli are necessary for the coordination of movements, the grading of muscular contraction, and the maintenance of equilibrium.

A progressive loss of proprioception has been reported in elderly persons with increased risk for falls and injury. As with tactile dysfunction, any factor that interrupts or impairs the reception, transmission, perception, or interpretation of proprioceptive stimuli also alters proprioception and increases risk for falls and injury. Two common causes are vestibular dysfunction and neuropathy.

Specific vestibular dysfunctions are vestibular nystagmus and vertigo. Vestibular nystagmus is the constant, involuntary movement of the eyeball and develops when
the semicircular canal system is overstimulated. **Vertigo** is the sensation of spinning that occurs with inflammation of the semicircular canals in the ear. The individual may feel either that he or she is moving in space or that the world is revolving. Vertigo often causes loss of balance, and nystagmus may occur. Ménière disease can cause loss of proprioception during an acute attack, so that standing or walking is impossible.

Peripheral neuropathies also can cause proprioceptive dysfunction. They may be caused by several conditions and commonly are associated with renal disease and diabetes mellitus. Although the exact sequence of events is unknown, neuropathies cause a diminished or absent sense of body position or position of body parts. Gait changes often occur.

**Quick Check 14-5**

1. How are different touch receptors distributed over the body?
2. What are two causes of alterations in proprioception?
**Geriatric Considerations**

### Aging & Changes in Hearing*

*Hearing loss affects about 33% of older people.*

Geriatric Considerations

Aging & Changes in Olfaction and Taste

• Decline in sensitivity to odors, usually after age 80, occurs.

• Loss of olfaction may diminish appetite, taste, and food selection and may affect nutrition.

• Inability to smell toxic fumes or gases can pose a safety hazard.

• Decline in taste sensitivity is more gradual than decline in sense of smell.

• Higher concentrations of flavors required to stimulate taste.

• Taste may be influenced by decreased salivary secretion.
Did You Understand?

Pain

1. Pain (nociception) is a complex, unpleasant sensory experience involving emotion, cognition, and motivation. Pain is protective.

2. Three portions of the nervous system are responsible for the sensation, perception, and response to pain: (1) the afferent pathways, (2) the central nervous system, and (3) the efferent pathways.

3. There are two types of nociceptors. Myelinated Aδ fibers transmit sharp, “fast” pain. Smaller, unmyelinated C fibers more slowly transmit dull, less localized pain.

4. Nociception involves four phases: transduction, transmission, perception, and modulation.

5. The somatosensory cortex mediates localization and intensity of pain. The reticular formation, limbic system, and brain stem control emotional and affective responses to pain. The cortex coordinates the meaning an experience of pain.

6. Pain threshold is the least experience of pain that a person can recognize. Pain tolerance is the greatest level of pain that an individual is prepared to tolerate. Both are subjective and influenced by many factors.

7. Neuromodulators of pain include substances that (1) stimulate pain nociceptors (e.g., prostaglandins, bradykinins, lymphokines, substance P, glutamate) and (2) suppress pain (e.g., GABA, endogenous opioids, endocannabinoids). Some substances excite peripheral nerves but inhibit central nerves (e.g., serotonin, norepinephrine).

8. Descending inhibitory and facilitatory pathways and nuclei inhibit or facilitate pain. Efferent pathways from the ventromedial thalamus and periaqueductal gray inhibit pain impulses at the dorsal horn. The rostroventromedial medulla (RVM) stimulates efferent pathways that facilitate or inhibit pain in the dorsal horn.

9. Segmental pain inhibition occurs when impulses from Aβ fibers (touch and vibration sensations) arrive at the same spinal level as impulses from Aδ or C fibers.
10. Diffuse noxious inhibitory control occurs when pain signals from two different sites are transmitted simultaneously and inhibit pain through a spinal-medullary-spinal pathway.

11. Endogenous opioids inhibit pain transmission and include enkephalins, endorphins, dynorphins, and endomorphins. They are produced in the central nervous system.

12. Classifications of pain include nociceptive pain (with a known physiologic cause), non-nociceptive pain (neurologic pain), acute pain (signal to the person of a harmful stimulus), and chronic pain (persistence of pain of unknown cause or unusual response to therapy).

13. Acute pain may be (1) somatic (superficial), (2) visceral (internal), or (3) referred (present in an area distant from its origin). The area of referred pain is supplied by the same spinal segment as the actual site of pain.

14. Chronic pain is pain lasting well beyond the expected normal healing time and may be intermittent (e.g., low back pain) or persistent (e.g., migraine headaches).

15. Psychologic, behavioral, and physiologic responses to chronic pain include depression, sleep disorders, preoccupation with pain, lifestyle changes, and physiologic adaptation.

16. Neuropathic pain is increased sensitivity to painful stimuli and results from abnormal processing of pain information in the peripheral or central nervous system.

**Temperature Regulation**

1. Temperature regulation is achieved through precise balancing of heat production, heat conservation, and heat loss. Body temperature is maintained in a range around 37° C (98.6° F).

2. Temperature regulation is mediated by the hypothalamus through thermoreceptors in the skin, hypothalamus, spinal cord, and abdominal organs.

3. Heat is produced through chemical reactions of metabolism and skeletal muscle contraction.
4. Heat is lost through radiation, conduction, convection, vasodilation, decreased muscle tone, evaporation of sweat, increased respiration, and voluntary mechanisms.

5. Heat is conserved through vasoconstriction and voluntary mechanisms.

6. Infants do not conserve heat well because of their greater body surface/mass ratio and decreased amounts of subcutaneous fat. Elderly persons have poor responses to environmental temperature extremes as a result of slowed blood circulation, structural and functional changes in the skin, and overall decrease in heat-producing activities.

7. Fever is triggered by the release of exogenous pyrogens from bacteria or the release of endogenous pyrogens (cytokines) from phagocytic cells. Fever is both a normal immunologic mechanism and a symptom of disease.

8. Fever involves the “resetting of the hypothalamic thermostat” to a higher level. When the fever breaks, the set point returns to normal.

9. Fever production aids responses to infectious processes. Higher temperatures kill many microorganisms, promote immune responses, and decrease serum levels of iron, zinc, and copper, which are needed for bacterial replication.

10. Fever of unknown origin is a body temperature greater than 38.3° C (101° F) for longer than 3 weeks that remains undiagnosed after 3 days of investigation.

11. Hyperthermia (marked warming of core temperature) can produce nerve damage, coagulation of cell proteins, and death. Forms of accidental hyperthermia include heat cramps, heat exhaustion, heat stroke, and malignant hyperthermia. Heat stroke and malignant hyperthermia are potentially lethal.

12. Hypothermia (marked cooling of core temperature) slows the rate of chemical reaction (tissue metabolism), increases the viscosity of the blood, slows blood flow through the microcirculation, facilitates blood coagulation, and stimulates profound vasoconstriction. Hypothermia may be accidental or therapeutic.

**Sleep**

1. Sleep is an active process and is divided into REM and non-REM stages, each of which has its own series of stages. While asleep, an individual progresses through
REM and non-REM (slow wave) sleep in a predictable cycle.

2. REM sleep is controlled by mechanisms in the pons and mesencephalon. Non-REM sleep is controlled by release of inhibitory signals from the hypothalamus and accounts for 75% to 80% of sleep time.

3. The sleep patterns of the newborn and young child vary from those of the adult in total sleep time, cycle length, and percentage of time spent in each sleep cycle. Elderly persons experience a total decrease in sleep time.

4. The restorative, reparative, and growth processes occur during slow-wave (non-REM) sleep. Sleep deprivation can cause profound changes in personality and functioning.

5. Sleep disorders include (1) dyssomnias (disorders of initiating sleep [i.e., insomnia, sleep disordered breathing, hypersomnia, or disorders of the sleep-wake schedule]) and (2) parasomnias (i.e., sleepwalking or night terrors and restless legs syndrome).

**The Special Senses**

1. The wall of the eye has three layers: sclera, choroid, and retina. The retina contains millions of baroreceptors known as rods and cones that receive light through the lens and then convey signals to the optic nerve and subsequently to the visual cortex of the brain.

2. The eye is filled with vitreous and aqueous humor, which prevent it from collapsing.

3. The eyelids, conjunctivae, and lacrimal apparatus protect the eye. Infections are the most common disorders; they include blepharitis, conjunctivitis, chalazion, and hordeolum.

4. Structural eye changes caused by aging result in decreased visual acuity.

5. The major alterations in ocular movement include strabismus, nystagmus, and paralysis of the extraocular muscles.

6. Alterations in visual acuity can be caused by amblyopia, scotoma, cataracts, papilledema, glaucoma, and macular degeneration.
7. A cataract is a cloudy or opaque area in the ocular lens and leads to visual loss when located on the visual axis.

8. Glaucomas are characterized by intraocular pressures greater than 12 to 20 mm Hg with death of retinal ganglion cells and their axons.

9. Age-related macular degeneration is irreversible loss of vision with dry or wet forms.

10. Alterations in accommodation develop with increased intraocular pressure, inflammation, and disease of the oculomotor nerve. Presbyopia is loss of accommodation caused by loss of elasticity of the lens with aging.

11. Alterations in refraction, including myopia, hyperopia, and astigmatism, are the most common visual disorders.

12. Alterations in color vision can be related to yellowing of the lens with aging and color blindness, an inherited trait.

13. Trauma or disease of the optic nerve pathways, or optic radiations, can cause blindness in the visual fields. Homonymous hemianopsia is caused by damage of one optic tract.

14. Blepharitis is an inflammation of the eyelid; a hordeolum (stye) is an infection of the eyelid's sebaceous gland; and a chalazion is an infection of the eyelid's meibomian gland.

15. Conjunctivitis can be acute or chronic, bacterial, viral, or allergic. Redness, edema, pain, and lacrimation are common symptoms. Chlamydial conjunctivitis is the leading cause of blindness in the world and is associated with poor sanitary conditions.

16. Keratitis is a bacterial or viral infection of the cornea that can lead to corneal ulceration. Photophobia, pain, and tearing are common symptoms.

17. The ear is composed of external, middle, and inner structures. The external structures are the pinna, auditory canal, and tympanic membrane. The tympanic cavity (containing three bones: the malleus, the incus, and the stapes), oval window, eustachian tube, and fluid compose the middle ear and transmit sound vibrations to the inner ear.
18. The inner ear includes the bony and membranous labyrinths that transmit sound waves through the cochlea to the acoustic division of the eighth cranial nerve. The semicircular canals and vestibule help maintain balance through the equilibrium receptors.

19. Approximately one third of all people older than 65 years have hearing loss.

20. Hearing loss can be classified as conductive, sensorineural, mixed, or functional.

21. Conductive hearing loss occurs when sound waves cannot be conducted through the middle ear.

22. Sensorineural hearing loss develops with impairment of the organ of Corti or its central connections. Presbycusis is the most common form of sensorineural hearing loss in elderly people.

23. A combination of conductive and sensorineural loss is a mixed hearing loss.

24. Loss of hearing with no known organic cause is a functional hearing loss.

25. Ménière disease is a disorder of the middle ear that affects hearing and balance.

26. Otitis externa is an infection of the outer ear associated with prolonged exposure to moisture.

27. Otitis media is an infection of the middle ear that is common in children. Accumulation of fluid (effusion) behind the tympanic membrane is a common finding.

28. The perception of flavor is altered if olfaction or taste dysfunctions occur. Sensitivity to odor and taste decreases with aging.

29. Hyposmia is a decrease in the sense of smell, and anosmia is the complete loss of the sense of smell. Inflammation of the nasal mucosa and trauma or tumors of the olfactory nerve lead to a diminished sense of smell.

30. Hypogeusia is a decrease in taste sensation, and ageusia is the absence of the sense of taste. Loss of taste buds or trauma to the facial or glossopharyngeal nerves decreases taste sensation.
Somatosensory Function

1. Tactile sensation is a function of receptors present in the skin (pacinian corpuscles), and the sensory response is conducted to the brain through the dorsal column and anterior spinothalamic tract.

2. Alterations in touch can result from disruption of skin receptors, sensory transmission, or central nervous system perception.

3. Proprioception is the position and location of the body and its parts. Proprioceptors are located in the inner ear, joints, and ligaments. Proprioceptive stimuli are necessary for balance, coordinated movement, and grading of muscular contraction.

4. Disorders of proprioception can occur at any level of the nervous system and result in impaired balance and lack of coordinated movement.

Alterations in Complex Motor Performance, 385
A person achieves cognitive and behavioral functional competence by integrated processes of cognitive systems, sensory systems, and motor systems. The purpose of this chapter is to present the concepts and processes of alterations in these systems as an approach to understanding the manifestations of neurologic dysfunction and disease.

The neural systems that are essential to cognitive function are: (1) attentional systems that provide arousal and maintenance of attention over time; (2) memory and language systems by which information is communicated; and (3) affective or emotive systems that mediate mood, emotion, and intention. These core systems are fundamental to the processes of abstract thinking and reasoning. The products of abstraction and reasoning are organized and made operational through the executive attentional networks. The normal functioning of these networks manifests through the motor network in a behavioral array viewed by others as appropriate to human activity and successful living.
Alterations in Cognitive Systems

Full consciousness is a state of awareness both of oneself and of the environment, and a set of responses to that environment. The fully conscious individual initiates spontaneous, purposeful activity independently to a perceived stimulus. Any decrease in this state of awareness and varied responses is a decrease in consciousness.

Consciousness has two distinct components: arousal (state of awareness) and awareness (content of thought). Arousal is mediated by the reticular activating system, which regulates aspects of attention and information processing and maintains consciousness. Awareness encompasses all cognitive functions and is mediated by attentional systems, memory systems, language systems, and executive systems.

Alterations in Arousal

Alterations in level of arousal may be caused by structural, metabolic, or psychogenic (functional) disorders.

Pathophysiology

**Structural alterations in arousal** are divided according to the original location of the pathologic condition. Causes include infection, vascular alterations, neoplasms, traumatic injury, congenital alterations, degenerative changes, polygenic traits, and metabolic disorders.

*Supratentorial disorders* (above the tentorium cerebelli) produce changes in arousal by either diffuse or localized dysfunction. Diffuse dysfunction may be caused by disease processes affecting the cerebral cortex or the underlying subcortical white matter (e.g., encephalitis). Disorders outside the brain but within the cranial vault (extracerebral) can produce diffuse dysfunction, including neoplasms, closed-head trauma with subsequent subdural bleeding, and accumulation of pus in the subdural space. Disorders within the brain substance (intracerebral)—bleeding, infarcts, emboli, and tumors—function primarily as masses. Such localized destructive processes directly impair function of the thalamic or hypothalamic activating systems or secondarily compress these structures in a process of herniation.

*Infratentorial disorders* (below the tentorium cerebelli) produce a decline in arousal by (1) direct destruction or compression of the reticular activating system and its pathways (e.g., accumulations of blood or pus, neoplasms, and demyelinating disorders) or (2) the brainstem (midbrain, pons, medulla) may be destroyed either
by direct invasion or by indirect impairment of its blood supply.  

**Metabolic disorders** produce a decline in arousal by alterations in delivery of energy substrates as occurs with hypoxia, electrolyte disturbances, or hypoglycemia. Metabolic disorders caused by liver or renal failure cause alterations in neuronal excitability because of failure to metabolize or eliminate drugs and toxins. All the systemic diseases that eventually produce nervous system dysfunction are part of this metabolic category.

**Psychogenic alterations in arousal** (unresponsiveness), although uncommon, may signal general psychiatric disorders. Despite apparent unconsciousness, the person actually is physiologically awake and the neurologic examination reflects normal responses.

**Clinical manifestations and evaluation**

Five patterns of neurologic function are critical to the evaluation process: (1) level of consciousness, (2) pattern of breathing, (3) pupillary reaction, (4) oculomotor responses, and (5) motor responses. Patterns of clinical manifestations help in determining the extent of brain dysfunction and serve as indexes for identifying increasing or decreasing central nervous system (CNS) function. Distinctions are made between metabolic and structurally induced manifestations (Table 15-1). The types of manifestations suggest the cause of the altered arousal state (Table 15-2).

TABLE 15-2
Differential Characteristics of States Causing Altered Arousal

<table>
<thead>
<tr>
<th>Mechanism</th>
<th>Manifestations</th>
</tr>
</thead>
</table>
| Supratentorial mass lesions compressing or displacing diencephalon or brainstem | Initiating signs usually of focal cerebral dysfunction: vomiting, headache, hemiparesis, ocular signs, seizures, coma  
Signs of dysfunction progress rostral to caudal  
Neurologic signs at any given time point to one anatomic area (e.g., diencephalon, mesencephalon, medulla)  
Motor signs often asymmetric |
| Infratentorial mass of destruction causing coma | History of preceding brainstem dysfunction or sudden onset of coma  
Localizing brainstem signs precede or accompany onset of coma and always include oculoarestential abnormality  
Cranial nerve palsies usually manifest “bizarre” respiratory patterns that appear at onset |
| Metabolic coma  
Exogenous toxins (drugs)  
Endogenous toxins (organ system failure) | Confusion and stupor commonly precede motor signs  
Motor signs usually are symmetric  
Pupillary reactions usually are preserved  
Asterixis, mydriasis, tremor, and seizures are common  
Acid-base imbalance with hyperventilation or hyperventilation is common |
| Psychiatric unresponsiveness | Lids close actively; pupils reactive or dilated (cycloplegics)  
Oculocephalic reflexes are unpredictable; oculoarestential reflexes are physiologic (nystagmus is present)  
Motor tone is inconsistent or normal  
Eupnea or hyperventilation is usual  
No pathologic reflexes are present  
Electroencephalogram (EEG) is normal |

Level of consciousness is the most critical clinical index of nervous system function, with changes indicating either improvement or deterioration of the individual's condition. A person who is alert and oriented to self, others, place, and time is considered to be functioning at the highest level of consciousness, which implies full use of all the person's cognitive capacities. From this normal alert state, levels of consciousness diminish in stages from confusion and disorientation (can occur simultaneously) to coma, each of which is clinically defined (Table 15-3).

TABLE 15-3
Levels of Altered Consciousness

<table>
<thead>
<tr>
<th>State</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Confusion</td>
<td>Loss of ability to think rapidly and clearly; impaired judgment and decision making</td>
</tr>
<tr>
<td>Disorientation</td>
<td>Beginning loss of consciousness; the person may exhibit restlessness, anxiety, and irritation; disorientation to time occurs first, followed by disorientation to place and familiar others (family members) and impaired memory; recognition of self is lost last</td>
</tr>
<tr>
<td>Lethargy</td>
<td>Limited spontaneous movement or speech; easy arousal with normal speech or touch; may or may not be oriented to time, place, or person</td>
</tr>
<tr>
<td>Obnubilation</td>
<td>Mild to moderate reduction in arousal (awakeness) with limited response to environment; falls asleep unless stimulated verbally or tactily; answers questions with minimal response</td>
</tr>
<tr>
<td>Stupor</td>
<td>Condition of deep sleep or unresponsiveness from which person may be aroused or caused to open eyes only by vigorous and repeated stimulation; response is often withdrawal or grabbing at stimulus</td>
</tr>
<tr>
<td>Light coma</td>
<td>Associated with purposeful movement on stimulation</td>
</tr>
<tr>
<td>Coma</td>
<td>Associated with nonpurposeful movement only on stimulation</td>
</tr>
<tr>
<td>Deep coma</td>
<td>Associated with unresponsiveness or no response to any stimulus</td>
</tr>
</tbody>
</table>

Patterns of breathing help evaluate the level of brain dysfunction and coma (Figure 15-1). Rate, rhythm, and pattern should be evaluated. Breathing patterns can be categorized as hemispheric or brainstem patterns (Table 15-4).
FIGURE 15-1 Abnormal Respiratory Patterns with Corresponding Level of Central Nervous System Activity. (From Urden LD et al: Critical care nursing: diagnosis and management, ed 6, St Louis, 2010, Mosby.)
### TABLE 15-4
Patterns of Breathing

<table>
<thead>
<tr>
<th>Breathing Pattern</th>
<th>Description</th>
<th>Location of Injury</th>

</thead>
<tbody>
<tr>
<td><strong>Hemispheric Breathing Patterns</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Normal</td>
<td>After a period of hyperventilation that lowers arterial carbon dioxide pressure (Paco₂), individual continues to breathe regularly but with reduced depth.</td>
<td>Response of nervous system to an external stressor—not associated with injury to CNS</td>
</tr>
<tr>
<td>Posthyperventilation apnea</td>
<td>Respirationstop after hyperventilation has lowered PCO₂ level below normal.</td>
<td>Associated with diffuse bilateral metabolic or structural disease of cerebrum</td>
</tr>
<tr>
<td>Cheyne-Stokes respirations</td>
<td>Breathing pattern has a smooth increase (crescendo) in rate and depth of breathing (hyperpnea), which peaks and is followed by a gradual smooth decrease (decrsendo) in rate and depth of breathing to point of apnea, when cycle repeats itself. Hyperpnoic phase lasts longer than apnec phase.</td>
<td>Bilateral dysfunction of deep cerebral or diencephalic structures; seen with supratentorial injury and metabolically induced coma states</td>
</tr>
<tr>
<td><strong>Brainstem Breathing Patterns</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Central neurogenic hyperventilation</td>
<td>A sustained, deep, rapid, but regular pattern (hyperpnea) occurs, with a decreased PaCO₂ and a corresponding increase in pH and PO₂.</td>
<td>May result from CNS damage or disease that involves midbrain and upper pons; seen after increased intracranial pressure and blunt head trauma</td>
</tr>
<tr>
<td>Apneusis</td>
<td>A prolonged inspiratory cramp (a pause at full inspiration) occurs; a common variant of this is a brief end-inspiratory pause of 2 or 3 sec, often alternating with an end-expiratory pause.</td>
<td>Indicates damage to respiratory control mechanism located at pontine level; most commonly associated with pontine infarction but documented with hypoglycemia, anoxia, and meningitis</td>
</tr>

</tbody>
</table>

CNS, Central nervous system.

With normal breathing, a neural center in the forebrain (cerebrum) produces a rhythmic pattern. When consciousness decreases, lower brainstem centers regulate the breathing pattern by responding only to changes in PacO₂ levels; this is called *posthyperventilation apnea*. Cheyne-Stokes respiration is an abnormal rhythm of ventilation with alternating periods of tachypnea and apnea (crescendo-decrescendo pattern). Increases in PacO₂ levels lead to tachypnea. The PacO₂ level then decreases to below normal and breathing stops (apnea) until the carbon dioxide reaccumulates and again stimulates tachypnea (see Figure 15-1). In cases of opiate or sedative drug overdose, the respiratory center is depressed so the rate of breathing gradually decreases until respiratory failure occurs.

Pupillary changes indicate the presence and level of brainstem dysfunction because brainstem areas that control arousal are adjacent to areas that control the pupils (Figure 15-2). For example, severe ischemia and hypoxia usually produce dilated, fixed pupils. Hypothermia may cause fixed pupils.
Some drugs affect pupils and must be considered in evaluating individuals in comatose states. Large doses of atropine and scopolamine fully dilate and fix pupils. Doses of sedatives (e.g., glutethimide) in sufficient amounts to produce coma cause the pupils to become midposition or moderately dilated, unequal, and commonly fixed to light. Opiates cause pinpoint pupils. Severe barbiturate intoxication may produce fixed pupils.

**Oculomotor responses** (resting, spontaneous, and reflexive eye movements) change at various levels of brain dysfunction in comatose individuals. Persons with metabolically induced coma, except with barbiturate-hypnotic and phenytoin poisoning, generally retain ocular reflexes even when other signs of brainstem damage are present. Destructive or compressive injury to the brainstem causes specific abnormalities of the oculocephalic and oculovestibular reflexes (**Figures 15-3** and **15-4**). Injuries that involve an oculomotor nucleus or nerve cause the involved eye to deviate outward, producing a resting dysconjugate lateral position of the eye.
FIGURE 15-3 Test for Oculocephalic Reflex Response (Doll's Eyes Phenomenon). A, Normal response—eyes turn together to side opposite from turn of head. B, Abnormal response—eyes do not turn in conjugate manner. C, Absent response—eyes move in direction of head movement (brainstem injury). (From Rudy EB: Advanced neurological and neurosurgical nursing, St Louis, 1984, Mosby.)
Assessment of **motor responses** helps to evaluate the level of brain dysfunction and determine the most severely damaged side of the brain. The pattern of response noted may be (1) purposeful; (2) inappropriate, generalized motor movement; or (3) not present. Motor signs indicating loss of cortical inhibition that are commonly associated with decreased consciousness include primitive reflexes and rigidity (paratonia) (**Figure 15-5**). Primitive reflexes include grasping, reflex sucking, snout reflex, and palmomental reflex, all of which are normal in the newborn but disappear in infancy. Abnormal flexor and extensor responses in the upper and lower extremities are defined in **Table 15-5** and illustrated in **Figure 15-6**.

Vomiting, yawning, and hiccups are complex reflex-like motor responses that are integrated by neural mechanisms in the lower brainstem. These responses may
be produced by compression or diseases involving tissues of the medulla oblongata (e.g., infection, neoplasm, infarction) but also occur relative to other more benign stimuli to the vagal nerve. Most CNS disorders produce nausea and vomiting. Vomiting without nausea indicates direct involvement of the central neural mechanism (or pyloric obstruction; see Chapters 36 and 37). Vomiting often accompanies CNS injuries that (1) involve the vestibular nuclei or its immediate projections, particularly when double vision (diplopia) also is present; (2) impinge directly on the floor of the fourth ventricle; or (3) produce brainstem compression secondary to increased intracranial pressure.

Quick Check 15-1

1. Why are structural as well as metabolic factors capable of producing coma?

2. Why is level of consciousness the most critical index of central nervous system function?

3. Why do Cheyne-Stokes respirations appear in coma?

4. Why are oculomotor changes associated with levels of brain injury?

Outcomes of Alterations in Arousal

Outcomes of alterations in arousal fall into two categories: extent of disability (morbidity) and mortality. Outcomes depend on the cause and extent of brain damage and the duration of coma. Some individuals may recover consciousness and an original level of function, some may have permanent disability, and some may never regain consciousness and experience neurologic death. Two forms of neurologic death—brain death and cerebral death—result from severe pathologic conditions and are associated with irreversible coma. Other possible outcomes are a vegetative state, a minimally conscious state, or locked-in syndrome. The extent of disability has four subcategories: recovery of consciousness, residual cognitive function, psychologic function, and vocational function.

Brain death (total brain death) occurs when the brain is damaged so completely that it can never recover (irreversible) and cannot maintain the body's internal homeostasis. State laws define brain death as irreversible cessation of function of the entire brain including the brainstem and cerebellum. On postmortem examination, the brain is autolyzing (self-digesting) or already autolyzed. Brain death has occurred when there is no evidence of brain function for an extended
The abnormality of brain function must result from structural or known metabolic disease and must not be caused by a depressant drug, alcohol poisoning, or hypothermia. An isoelectric, or flat, electroencephalogram (EEG) (electrocerebral silence) for 6 to 12 hours in a person who is not hypothermic and has not ingested depressant drugs indicates brain death. The clinical criteria used to determine brain death are noted in Box 15-1. A task force for determination of brain death in children recommended the same criteria as for adults, but with a longer observation period.

**Box 15-1**

**Criteria for Brain Death**

1. Completion of all appropriate diagnostic and therapeutic procedures with no possibility of brain function recovery

2. Unresponsive coma (no motor or reflex movements)

3. No spontaneous respiration (apnea)

4. No brainstem functions (ocular responses to head turning or caloric stimulation; dilated, fixed pupils; no gag or corneal reflex [see Figures 15-3 and 15-4])

5. Isoelectric (flat) EEG (electrocerebral silence)

6. Persistence of these signs for an appropriate observation period

**Cerebral death**, or **irreversible coma**, is death of the cerebral hemispheres exclusive of the brainstem and cerebellum. Brain damage is permanent, and the individual is forever unable to respond behaviorally in any significant way to the environment. The brainstem may continue to maintain internal homeostasis (i.e., body temperature, cardiovascular functions, respirations, and metabolic functions). The survivor of cerebral death may remain in a coma or emerge into a persistent vegetative state (VS) or a minimally conscious state (MCS). In coma, the eyes are usually closed with no eye opening. The person does not follow commands, speak, or have voluntary movement.

A **persistent vegetative state** is complete unawareness of the self or surrounding environment and complete loss of cognitive function. The individual does not speak
any comprehensible words or follow commands. Sleep-wake cycles are present, eyes open spontaneously, and blood pressure and breathing are maintained without support. Brainstem reflexes (pupillary, oculocephalic, chewing, swallowing) are intact but cerebral function is lost. There is bowel and bladder incontinence. Recovery is unlikely if the state persists for 12 months. In a minimally conscious state (MCS) individuals may follow simple commands, manipulate objects, gesture or give yes/no responses, have intelligible speech, and have movements such as blinking or smiling.4

With locked-in syndrome there is complete paralysis of voluntary muscles with the exception of eye movement. Content of thought and level of arousal are intact, but the efferent pathways are disrupted (injury at the base of the pons with the reticular formation intact, often caused by basilar artery occlusion).5 Thus, the individual cannot communicate through speech or body movement but is fully conscious, with intact cognitive function. Vertical eye movement and blinking are a means of communication.

Alterations in Awareness

Awareness (content of thought) encompasses all cognitive functions, including awareness of self, environment, and affective states (i.e., moods). Awareness is mediated by all of the core networks under the guidance of executive attention networks including selective attention and memory. Executive attention networks involve abstract reasoning, planning, decision making, judgment, error correction, and self-control. Each attentional function is a network of interconnected brain areas and not localized to a single brain area.

Selective attention (orienting) refers to the ability to select specific information to be processed from available, competing environmental and internal stimuli, and to focus on that stimulus (i.e., to concentrate on a specific task without being distracted).6 Selective visual attention is the ability to select objects from multiple visual stimuli and process them to complete a task. Selective auditory or hearing attention is the ability to select or filter specific sounds and process them to complete a task. Multiple areas of the brain are involved in selective attention including cortical areas, thalamic nuclei, and the limbic system. Selective attention deficits can be temporary, permanent, or progressive. Disorders associated with selective attention deficits include seizure activity, parietal lobe contusions, subdural hematomas, stroke, gliomas or metastatic tumor, late Alzheimer dementia, frontotemporal dementia, and psychotic disorders.

Memory is the recording, retention, and retrieval of information. Amnesia is the loss of memory and can be mild or severe. Two types of amnesia are retrograde
amnesia and anterograde amnesia. The person experiencing retrograde amnesia has difficulty retrieving past personal history memories or past factual memories. Anterograde amnesia is the inability to form new personal or factual memories but memories of the distant past are retained and retrieved. Image processing is a higher level of memory function and includes the ability to use sensory data and language to form concepts, assign meaning, and make abstractions. Alterations in image processing include an inability to form concepts and generalizations or to reason. Thinking is very concrete. These memory disorders may be temporary (e.g., after a seizure) or permanent (e.g., after severe head injury or in Alzheimer disease). There may be only the memory disorder, or the memory disorder may be associated with other cognitive disorders.

Executive attention deficits include the inability to maintain sustained attention and a working memory deficit. Sustained attention deficit is an inability to set goals and recognize when an object meets a goal. A working memory deficit is an inability to remember instructions and information needed to guide behavior. Executive attention deficits may be temporary, progressive, or permanent. Attention-deficit/hyperactivity disorder (ADHD) is a common disorder of childhood that can continue through adulthood (Box 15-2). Table 15-6 summarizes alterations in memory and attention.

Box 15-2
Attention-Deficit/Hyperactivity Disorder (ADHD)

Initially ADHD was viewed as a neurodevelopmental disorder of childhood. It is now recognized that 50% to 75% of persons diagnosed in childhood have continuing symptoms into adulthood. Often the diagnosis is first made in adolescence or young adulthood when behavioral control and self-organization are expected of the person. The ability to function at work, at home, and in social situations is often impaired because of inattentiveness, hyperactivity, impulsivity, and problems with executive function. Continued treatment including medications for symptomatic adults is supported; substance abuse, which is more common in persons with ADHD, is reduced with continued treatment. The multifactorial patterns of inheritance and gene-environment interactions are under investigation as are the pathogenesis and pathophysiology of this complex disorder. Findings from structural and functional neuroimaging suggest the involvement of developmentally abnormal brain networks related to cognition, attention, emotion, and sensorimotor functions. Hopefully new findings will lead to improved

Pathophysiology

Very generally, the primary pathophysiologic mechanisms that operate in disorders of awareness are (1) direct destruction caused by ischemia and hypoxia or indirect destruction resulting from compression and (2) the effects of toxins and chemicals or metabolic disorders. Disorders of selective attention, at least as they relate to visual orienting behavior, are produced by disease that involves portions of the midbrain. Disease affecting the superior colliculi manifests as a slowness in orienting attention. Parietal lobe disease may produce unilateral neglect syndrome or lack of awareness of one side of the body or lack of response to stimuli on one side of the body and can occur after a stroke. An individual may groom or dress on only one side or eat food from only one side of the plate. Sensory inattentiveness is a form of neglect. The person is able to recognize individual sensory input from the dysfunctional side when asked, but ignores the sensory input from the dysfunctional side when stimulated from both sides (extinction). The entire complex of denial of dysfunction, loss of recognition of one's own body parts, and extinction sometimes is referred to as hemineglect or neglect syndrome. A disorder in vigilance may be produced by disease in the prefrontal areas. Dysfunction in the right anterior cingulate gyrus and basal ganglia may cause detection problems, whereas problems with working memory may be produced with left lateral frontal injury. Anterograde amnesia originates from pathologic conditions in the hippocampus and related temporal lobe structures; the diencephalic region including the thalamus; and the basal forebrain. Retrograde amnesia and higher level memory deficits originate from pathologic conditions in the widely distributed association areas of the cerebral cortex (see Figure 13-7, C). Executive attention deficits are associated with alterations in the frontal and prefrontal cortex including the anterior cingulate gyrus, supplementary motor area, and portions of the basal ganglia.

Clinical manifestations

Clinical manifestations of selective attention deficits, memory deficits, and executive attention function deficits are presented in Table 15-6.

Evaluation and treatment

Immediate medical management is directed at diagnosing the cause and treating reversible factors. Rehabilitative measures generally focus on compensatory or restorative activities and recently have been greatly facilitated by computer technology and other electronic devices.
Quick Check 15-2

1. Why is irreversible coma different from brain death?

2. What is the difference between anterograde and retrograde amnesia?

3. What is an example of neglect syndrome?

Data Processing Deficits

Data processing deficits are problems associated with recognizing and processing sensory information and include agnosia, dysphasia, and acute confusional states.

Agnosia

Agnosia is a defect of pattern recognition—a failure to recognize the form and nature of objects. Agnosia can be tactile, visual, or auditory, but generally only one sense is affected. For example, an individual may be unable to identify a safety pin by touching it with a hand but is able to name it when looking at it. Agnosia may be as minimal as a finger agnosia (failure to identify by name the fingers of one's hand) or more extensive, such as a color agnosia. Although agnosia is associated most commonly with cerebrovascular accidents, it may arise from any pathologic process that injures specific areas of the brain.

Dysphasia

Dysphasia is impairment of comprehension or production of language with impaired communication. Comprehension or use of symbols, in either written or verbal language, is disturbed or lost. Aphasia is a more severe form of dysphasia and an inability to communicate using language. Often the terms dysphasia and aphasia are used interchangeably. The term dysphasia is used here. Dysphasia results from dysfunction in the left cerebral hemisphere (i.e., Broca area [inferior frontal gyrus] and Wernicke area [superior temporal gyrus]) and the subcortical and cortical connecting networks (Figure 15-7 and see Figure 13-7). Dysphasias usually are associated with a cerebrovascular accident involving the middle cerebral artery or one of its many branches. Language disorders, however, may arise from a variety of injuries and diseases including vascular, neoplastic, traumatic, degenerative, metabolic, or infectious causes. Most language disorders result from acute processes or a chronic residual deficit of the acute process.
Dysphasias have been classified anatomically (i.e., Wernicke or Broca area dysphasias) or functionally as disorders of fluency (quality and content of speech). *Expressive dysphasia*, also known as Broca, motor, or nonfluent dysphasia, involves loss of ability to produce spoken or written language with slow or difficult speech. Verbal comprehension is usually present. Expressive dysphasia is differentiated from *dysarthria*, in which words cannot be articulated clearly as a result of cranial nerve damage or muscle impairment. *Receptive dysphasia*, also known as Wernicke, sensory, or fluent dysphasia, involves an inability to understand written or spoken language. Speech is fluent, flowing at a normal rate, but words and phrases have no meaning. *Anomic aphasia* is a sensory aphasia distinguished by difficulty finding words and naming a person or object. Circumlocution, or describing an object as a way of trying to name something, is common in anomic aphasia. Auditory comprehension is present in *conductive dysphasia*, but there is impaired verbatim repetition. Naming also can be impaired. The person recognizes the errors and tries to correct them. Speech is fluent but words and sounds may be transposed. Damage is in the left hemisphere to networks that connect Broca and Wernicke areas. *Transcortical dysphasias* are rare and can be motor, sensory, or mixed. They involve areas of the brain that connect into the language centers. *Global dysphasia* is
the most severe dysphasia and involves both expressive and receptive dysphasia. The individual is nonfluent or mute; cannot read or write; and has impaired comprehension, naming, reading, and writing. Global dysphasia is usually associated with a cerebrovascular accident involving the middle cerebral artery. Table 15-7 compares types of dysphasias, and Table 15-8 illustrates some of the language disturbances. Pure dysphasias are rare and are often mixed, making diagnosis difficult. All types of dysphasia usually improve with speech rehabilitation.

### Acute Confusional States and Delirium

**Acute confusional states** (also may be known as acute organic brain syndromes) are transient disorders of awareness and may have either a sudden or a gradual onset. Delirium can be considered as a type of acute confusional state, but for this discussion acute confusional states and delirium are considered to be synonymous. There are many medical conditions associated with delirium, and they are summarized in **Box 15-3**.

#### Box 15-3

**Conditions Causing Acute Confusional States or Delirium**

- Drug intoxication
- Alcohol or drug withdrawal
- Metabolic disorders (e.g., hypoglycemia, thyroid storm)
- Brain trauma or surgery
Postanesthesia

Febrile illnesses or heat stroke

Electrolyte imbalance, dehydration

Heart, kidney, or liver failure

**Pathophysiology**

Acute confusional states arise from disruption of a widely distributed neural network involving the reticular activating system of the upper brainstem and its projections into the thalamus, basal ganglion, and specific association areas of the cortex and limbic areas. Delirium (hyperactive confusional state) is associated with autonomic nervous system overactivity and typically develops over 2 to 3 days. It most commonly occurs in critical care units, following surgery, or during withdrawal from central nervous system depressants (i.e., alcohol or narcotic agents). Delirium is associated with right-upper middle-temporal gyrus or left temporal-occipital junction disruption and several neurotransmitters (i.e., acetylcholine and dopamine) are involved.7 Excited delirium syndrome (ExDS), also known as agitated delirium, is a type of hyperkinetic delirium that can lead to sudden death. Its symptoms include altered mental status, combativeness, aggressiveness, tolerance to significant pain, rapid breathing, sweating, severe agitation, elevated temperature, noncompliance or poor awareness to direction from police or medical personnel, inability to become fatigued, unusual or superhuman strength, and inappropriate clothing for the current environment. Hypoactive delirium (hypoactive confusional state) is more likely to be associated with right-sided frontal-basal ganglion disruption.

Most metabolic disturbances (i.e., hypoglycemia, thyroid disorders, liver or kidney disease) that produce delirium interfere with neuronal metabolism or synaptic transmission. Many drugs and toxins also interfere with neurotransmission function at the synapse.

**Clinical manifestations**

Delirium initially manifests as difficulty in concentrating, restlessness, irritability, insomnia, tremulousness, and poor appetite. Some persons experience seizures. Unpleasant, even terrifying, dreams or hallucinations may occur. In a fully developed delirium state, the individual is completely inattentive and perceptions are grossly altered, with extensive misperception and misinterpretation. The person appears distressed and often perplexed; conversation is incoherent. Frank tremor
and high levels of restless movement are common. Violent behavior may be present. The individual cannot sleep, is flushed, and has dilated pupils, a rapid pulse rate (tachycardia), elevated temperature, and profuse sweating (diaphoresis). Delirium typically abates suddenly or gradually in 2 to 3 days, although occasionally delirium states persist for weeks.

Hypoactive delirium is associated with underactivity and may occur in individuals who have fevers or metabolic disorders (i.e., chronic liver or kidney failure), or who are under the influence of central nervous system depressants. The individual exhibits decreases in mental function, specifically alertness, attention span, accurate perception, interpretation of the environment, and reaction to the environment. Forgetfulness and apathy are prominent, speech may be slow and the individual dozes frequently.

**Evaluation and treatment**

The initial goals are to (1) establish that the individual is confused and (2) determine the cause of the confusion (organic or functional) (Table 15-9). The next step is to differentiate whether the confusion is delirium or an underlying dementia. Individuals with dementia are at increased risk for developing delirium. A complete history, physical examination and laboratory tests (electrocardiogram and blood, urine, cerebrospinal fluid, and radiologic studies) are needed. Several assessment scales are available to guide evaluation (such as Clinical Assessment of Confusion A and B, Confusion State Evaluation, Confusion Assessment Method for the Intensive Care Unit [CAM-ICU], and Intensive Care Delirium Screening Checklist). Once the cause is established, treatment is directed at controlling the primary disorder with supportive measures used as appropriate. Delirium is preventable in some individuals. Table 15-10 contains a comparison of the features differentiating delirium and dementia.

**Dementia**

**Dementia** is an acquired deterioration and a progressive failure of many cerebral functions that includes impairment of intellectual processes with a decrease in orienting, memory, language, judgment, and decision making. Because of declining intellectual ability, the individual may exhibit alterations in behavior, for example, agitation, wandering, and aggression.

**Pathophysiology**
Mechanisms leading to dementia include neuron degeneration, compression of brain tissue, atherosclerosis of cerebral vessels, and brain trauma. Genetic predisposition is associated with the neurodegenerative diseases, including Alzheimer, Huntington, and Parkinson diseases. CNS infections, including the human immunodeficiency virus (HIV) and slow-growing viruses associated with Creutzfeldt-Jakob disease, also lead to nerve cell degeneration and brain atrophy.

**Clinical manifestations**

Clinical manifestations of the major dementias are presented in Table 15-11.

</tbody>
</table>

CBD, Cortical basal degeneration; PSP, progressive supranuclear palsy; REM, rapid eye movement.

**Evaluation and treatment**

Establishing the cause for dementia may be complicated, but individuals with clinical manifestations of dementia should be evaluated with laboratory and neuropsychologic testing to identify underlying conditions that may be treatable. Unfortunately, no specific cure exists for most progressive dementias. Therapy is directed at maintaining and maximizing use of the remaining capacities, restoring functions if possible, and accommodating to lost abilities. Helping the family to understand the process and to learn ways to assist the individual is essential.

**Alzheimer Disease**

*Alzheimer disease (AD) (dementia of Alzheimer type [DAT], senile disease complex)* is the leading cause of severe cognitive dysfunction in older persons. The
three forms of AD are nonhereditary sporadic or late-onset AD (70% to 90%), early-onset familial AD (FAD), and early-onset AD (very rare). Approximately 5.2 million Americans have AD and the numbers are expected to be 7.1 million by 2015.13

Pathophysiology
The exact cause of Alzheimer disease is unknown. Early-onset FAD has been linked to three genes with mutations on chromosome 21 (abnormal amyloid precursor protein 14 [APP14], abnormal presenilin 1 [PSEN1], and abnormal presenilin 2 [PSEN2]). Late-onset AD may be related to the involvement of chromosome 19 with the apolipoprotein E gene-allele 4 (APOE4). Studies are ongoing to classify the genetic variations of AD.14 DNA methylation is an epigenetic marker for Alzheimer disease.15 Sporadic late-onset AD is the most common, and does not have a specific genetic association; however, the cellular pathology is the same as that for gene-associated early- and late-onset AD.16 Pathologic alterations in the brain include accumulation of extracellular neuritic plaques containing a core of amyloid beta protein, intraneuronal neurofibrillary tangles, and degeneration of basal forebrain cholinergic neurons with loss of acetylcholine. Failure to process and clear amyloid precursor protein results in the accumulation of toxic fragments of amyloid beta protein that leads to formation of diffuse neuritic plaques, disruption of nerve impulse transmission, and death of neurons. The tau protein, a microtubule-binding protein, in neurons detaches and forms an insoluble filament called a neurofibrillary tangle, contributing to neuronal death (Figure 15-8). Neuritic plaques and neurofibrillary tangles are more concentrated in the cerebral cortex and hippocampus. The loss of neurons results in brain atrophy with widening of sulci and shrinkage of gyri (see Figure 15-8). Loss of synapses, acetylcholine and other neurotransmitters contributes to the decline of memory and attention and the loss of other cognitive functions associated with AD.17
FIGURE 15-8  Common Pathologic Findings in Alzheimer Disease. The middle panel represents coronal slices through the left brain (facing anterior).
Clinical manifestations

AD has a long preclinical and prodromal course, and pathophysiologic changes can occur decades before the appearance of the clinical dementia syndrome. The disease progresses from mild short-term memory deficits culminating in total loss of cognitive and executive functions. Initial clinical manifestations are insidious and often are attributed to forgetfulness, emotional upset, or other illness. The individual becomes progressively more forgetful over time, particularly in relation to recent events. Memory loss increases as the disorder advances, and the person becomes disoriented and confused and loses the ability to concentrate. Abstraction, problem solving, and judgment gradually deteriorate with failure in mathematic calculation ability, language, and visuospatial orientation. Dyspraxia may appear. The mental status changes induce behavioral changes, including irritability, agitation, and restlessness. Mood changes also result from the deterioration in cognition. The person may become anxious, depressed, hostile, emotionally labile, and prone to mood swings. Motor changes may occur if the posterior frontal lobes are involved, causing rigidity and flexion posturing. Weight loss can be significant. Great variability in age of onset, intensity and sequence of symptoms, and location and extent of brain abnormalities is common. Stages for the progression of Alzheimer disease are summarized in Table 15-12.

### Evaluation and treatment

The diagnosis of Alzheimer disease is made by ruling out other causes. Clinical criteria have been developed to assist diagnosis. The clinical history, including
mental status examinations (mini–mental status examination, clock drawing, and geriatric depression scale), laboratory tests, brain imaging of structure, blood flow and metabolism, and the course of the illness (which may span 5 years or more), is used to assess progression of the disease. Efforts are in progress to identify imaging and biochemical markers for risk assessment and early diagnosis and progression of Alzheimer type and other neurodegenerative causes of dementia (see Health Alert: Biomarkers and Neurodegenerative Dementia).\textsuperscript{19}

**Health Alert**

**Biomarkers and Neurodegenerative Dementia**

Neurodegenerative disease processes that lead to dementia begin many years before clinical manifestations are evident for Alzheimer disease, Huntington disease, and Parkinson disease. Efforts are under way to identify neuroimaging techniques and predictive biomarkers in the brain, spinal fluid, and blood that will guide a more comprehensive understanding of the etiology and biologic pathways that mediate neurodegeneration. Identification and profiling of such molecules and images will promote early identification of risk factors, enhance preventive and protective measures, provide alerts for progression from mild to advanced stages, and accelerate development of presymptomatic treatment for these diseases.

Treatment is directed at using devices to compensate for the impaired cognitive function, such as memory aids; maintaining unimpaired cognitive functions; and maintaining or improving the general state of hygiene, nutrition, and health. Cholinesterase inhibitors have shown a modest effect on cognitive function in mild to moderate Alzheimer disease. An $N$-methyl-$d$-aspartate (NMDA) receptor antagonist blocks glutamate activity and may slow progression of disease in moderate to severe AD. Treatments, beginning in the preclinical stage, are being developed to prevent, modify, or halt disease pathology.\textsuperscript{20}

**Frontotemporal Dementia**

**Frontotemporal dementia** (FTD), previously known as Pick disease, is the second most common form of dementia and is a degenerative disease of the frontal and anterior frontal lobes. There is a familial association with an age of onset less than 60 years and an estimated incidence of 15 per 100,000. The majority of cases
Seizure Disorders

Seizure disorders represent a manifestation of disease and not a specific disease entity. A seizure is a sudden, transient disruption in brain electrical function caused by abnormal excessive discharges of cortical neurons. Epilepsy is the recurrence of seizures and a type of seizure disorder for which no underlying, correctable cause for the seizure can be found. The term convulsion is sometimes applied to seizures and refers to the tonic-clonic (jerky, contract-relax) movement associated with some seizures. Seizures in children are presented in Chapter 17.

Conditions Associated with Seizure Disorders

Any disorder that alters the neuronal environment may cause seizure activity. Conditions that may produce a seizure are metabolic disorders, congenital malformations, genetic predisposition, perinatal injury, postnatal trauma, myoclonic syndromes, infection, brain tumor, vascular disease, and drug or alcohol abuse. The onset of seizures also may indicate the presence of an ongoing primary neurologic disease. Metabolic and structural causes of recurrent seizures in adults are summarized in Table 15-13. The cause of seizures is often unknown.

CNS, Central nervous system.

The threshold for seizures may be lowered by hypoglycemia, fatigue or lack of sleep, emotional or physical stress, fever, large amounts of water ingestion, constipation, use of antipsychotic drugs (i.e., chlorpromazine and clozapine) especially when combined with alcohol, withdrawal from depressant drugs (including alcohol), or hyperventilation (respiratory alkalosis). Some environmental stimuli, such as blinking lights, a poorly adjusted television screen, loud noises, certain music, certain odors, or merely being startled, have been known to initiate a seizure. Women may have increased seizure activity immediately before or during menses.

**Types of Seizure**

Seizures are classified in different ways: by clinical manifestations, site of origin, EEG correlates, or response to therapy. Types of seizures and clinical manifestations are presented in Chapter 17 (see Table 17-6). Terms used to describe seizure activity are defined in Table 15-14.

<table>

</tr>
</tbody>
</table>

Epilepsy now is considered to be the result of the interaction of complex genetic mutations with environmental effects that cause abnormalities in synaptic transmission, an imbalance in the brain’s neurotransmitters, or the development of abnormal nerve connections after injury. A group of neurons may exhibit a paroxysmal depolarization shift and function as an epileptogenic focus. These neurons are hypersensitive and are more easily activated by hyperthermia, hypoxia, hypoglycemia, hyponatremia, repeated sensory stimulation, and certain sleep phases. Epileptogenic neurons fire more frequently and with greater amplitude. When the intensity reaches a threshold point, cortical excitation spreads. Excitation of the subcortical, thalamic, and brainstem areas corresponds to the tonic phase (muscle contraction with increased muscle tone) and is associated with loss of
consciousness. The clonic phase (alternating contraction and relaxation of muscles) begins when inhibitory neurons in the cortex, anterior thalamus, and basal ganglia react to the cortical excitation. The seizure discharge is interrupted, producing intermittent muscle contractions that gradually decrease and finally cease. The epileptogenic neurons are exhausted.

During seizure activity, oxygen is consumed at a high rate—about 60% greater than normal. Although cerebral blood flow also increases, oxygen is rapidly depleted, along with glucose, and lactate accumulates in brain tissue. Continued, severe seizure activity has the potential for progressive brain injury and irreversible damage. In addition, if a seizure focus in the brain is active for a prolonged period, a mirror focus may develop in contralateral normal tissue and cause seizure activity.

Clinical manifestations

The clinical manifestations associated with seizure depend on its type (see Table 17-6). Two types of symptoms signal the preictal phase of a generalized tonic-clonic seizure: prodroma, early manifestations occurring hours to days before a seizure and may include anxiety, depression, or inability to think clearly; and a partial seizure that immediately precedes the onset of a generalized tonic-clonic seizure. Both may become familiar to the person experiencing recurrent generalized seizures and may enable the person to prevent injuries during the seizure. The ictus is the episode of the epileptic seizure with tonic-clonic activity. Relaxation of urinary and bowel sphincters may occur, leading to bladder and bowel incontinence. Airway maintenance needs to be ensured. Status epilepticus in adults is a state of continuous seizures lasting more than 5 minutes, or rapidly recurring seizures before the person has fully regained consciousness from the preceding seizure, or a single seizure lasting more than 30 minutes. The postictal state follows an epileptic seizure and can include signs of headache, confusion, dysphasia, memory loss, and paralysis that may last hours or a day or two. Deep sleep also is common.23

Evaluation and treatment

The health history, physical examination, and laboratory tests of blood and urine (concentrations of blood glucose, serum calcium, blood urea nitrogen, and urine sodium; and creatinine clearance time) can identify systemic diseases known to promote seizures. Brain imaging and cerebrospinal fluid (CSF) examination help identify neurologic diseases associated with seizures. The EEG is used to assess the type of seizure and determine its focus in brain tissue.

Treatment for a seizure disorder is to first correct or control its cause if possible. If this is not possible, the major means of management is the judicious
administration of antiseizure medications. Dietary treatments (e.g., ketogenic and Adkins diet) are effective for some individuals. Surgical interventions can improve seizure control and quality of life in people with drug-resistant epilepsy.\textsuperscript{24,25}

\textbf{Quick Check 15-4}

1. What is an eliptogenic focus?

2. Why can so many conditions precipitate seizures?

3. Why is continued seizing dangerous?
Alterations in Cerebral Hemodynamics

An injured brain reacts with structural, chemical, and pathophysiologic changes. Primary brain injury is the original trauma and secondary brain injury is a consequence of alterations in cerebral blood flow, intracranial pressure, and oxygen delivery (Box 15-4 and see Chapter 16).

<table>
<thead>
<tr>
<th><strong>Box 15-4</strong></th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Cerebral Hemodynamics</strong></td>
</tr>
</tbody>
</table>

- **Cerebral blood flow** (CBF) to the brain is normally maintained at a rate that matches local metabolic needs of the brain.
- **Cerebral perfusion pressure** (CPP) (70-90 mm Hg) is the pressure required to perfuse the cells of the brain.
- **Cerebral blood volume** (CBV) is the amount of blood in the intracranial vault at a given time.
- **Cerebral blood oxygenation** is measured by oxygen saturation in the internal jugular vein.
- **Intracranial pressure** (ICP) normally is 1 to 15 mm Hg, or 60 to 180 cm H₂O.

Alterations in cerebral blood flow (CBF) may be related to three injury states: inadequate cerebral perfusion, normal cerebral perfusion but with an elevated intracranial pressure, and excessive cerebral blood volume (CBV). Treatments for these injury states are directed at improving or maintaining cerebral perfusion pressure (CPP), as well as controlling intracranial pressure.

**Increased Intracranial Pressure**

Increased intracranial pressure (IICP) may result from an increase in intracranial content (as occurs with tumor growth), edema, excess CSF, or hemorrhage. It necessitates an equal reduction in volume of the other cranial contents. The most readily displaced content is CSF. If intracranial pressure remains high after CSF displacement out of the cranial vault, cerebral blood volume and blood flow are altered.
In stage 1 of intracranial hypertension, vasoconstriction and external compression of the venous system occur in an attempt to further decrease the intracranial pressure. Thus, during the first stage of intracranial hypertension, intracranial pressure (ICP) may not change because of the effective compensatory mechanisms, and there may no detectable symptoms (Figure 15-9). Small increases in volume, however, cause an increase in pressure, and the pressure may take longer to return to baseline. This pressure change can be detected with ICP monitoring.

In stage 2 of intracranial hypertension, there is continued expansion of intracranial contents. The resulting increase in ICP may exceed the ability of the brain's compensatory mechanisms to adjust. The pressure begins to compromise neuronal oxygenation, and systemic arterial vasoconstriction occurs in an attempt to elevate the systemic blood pressure sufficiently to overcome the IICP. Clinical manifestations at this stage usually are subtle and transient, including episodes of confusion, restlessness, drowsiness, and slight pupillary and breathing changes (see Figure 15-9). Interventions at this stage reduce ICP and promote better clinical outcomes.

In stage 3 of intracranial hypertension, ICP begins to approach arterial pressure,
the brain tissues begin to experience hypoxia and hypercapnia, and the individual's condition rapidly deteriorates. Clinical manifestations include decreasing levels of arousal or central neurogenic hyperventilation, widened pulse pressure, bradycardia, and small, sluggish pupils (see Figure 15-9).

Dramatic sustained rises in ICP are not seen until all compensatory mechanisms have been exhausted. Then dramatic rises in ICP occur over a very short period. **Autoregulation**, the compensatory alteration in the diameter of the intracranial blood vessels designed to maintain a constant blood flow during changes in cerebral perfusion pressure, is lost with progressively increased ICP. Accumulating carbon dioxide may still cause vasodilation locally, but without autoregulation this vasodilation causes the blood pressure in the vessels to drop and the blood volume to increase. The brain volume is thus further increased and ICP continues to rise. Small increases in volume cause dramatic increases in ICP, and the pressure takes much longer to return to baseline. As the ICP begins to approach systemic blood pressure, cerebral perfusion pressure falls and cerebral perfusion slows dramatically. The brain tissues experience severe hypoxia, hypercapnia, and acidosis.

In **stage 4 of intracranial hypertension**, brain tissue shifts (herniates) from the compartment of greater pressure to a compartment of lesser pressure and IICP in one compartment of the cranial vault is not evenly distributed throughout the other vault compartments (see Figures 15-9 and 15-10). With this shift in brain tissue, the herniating brain tissue's blood supply is compromised, causing further ischemia and hypoxia in the herniating tissues. The volume of content within the lower pressure compartment increases, exerting pressure on the brain tissue that normally occupies that compartment, and thus impairs its blood supply. For example, herniation into the brainstem impairs the vital cardiovascular and respiratory regulatory centers and can cause death. The herniation process markedly and rapidly increases intracranial pressure. Mean systolic arterial pressure soon equals ICP, and cerebral blood flow ceases at this point. The types of herniation syndromes are outlined in Box 15-5.
Brain Herniation Syndromes. Herniations can occur both above and below the tentorial membrane. Supratentorial: 1, uncal (transtentorial); 2, central; 3, cingulate; 4, transcalvarial (external herniation through an opening in the skull). Infratentorial: 5, upward herniation of cerebellum; 6, cerebellar tonsillar move down through foramen magnum.

Box 15-5
Brain Herniation Syndrome

Supratentorial Herniation

1. Uncal herniation. Occurs when the uncus or hippocampal gyrus, or both, shifts from the middle fossa through the tentorial notch into the posterior fossa, compressing the ipsilateral third cranial nerve, the contralateral third cranial nerve, and the mesencephalon. Uncal herniation generally is caused by an expanding mass in the lateral region of the middle fossa. The classic manifestations of uncal herniation are a decreasing level of consciousness, pupils that become sluggish before fixing and dilating (first the ipsilateral, then the contralateral pupil), Cheyne-Stokes respirations (which later shift to central neurogenic hyperventilation), and the appearance of decorticate and then decerebrate posturing.
2. **Central herniation.** Occurs when there is a straight downward shift of the diencephalon through the tentorial notch. It may be caused by injuries or masses located around the outer perimeter of the frontal, parietal, or occipital lobes; extracerebral injuries around the central apex (top) of the cranium; bilaterally positioned injuries or masses; and unilateral cingulate gyrus herniation. The individual rapidly becomes unconscious; moves from Cheyne-Stokes respirations to apnea; develops small, reactive pupils and then dilated, fixed pupils; and passes from decortication to decerebration.

3. **Cingulate gyrus herniation.** Occurs when the cingulate gyrus shifts under the falx cerebri. Little is known about its clinical manifestations.

4. **Transcalvarial.** The brain shifts through a skull fracture or a surgical opening in the skull. This type of external herniation may occur during a craniectomy—surgery in which a flap of skull is removed. This type of herniation prevents the piece of skull from being replaced.

**Infratentorial Herniation**

1. The most common syndrome is **cerebellar tonsillar.** The cerebellar tonsil shifts through the foramen magnum because of increased pressure within the posterior fossa. The clinical manifestations are an arched stiff neck, paresthesias in the shoulder area, decreased consciousness, respiratory abnormalities, and pulse rate variations. Occasionally the force produces an **upward transtentorial** herniation of a cerebellar tonsil or the lower brainstem. There is increased ICP but no specific set of clinical manifestations associated with infratentorial herniation (see Figure 15-10).

**Cerebral Edema**

**Cerebral edema** is an increase in the fluid content of brain tissue (Figure 15-11). The result is increased extracellular or intracellular tissue volume. It occurs after brain insult from trauma, infection, hemorrhage, tumor, ischemia, infarction, or hypoxia. The harmful effects of cerebral edema are caused by distortion of blood vessels, displacement of brain tissues, increase in intracranial pressure, and eventual herniation of brain tissue to a different brain compartment.
Three types of cerebral edema are (1) vasogenic edema, (2) cytotoxic (metabolic) edema, and (3) interstitial edema. **Vasogenic edema** is clinically the most important type and is caused by the increased permeability of the capillary endothelium of the brain after injury to the vascular structure. The selective permeability of capillaries that comprise the blood-brain barrier is disrupted. Plasma proteins leak into the extracellular spaces, drawing water to them and increasing the water content of the brain parenchyma. Vasogenic edema begins in the area of injury and spreads, with fluid accumulating in the white matter of the ipsilateral side because the parallel myelinated fibers separate more easily. Edema promotes more edema because of ischemia from the increasing ICP.

Clinical manifestations of vasogenic edema include focal neurologic deficits, disturbances of consciousness, and a severe increase in ICP. Vasogenic edema resolves by slow diffusion.

In **cytotoxic (metabolic) edema**, toxic factors directly affect the cellular elements of the brain parenchyma (neuronal, glial, and endothelial cells), causing failure of the active transport systems. The cells lose their potassium and gain larger amounts of sodium. Water follows by osmosis into the cells, so that the cells swell. Cytotoxic edema occurs principally in the gray matter and may increase vasogenic edema.

**Interstitial edema** is seen most often with noncommunicating hydrocephalus. The edema is caused by transependymal movement of CSF from the ventricles into the extracellular spaces of the brain tissues. The brain fluid volume increases
predominantly around the ventricles, with increased hydrostatic pressure within the white matter. The size of the white matter is reduced because of the rapid disappearance of myelin lipids.

**Hydrocephalus**

The term hydrocephalus refers to various conditions characterized by excess fluid in the cerebral ventricles, subarachnoid space, or both. Hydrocephalus occurs because of interference with CSF flow caused by increased fluid production, obstruction within the ventricular system, or defective reabsorption of the fluid. A tumor of the choroid plexus may, in rare instances, cause overproduction of CSF. The types of hydrocephalus are reviewed in Table 15-15.

CSF, Cerebrospinal fluid.

Hydrocephalus may develop from infancy through adulthood. **Communicating hydrocephalus** is defective resorption of CSF from the cerebral subarachnoid space and is found more often in adults. **Noncommunicating hydrocephalus (internal hydrocephalus, intraventricular hydrocephalus)** is obstruction within the ventricular system and is seen more often in children (see Figure 17-6). Congenital hydrocephalus is ventricular enlargement before birth and is rare.

**Pathophysiology**

The obstruction of CSF flow associated with hydrocephalus produces increased pressure and dilation of the ventricles proximal to the obstruction. The increased pressure and dilation cause atrophy of the cerebral cortex and degeneration of the white matter tracts. Selective preservation of gray matter occurs. When excess CSF fills a defect caused by atrophy, a degenerative disorder, or a surgical excision, this fluid is not under pressure; therefore atrophy and degenerative changes do not occur.
**Clinical manifestations**

Most cases of hydrocephalus develop gradually and insidiously over time. **Acute hydrocephalus** presents with signs of rapidly developing IICP. The person quickly deteriorates into a deep coma if not promptly treated. **Normal-pressure hydrocephalus** (dilation of the ventricles without increased pressure) develops slowly, with the individual or family noting declining memory and cognitive function. The triad symptoms of an unsteady, broad-based gait with a history of falling; incontinence; and dementia is common and may be treated surgically.26

**Evaluation and treatment**

The diagnosis is based on physical examination, computed tomography (CT) scan, and magnetic resonance imaging (MRI). A radioisotopic cisternogram may be performed to diagnose normal-pressure hydrocephalus. Hydrocephalus can be treated by surgery to resect cysts, neoplasms, or hematomas or by ventricular bypass into the normal intracranial channel or into an extracranial compartment using a shunting procedure, one of the three most common neurosurgical procedures. Excision or coagulation of the choroid plexus occasionally is needed when a papilloma is present. In normal-pressure hydrocephalus, reduction in CSF is achieved through diuresis or placement of a ventriculoperitoneal shunt.27

**Quick Check 15-5**

1. What are the four stages of increased intracranial pressure?

2. How does supratentorial herniation differ from infratentorial herniation?

3. What are the different types of cerebral edema?

4. How is communicating hydrocephalus different from noncommunicating hydrocephalus?
Alterations in Neuromotor Function

Movements are complex patterns of activity controlled by the cerebral cortex, the pyramidal system, the extrapyramidal system, and the motor units. Dysfunction in any of these areas can cause motor dysfunction. General neuromotor dysfunctions are associated with changes in muscle tone, movement, and complex motor performance.

Alterations in Muscle Tone

Normal muscle tone involves a slight resistance to passive movement. Throughout the range of motion, the resistance is smooth, constant, and even. The alterations of muscle tone and their characteristics and causes are presented in Table 15-16.

**TABLE 15-16**

Alterations in Muscle Tone

<table>
<thead>
<tr>
<th>Alterations</th>

<td>Occurs as a result of constant, involuntary contraction of muscle—usually involves extrapyramidal tracts (e.g., Parkinson disease)</td>
</tr>
<tr>
<td>Plastic or lead-pipe rigidity</td>
<td>Increased muscular tone relatively independent of degree of force used in passive movement; does not vary throughout the passive movement</td>
<td>Associated with basal ganglion damage (e.g., Parkinson disease)</td>
</tr>
<tr>
<td>Cogwheel rigidity</td>
<td>Uniform resistance may be interrupted by a series of brief jerks, resulting in movements much like a ratchet, “cogwheel” phenomenon</td>
<td>Associated with basal ganglion damage</td>
</tr>
<tr>
<td>Gamma rigidity</td>
<td>Characterized by extensor posturing (decerbrate rigidity)</td>
<td>Loss of excitation of extensor inhibitory areas by cerebral cortex decreasing inhibition of alpha and gamma motor neurons</td>
</tr>
<tr>
<td>Alpha rigidity</td>
<td>Impaired relaxation characterized by extensor rigidity of skeletal muscle after contraction</td>
<td>Loss of cerebellum input to lateral vestibular nuclei</td>
</tr>
</tbody>
</table>

**Hypotonia**

In hypotonia (decreased muscle tone), passive movement of a muscle occurs with little or no resistance. Causes include cerebellar damage and pure pyramidal tract...
damage (a rare occurrence). The hypotonia contributes to the ataxia and intention tremor in cerebellar damage and manifests with minimal weakness and normal or slightly exaggerated reflexes. A pure pyramidal tract injury produces hypotonia and weakness. Hypotonia also occurs when the nerve impulses needed for muscle tone are lost, such as in spinal cord injury or cerebrovascular accident.

Individuals with hypotonia tire easily or are weak. They may have difficulty rising from a sitting position, sitting down without using arm support, and walking up and down stairs, as well as an inability to stand on their toes. Because of their weakness, accidents during ambulatory and self-care activities are common. The joints become hyperflexible, so persons with hypotonia may be able to assume positions that require extreme joint mobility. The joints may appear loose. The muscle mass atrophies because of decreased input entering the motor unit, and muscles appear flabby and flat. Muscle cells are gradually replaced by connective tissue and fat. Fasciculations may be present in some cases.

**Hypertonia**

In hypertonia (increased muscle tone), passive movement of a muscle occurs with resistance to stretch and is caused by upper motor neuron damage (see p. 381). The four types of hypertonia are spasticity (usually corticospinal in origin) (Figures 15-12 and 15-13), paratonia (gegenhalten), dystonia (Figure 15-14), and rigidity (usually extrapyramidal in origin). Four types of rigidity are described: plastic or lead-pipe, cogwheel, gamma (independent of stretch reflex pathways), and alpha (dependent on stretch reflex pathways) (see Table 15-16).
Individuals with hypertonia tire easily or are weak. Passive movement and active movement are affected equally, except in paratonia, in which more active than
passive movement is possible. As a result of hypertonia and weakness, accidents occur during ambulatory and self-care activities.

The muscles may atrophy because of decreased use. However, hypertrophy occasionally occurs as a result of the overstimulation of muscle fibers. Overstimulation occurs when the motor unit reflex arc remains intact and functioning but is not inhibited by higher centers. This causes continual muscle contraction, resulting in enlargement of the muscle mass and the development of firm muscles.

**Alterations in Muscle Movement**

Movement requires a change in the contractile state of muscles. Abnormal movements occur when CNS dysfunction alters muscle innervation. The neurotransmitter *dopamine* has a role in several movement disorders. Some movement disorders (e.g., the akinesias) result from too little dopaminergic activity, whereas others (e.g., chorea, ballism, tardive dyskinesia) result from too much dopaminergic activity. Still others are not primarily related to dopamine function. Movement disorders are not necessarily associated with muscle mass, strength, or tone but are neurologic dysfunctions resulting in insufficient or excessive movement or involuntary movement.

**Hyperkinesia** is excessive, purposeless movement and represents the second broad category of abnormal movements. Within this category are a number of specific dysfunctions including tremors (*Table 15-17*). Also included under the general category of hyperkinesias are *dyskinesias* and abnormal involuntary movements. Huntington disease symptoms are the hallmark of hyperkinesia.

Choreoathetosis involves both chorea and athetosis; precise pathophysiology is unknown.

**Paroxysmal dyskinesias** are abnormal, involuntary movements that occur as spasms. The type of dyskinesia varies depending on the specific disorder.
**Tardive dyskinesia** is the involuntary movement of the face, lip, tongue, trunk, and extremities. Although the condition occurs occasionally in individuals with Parkinson disease, it usually occurs as a side effect of prolonged antipsychotic drug therapy. The most common symptom of tardive dyskinesia is rapid, repetitive, stereotypic movements, such as continual chewing with intermittent protrusions of the tongue, lip smacking, and facial grimacing. The symptoms also are called extrapyramidal symptoms because the extrapyramidal system controls involuntary reflexes and coordination of movement and posture (see p. 386).

Other movement disorders in this category are (1) complex repetitive movements, including automatism (unconscious behavior), stereotypy (ritualistic behavior such as rocking), complex tics such as **Tourette syndrome** (see **Health Alert: Tourette Syndrome**), compulsions, perseverations, and mannerisms; (2) excessive reactions to certain stimuli; and (3) paroxysmal excessive activity, including cataplexy and excessive startle reaction.

---

**Health Alert**

**Tourette Syndrome**

There is growing evidence that Tourette syndrome (TS) occurs worldwide and has common features across all races and cultures. The hallmark of TS is the presence of motor tics (sudden, rapid, repetitive nonrhythmic movements) and vocal tics. The tics may be either simple, involving only an individual muscle group (e.g., eye blinking or grunting), or complex, requiring coordinated movement of muscle groups (e.g., head banging or repeating of another person's words). Sensory tics involve unpleasant sensations in the face, head, and neck areas. Probably underdiagnosed, the onset of TS is typically between the ages of 2 and 15 years, with the tics lessening in adulthood. The syndrome has a complex multifactorial etiology with undetermined genetic, environmental, immune, and hormonal factors. The pathophysiology of TS is unclear and currently under study. There is evidence of cortico-striato-thalamocortical dysfunction and, in some cases, altered dopaminergic neurotransmission. TS is often diagnosed in association with anxiety, depression, attention-deficit/hyperactivity disorder (ADHD), and obsessive-compulsive disorder. Habit reversal therapy is the most common behavioral therapy and all behavioral therapy needs further investigation. Pharmacologic treatments target symptoms and have significant side effects. New drugs are being evaluated to identify the best outcomes. Deep brain stimulation is under investigation.

Hypokinesia is decreased amplitude of movement, bradykinesia is decreased speed of movement, and akinesia is absence of voluntary movement. These are all terms that represent a deficit of voluntary movement. Parkinson disease symptoms are the hallmark of a lack of voluntary movement.

**Huntington Disease**

**Huntington disease (HD),** also known as *chorea,* is a relatively rare, hereditary, degenerative hyperkinetic movement disorder diffusely involving the basal ganglia and cerebral cortex. The onset of Huntington disease is usually between 25 and 45 years of age, when the trait may already have been passed to the person's children. The disorder has a prevalence rate of approximately 5 to 10 per 100,000 persons and occurs in all races.\(^{28}\)

**Pathophysiology**

HD is inherited from one or both parents who have the autosomal dominant trait with high penetrance. The genetic defect of HD is on the short arm of chromosome 4. There is an abnormally long polyglutamine tract in the huntingtin (htt) protein that is toxic to neurons caused by a cytosine-adenine-guanine (CAG) trinucleotide repeat expansion (40 to 70 repeats instead of 9 to 34) with abnormal protein folding. Age of symptom onset is related to the length of the repeat sequences and mechanisms of toxicity. Repeat lengths greater than 60 cause the juvenile form of the disease.\(^{29}\) Fathers, but not mothers, with high normal alleles do not develop HD but are at risk of transmitting potentially penetrant HD alleles (≥36) to their offspring, who can develop HD.\(^ {30}\)

The principal pathologic feature of Huntington disease is severe degeneration of the basal ganglia, particularly the caudate nucleus. Tangles of protein (huntingtin protein) collect in the brain cells and chains of glutamine on the abnormal molecules stick to each other and contribute to neuronal loss. Basal ganglia and nigral depletion of gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter, is the principal biochemical alteration in Huntington disease. It alters the integration of motor and mental function.\(^ {31}\)

**Clinical manifestations**
Symptoms of Huntington disease progress slowly and include involuntary fragmentary movements, such as chorea, athetosis, and ballism (see Table 15-17). Chorea, the most common type of abnormal movement, begins in the face and arms, eventually affecting the entire body. There is emotional lability and progressive dysfunction of intellectual and thought processes (dementia). Any one of these features may mark the onset of the disease. Cognitive deficits include loss of working memory and reduced capacity to plan, organize, and sequence. Thinking is slow, and apathy is present. Restlessness, disinhibition, and irritability are common. Euphoria or depression may be present.

**Evaluation and treatment**

The diagnosis of Huntington disease is based on family history and clinical presentation of the disorder. Neuroradiologic abnormalities can be demonstrated up to 15 years before clinical symptoms. No known treatment is effective in halting the degeneration or progression of symptoms and the disease is fatal. Symptomatic drug therapies are available.\(^{32}\)

**Hypokinesia**

Hypokinesia (decreased movement) is loss of voluntary movement despite preserved consciousness and normal peripheral nerve and muscle function. Types of hypokinesia include akinesia, bradykinesia, and loss of associated movement.

**Akinesia and bradykinesia.**

Akinesia is a decrease in voluntary and associated movements. It is related to dysfunction of the extrapyramidal system and caused by either a deficiency of dopamine or a defect of the postsynaptic dopamine receptors, which occurs in parkinsonism. Bradykinesia is slowness of voluntary movements. All voluntary movements become slow, labored, and deliberate, with difficulty in (1) initiating movements, (2) continuing movements smoothly, and (3) performing synchronous (at the same time) and consecutive tasks. Both akinesia and bradykinesia involve a delay in the time it takes to start to perform a movement.

**Loss of associated movement.**

In hypokinesia, the normal, habitually associated movements that provide skill, grace, and balance to voluntary movements are lost. Decreased associated movements accompanying emotional expression cause an expressionless face, a statue-like posture, absence of speech inflection, and absence of spontaneous gestures. Decreased associated movements accompanying locomotion cause
reduction in arm and shoulder movements, hip swinging, and rotary motion of the cervical spine.

**Parkinson Disease**

*Parkinson disease* (PD) is a complex motor disorder accompanied by systemic nonmotor and neurologic symptoms. Etiologic classification of parkinsonism includes primary parkinsonism and secondary parkinsonism. Primary PD begins after the age of 40 years, with the incidence increasing after 60 years. It is more prevalent in males and a leading cause of neurologic disability in individuals older than 60 years. Approximately 60,000 new cases are diagnosed in the United States each year. The familial form represents about 10% of PD; however, the majority of cases are sporadic or idiopathic. Secondary parkinsonism is parkinsonism caused by disorders other than Parkinson disease (i.e., head trauma, infection, neoplasm, atherosclerosis, toxins, drug intoxication). Drug-induced parkinsonism, caused by neuroleptics, antiemetics, and antihypertensives, is the most common secondary form and usually is reversible.

**Pathophysiology**

The pathogenesis of primary PD is unknown. Several gene mutations have been identified that influence nerve function in PD. Gene-environment interactions are probable causes of neurodegeneration in PD. The primary pathology is degeneration of the basal ganglia (see Figure 13-10) with dysfunctional or misfolded α-synuclein protein and loss of dopamine-producing neurons in the substantia nigra and dorsal striatum. The resulting depletion of dopamine, an inhibitory neurotransmitter, and relative excess of cholinergic (excitatory) activity in the feedback circuit are manifested by hypertonia (tremor and rigidity) and akinesia, producing a syndrome of abnormal movement called *parkinsonism* (*Parkinson syndrome, parkinsonian syndrome, paralysis agitans*) (Figure 15-15). Neuroimaging shows degeneration of dopaminergic neurons preceding the onset of motor symptoms by as long as 3 to 6 years. Dementia may develop over decades with infiltration of Lewy bodies (accumulation of abnormal protein in nerve cells) and plaque formation similar to Alzheimer disease. Loss of cholinergic subcortical input into the cortex is associated with nonmotor symptoms of PD.
Clinical manifestations
The classic manifestations of Parkinson disease are resting tremor, rigidity, bradykinesia/akinesia, postural disturbance, dysarthria, and dysphagia. They may develop alone or in combination, but as the disease progresses, all are usually present. There is no true paralysis. The symptoms are always bilateral but usually involve one side early in the illness. Because the onset is insidious, the beginning of symptoms is difficult to document. Early in the disease, reflex status, sensory status, and mental status usually are normal. Loss of smell can be an early nonmotor symptom. Postural abnormalities (flexed, forward leaning), difficulty walking, and weakness develop as neurodegeneration progresses (Figure 15-16). Speech may be slurred.
Disorders of equilibrium result from postural abnormalities. The person with Parkinson disease cannot make the appropriate postural adjustment to tilting or falling and falls like a post when starting to tilt. The festinating gait (short, accelerating steps) of the individual with Parkinson disease is an attempt to maintain an upright position while walking. Individuals are also unable to right themselves when changing from a reclining or crouching position to a standing position and when rolling over from a supine to a lateral or prone position. Sleep disorders and excessive daytime sleepiness are commonly experienced. Sensory disturbances (pain and impaired smell and vision), urinary urgency, difficulty concentrating, depression, and hallucinations are some of the nonmotor symptoms of Parkinson disease.\textsuperscript{37,38} Autonomic-neuroendocrine changes also contribute to nonmotor symptoms and include inappropriate diaphoresis, orthostatic hypotension, drooling, gastric retention, constipation, and urinary retention.

Progressive dementia is more common in persons older than 70 years. Mental status may be further compromised by the side effects of the medication taken to control symptoms.
Evaluation and treatment

The diagnosis of Parkinson disease is based on the history and clinical features of the disease. Causes of secondary parkinsonism are first excluded. Specific gene panels and imaging studies are evolving for early diagnosis. Treatment of Parkinson disease is symptomatic with drug therapy to decrease akinesia. Because of troublesome side effects and loss of effectiveness, however, drug therapy may not be started until the symptoms become incapacitating. Deep brain stimulation (i.e., subthalamic neurostimulation) is replacing surgery to treat persons unresponsive to drug therapy. Implants of stem cells and fetal cells, as well as gene therapy, are strategies for future treatments. Dysphagia and general immobility are special problems of the individual with PD requiring interdisciplinary efforts to improve functional status.

Upper and Lower Motor Neuron Syndromes

Paresis and paralysis are symptoms of upper and lower motor neuron syndromes (Table 15-18). Paresis (weakness) is partial paralysis with incomplete loss of muscle power. Paralysis is loss of motor function so that a muscle group is unable to overcome gravity.

Upper Motor Neuron Syndromes

Upper motor neuron syndromes are the result of damage to descending motor pathways at cortical, brainstem, or spinal cord levels. Upper motor neuron paresis/paralysis is known also as spastic paresis/paralysis, and different terms are used to describe the specific disorders (Box 15-6).
### Box 15-6

**Upper Motor Neuron Paralysis**

**Hemiparesis/hemiplegia** is paresis/paralysis of the upper and lower extremities on one side.

**Diplegia** is paralysis of corresponding parts of both sides of the body as a result of cerebral hemisphere injuries.

**Paraparesis/paraplegia** is weakness/paralysis of the lower extremities as a result of lower spinal cord injury.

**Quadriparesis/quadriplegia** is paresis/paralysis of all four extremities as a result of upper spinal cord injury (spinal cord injury is discussed in Chapter 16).

Upper motor neuron paresis/paralysis is associated with a **pyramidal motor syndrome**, which involves a series of motor dysfunctions resulting from interruption of the pyramidal system (*Figures 15-17 and 15-18*). The injury may be in the cerebral cortex, the subcortical white matter, the internal capsule, the brainstem, or the spinal cord. The clinical manifestations reflect muscle overactivity and include excessive movements, such as clonus and spasms, occurring regularly as a result of loss of higher motor center control. There is great variation depending on the suddenness of onset and the age of the individual.
Disturbances in motor function are classified pathologically along upper and lower motor neuron structures. It should be noted that the same pathologic condition occurs at more than one site in an upper motor neuron (top right). A few pathologic conditions involve both upper and lower motor neuron structures, as in amyotrophic lateral sclerosis, for example. Other lesion sites include myoneural junction and primary muscle, making it possible to classify conditions as neuromuscular and muscular, respectively.
**FIGURE 15-18** Structures of the Upper Motor Neuron, or Pyramidal, System. Pyramidal system fibers are shown to originate primarily in cells in the precentral gyrus of the motor cortex; to converge at the internal capsule; to descend to form the central third of the cerebral peduncle; to descend further through the pons, where small fibers supply cranial nerve motor nuclei along the way; to form pyramids at the medulla, where most of the fibers decussate; and then to continue to descend in the lateral column of white matter of the spinal cord. A few fibers descend without crossing at the level of the medulla (i.e., the ventral (anterior) corticospinal tract).

**Spinal Shock** is the temporary loss of all spinal cord functions below the lesion (below the level of the pons). It is characterized by complete flaccid paralysis, absence of reflexes, and marked disturbances of bowel and bladder function. Hypotension can occur from loss of sympathetic tone at higher levels of spinal cord injury. A major factor in spinal shock is the sudden destruction of the efferent pathways. If destruction occurs more slowly, spinal shock may not develop (see Chapter 16).

If the pyramidal system is interrupted above the level of the pons, the hand and arm muscles are greatly affected. Paralysis rarely involves all the muscles on one side of the body, even when the hemiplegia results from complete damage to the internal capsule. Bilateral movements, such as those of the eye, jaw, and larynx, as well as those of the trunk, are affected only slightly, if at all. Predominantly the limbs are influenced.

Paralysis associated with a pyramidal motor syndrome rarely remains flaccid for a prolonged time. After a few days or weeks, a gradual return of spinal reflexes marks the end of spinal shock. Reflexes then become hyperactive, and muscle tone increases significantly, particularly in antigravity muscles. **Spasticity** is common, although rigidity occasionally occurs (see p. 377). Most often, passive range-of-motion movements cause “clasp-knife” rigidity, probably by activating the stretch receptors in the muscle spindles and the Golgi tendon organ. (Muscle function is discussed in Chapter 38.) With pyramidal motor syndrome, predominantly the flexors of the arms and the extensors of the legs are affected.

**Lower Motor Neuron Syndromes**

Lower (primary, alpha) motor neurons are the large motor neurons in the anterior (or ventral) horn of the spinal cord and the motor nuclei of the brainstem. The axons from these nerve cell bodies bring nerve impulses from upper motor neurons to the skeletal muscles through the anterior spinal roots or cranial nerves (Figure 15-19). **Lower motor neuron syndromes** impair both voluntary and involuntary movement. The degree of paralysis or paresis is proportional to the number of lower motor neurons affected. If only some of the motor units that supply a muscle are affected, only partial paralysis (or paresis) results. If all motor units are affected, complete paralysis results. Other clinical manifestations also are
proportional to the degree of dysfunction, but the precise manifestations depend on the location of the dysfunction in the motor unit and in the CNS.

Small motor (gamma) neurons, which maintain muscle tone and protect the muscle from injury, are needed for normal motor movement. They depend on input from the muscle spindle (arriving through an afferent limb rising to the cord). Dysfunction in this motor system (the gamma loop) impairs tone and reduces tendon reflexes, causing hyporeflexia. The muscles become susceptible to damage
from hyperextensibility. Generally, the large and small motor neuron systems are equally affected. Therefore the muscle has reduced or absent tone and is accompanied by hyporeflexia or areflexia (loss of tendon reflexes) and flaccid paresis/paralysis.

Denervated muscles (i.e., muscles that have lost their nervous system input) atrophy over weeks to months, mostly from disuse, and demonstrate fasciculations (muscle rippling or quivering under the skin). Occasionally, denervated muscles cramp. Fibrillation is isolated contraction of a single muscle fiber because of metabolic changes in denervated muscle and is not clinically visible.

**Motor Neuron Diseases**

Motor neuron diseases result from progressive degeneration of upper or lower motor neurons in the spinal cord, brainstem, or cortex. Amyotrophic lateral sclerosis and paralytic poliomyelitis (see Chapter 8) are examples of these diseases.

Several pathologic processes may give rise to motor neuron diseases that can be sporadic or inherited. A virally induced or postinfectious or postvaccination inflammatory process may injure or destroy anterior horn cells or cranial nerve cell bodies. Most of these inflammatory processes are mild and are followed by rapid cellular recovery (Box 15-7).

**Box 15-7**

**Bell Palsy**

The etiology of Bell palsy (unilateral facial nerve palsy) remains unknown. There is usually an inflammatory reaction compressing the facial nerve, particularly in the narrowest segment, followed by demyelinating neural change. The most distressing signs are unilateral facial weakness and the inability to smile or whistle. Bell palsy may be caused by reactivation of herpesviruses in cranial nerve VII (facial), geniculate ganglia, or an autoimmune response. The signs usually have an acute onset (within 72 hours). Herpes simplex type 1 has been detected in up to 78% of cases and herpes zoster in 30% of cases. Severe pain with facial palsy and a vesicular rash in the ear or mouth suggest herpes zoster infection. Ramsay Hunt syndrome (herpes zoster oticus) is rare, but complete recovery is less than 50%. Recovery from Bell palsy is usually complete. Both disorders may be treated with combination antivirals and oral steroids. Treatment should be individualized according to severity of symptoms.

Data from Baugh RF et al: *Otolaryngol Head Neck Surg* 149(3 Suppl):S1-S27, 2013 (available at:
In motor neuron disease muscle strength, muscle tone, and muscle bulk are affected in the muscles innervated by the involved motor neurons. The paresis and paralysis associated with anterior horn cell injury are segmental, but because each muscle is supplied by two or more roots, the segmental character of the weakness may be difficult to recognize. When cranial nerve motor nuclei are affected (these lack nerve roots and have only small rootlets near the point of exit from the brainstem), the distribution of the motor weakness follows that of the peripheral nerve. The weakness may involve distal muscles, proximal muscles, and the muscles of midline structures. Hypotonia and hyporeflexia or areflexia are present.

The atrophy associated with motor neuron disease is segmental when the anterior horn cells of the spinal cord are involved and follows the distribution of the peripheral nerve when the motor nuclei of the cranial nerves are affected. The atrophy may be in distal, proximal, or midline muscles. Fasciculations are particularly associated with primary motor neuron injury, and muscle cramps are common. Mild fatigue is a common complaint. If the pathologic process is limited to the primary motor neuron, no sensory changes are evident.

Because degenerative disorders can cause loss of nerve cells in the anterior horn or motor nuclei, the surviving cells are small, shrunken, and filled with lipofuscin. Lost neurons are replaced by astrocytes. The roots or rootlets are thin, and the muscles show denervation and atrophy.

Several brainstem syndromes involve damage to one or more of the cranial nerve nuclei. These are called cranial nerve palsy and may be caused by vascular occlusion, tumor, aneurysm, tuberculosis, or hemorrhage.

The anterior horn cells and the motor nuclei of the cranial nerves may be affected secondarily in many severe pathologic processes that primarily involve the peripheral nerves. The condition may extend proximally to affect the nerve roots or rootlets and the motor neurons themselves, a process commonly seen, for example, in Guillain-Barré syndrome (see Chapter 16). If sufficient numbers of motor neurons are destroyed, permanent loss of motor function results because regeneration of the damaged axons requires a living neuronal cell body.

A group of degenerative disorders principally cause progressive motor cell atrophy. One of these is progressive spinal muscular atrophy, in which the anterior horn cells of the spinal cord are the affected motor neurons that degenerate. This disorder occurs in adults and closely resembles the familial progressive muscular atrophies that occur in infants and children and are considered inherited metabolic
disorders (see Chapter 40). If the motor nuclei of the cranial nerves are affected instead of the anterior horn cells, the disorder is labeled **progressive bulbar palsy**, so named because the myelencephalon originally was called the *bulb* and a degenerative process causes a progressively more serious condition. When any lower motor neuron syndrome involves the cranial nerves that arise from the bulb (i.e., cranial nerves IX, X, and XII), the dysfunction is called a **bulbar palsy**.

The clinical manifestations of bulbar palsy include paresis or paralysis of the jaw, face, pharynx, and tongue musculature. Articulation is affected, especially articulation of the lingual (*r, n, l*), labial (*b, m, p, f*), dental (*d, t*), and palatal (*k, g*) consonants. Modulation is impaired, making the voice rasping or nasal. Pharyngeal reflexes are diminished or lost. Palate and vocal cord movement during phonation is impaired, and chewing and swallowing are affected. The facial muscles are weak, and the face appears to droop. The jaw jerk is decreased. Atrophy eventually becomes apparent, as do fasciculations. All these manifestations become progressively worse, leading to aspiration, malnutrition, possible dehydration, and an inability to communicate verbally.

**Amyotrophic Lateral Sclerosis**

**Amyotrophic lateral sclerosis** (ALS, sporadic motor neuron disease, sporadic motor system disease, motor neuron disease [MND], Lou Gehrig disease) is a worldwide neurodegenerative disorder that diffusely involves lower and upper motor neurons, resulting in progressive muscle weakness. **Amyotrophic** (without muscle nutrition or progressive muscle wasting) refers to the predominant lower motor neuron component of the syndrome. **Lateral sclerosis**, scarring of the corticospinal tract in the lateral column of the spinal cord, refers to the upper motor neuron component of the syndrome.

ALS may begin at any time from the fourth decade of life; its peak occurrence is between 60 and 69 years, with about 3.9 cases per 100,000 population in the United States. The prevalence is higher in males. Most cases of ALS are sporadic. A subset (about 10%) of persons has a familial form with genetic mutations in superoxide dismutase (SODI) that contribute to the neurotoxicity affecting motor neurons. Mutated TAR RNA-binding protein 43 (TDP-43) is a major constituent of the neuronal protein inclusions in ALS. Gene and environmental interactions are being evaluated as a cause of ALS.

**Pathophysiology**

The cause of ALS is unknown. Oxidative stress, mitochondrial dysfunction, defects in axonal transport, excitotoxicity and glutamate transport, neuronal cytoplasmic
inclusions (i.e., TDP-43 protein), and neuroinflammation as causes of neuron degeneration are under investigation.\textsuperscript{44}

The principal pathologic feature of ALS is degeneration of lower and upper motor neurons. There is a decrease in large motor neurons in the spinal cord, brainstem, and cerebral cortex (premotor and motor areas), with ongoing degeneration in the remaining motor neurons. Death of the motor neuron results in axonal degeneration and secondary demyelination with glial proliferation and sclerosis (scarring). Widespread neural degeneration of nonmotor neurons in the spinal cord and motor cortices, as well as in the premotor, sensory, and temporal cortices, has been found.

Lower motor neuron degeneration denervates motor units. Adjacent, still viable lower motor neurons attempt to compensate by distal intramuscular sprouting, reinnervation, and enlargement of motor units.

**Clinical manifestations**

The initial symptoms of the disease are heterogeneous and may be related to lower or upper motor neuron dysfunction or both. About 60\% of individuals have a spinal form of the disease with focal muscle weakness beginning in the arms and legs and progressing to muscle atrophy, spasticity, and loss of manual dexterity and gait. No associated mental, sensory, or autonomic symptoms are present. ALS with progressive bulbar palsy presents with difficulty speaking and swallowing, and peripheral muscle weakness and atrophy usually occur within 1 to 2 years. These individuals have a poorer response to treatment with mechanical ventilation.\textsuperscript{45} Frontotemporal dementia may occur concurrently.\textsuperscript{46}

**Evaluation and treatment**

Diagnosis of the syndrome is based predominantly on the history and physical examination with no evidence of other neuromuscular disorders. Electromyography and muscle biopsy results verify lower motor neuron degeneration and denervation. Imaging studies and cerebrospinal fluid biomarkers can assist in making the diagnosis. Little treatment is available to alter the overall course of the ALS syndrome. The drug riluzole (Rilutek), an antiglutamate, has extended the length of time patients do not require ventilatory assistance. Supportive and rehabilitative management are directed toward preventing complications of immobility. Psychologic support of the affected individual and the family is extremely important.\textsuperscript{47} ALS is fatal from respiratory failure usually within 3 years of diagnosis. A small percentage of individuals live 5 to 10 years or longer.\textsuperscript{48}
Alterations in Complex Motor Performance

The alterations in complex motor performance include disorders of posture (stance), disorders of gait, and disorders of expression.

Disorders of Posture (Stance)

An inequality of tone in muscle groups, because of a loss of normal postural reflexes, results in a posturing of limbs. Equilibrium and balance are disrupted. Many reflex systems govern tone and posture, but the most important factor in posture control is the stretch reflex, in which extensor (antigravity) muscle stretching causes increased extensor tone and inhibited flexor tone. Four types of disorders of posture are (1) dystonic posture, (2) decerebrate posture/response, (3) basal ganglion posture, and (4) basal ganglion posture.

Dystonia is the maintenance of an abnormal posture through muscular contractions. When muscular contractions are sustained for several seconds, they are called dystonic movements; when contractions last for longer periods, they are called dystonic postures. Dystonic postures may last for weeks, causing permanent, fixed contractures. Dystonia has been associated with basal ganglia abnormality, but the exact pathophysiologic mechanisms are unknown. One dystonic posture is decorticate posture/response (striatal posture or upper motor neuron dysfunction posture), which may be unilateral or bilateral.

Decorticate posture/response (also referred to as antigravity posture or hemiplegic posture) is characterized by upper extremities flexed at the elbows and held close to the body and by lower extremities that are externally rotated and extended (see Figure 15-6). Decorticate posture/response is thought to occur when the brainstem is not inhibited by the cerebral cortex motor area. Upper motor neuron posture is more commonly described as the arm flexed at the elbow with a wrist drop, the leg inadequately bent at the knee, the hip excessively circumabducted, and the presence of footdrop.

Decerebrate posture/response refers to increased tone in extensor muscles and trunk muscles, with active tonic neck reflexes. When the head is in a neutral position, all four limbs are rigidly extended (see Figure 15-6). The decerebrate posture is caused by severe injury to the brain and brainstem, resulting in overstimulation of the postural righting and vestibular reflexes.

Basal ganglion posture refers to a stooped, hyperflexed posture with a narrow-based, short-stepped gait. This posture abnormality results from the loss of normal postural reflexes and not from defects in proprioceptive, labyrinthine, or visual function. Dysfunctional equilibrium results when the individual loses stability and
cannot make the appropriate postural adjustment to tilting or loss of balance, falling instead. Dysfunctional righting is the inability to right oneself when changing from a lying or crouching to a standing position or when rolling from the supine to the lateral or prone position. Dysfunctional postural fixation is the involuntary flexion of the head and neck, causing the person difficulty in maintaining an upright trunk position while standing or walking. Basal ganglion dysfunction accounts for this posture.

**Disorders of Gait**

Four predominant types of gait associated with neurologic disorders are (1) upper motor neuron dysfunction gait, (2) cerebellar (ataxic) gait, (3) basal ganglion gait, and (4) frontal lobe ataxic gait. As with posture, equilibrium and balance are affected with gait disturbances.49

Several upper motor neuron gaits exist. With mild forms, the individual may have footdrop with fatigue and hip and leg pain. A spastic gait, which is associated with unilateral injury, manifests by a shuffling gait with the leg extended and held stiff, causing a scraping over the floor surface. The leg swings improperly around the body rather than being appropriately lifted and placed. The foot may drag on the ground, and the person tends to fall to the affected side. A scissors gait is associated with bilateral injury and spasticity. The legs are adducted so they touch each other. As the person walks, the legs are swung around the body but then cross in front of each other because of adduction. Injury to the pyramidal system accounts for these gaits (e.g., stroke, cerebral palsy, multiple sclerosis, spinal cord tumor).

A cerebellar (ataxic) gait is wide-based with the feet apart and often turned outward or inward for greater stability. The pelvis is held stiff, and the individual staggers when walking. Cerebellar dysfunction with loss of coordination accounts for this particular gait.

A basal ganglion gait is a broad-based gait in which the person walks with small steps and a decreased arm swing. The head and body are flexed and the arms semiflexed and abducted, whereas the legs are flexed and rigid in more advanced states. Basal ganglion dysfunction accounts for this gait and is associated with Parkinson disease.

A frontal lobe ataxic gait is wide-based with increased body sway and falls, loss of control of truncal motion, gait ignition failure, start hesitation, shuffling, and freezing. The gait is associated with frontal lobe damage or degeneration. The pattern may change as the frontal disease progresses. The slowness of walking, lack of heel-shin or upper limb ataxia, dysarthria, or nystagmus distinguishes the wide stance from cerebellar gait ataxia.50
Gait disorders are often accompanied by balance, coordination, and sensory dysfunction that further alter mobility and increase risk for falls. Assessment and intervention strategies are important for prevention of injury.

**Disorders of Expression**

Disorders of expression involve the motor aspects of communication and include (1) hypermimesis, (2) hypomimesis, and (3) apraxia/dyspraxia. **Hypermimesis** commonly manifests as pathologic laughter or crying. Pathologic laughter is associated with right hemisphere injury, and pathologic crying is associated with left hemisphere injury. The exact pathophysiology is not known. **Hypomimesis** manifests as *aprosody*—the loss of emotional language. *Receptive aprosody* involves an inability to understand emotion in speech and facial expression. *Expressive aprosody* involves the inability to express emotion in speech and facial expression. Aprosody is associated with right hemisphere damage.

**Apraxia/dyspraxia** is a disorder of learned skilled movements with difficulty planning and executing coordinated motor movements. The term is often used interchangeably with *dyspraxia*. It can be developmental, beginning at birth (developmental apraxia), or associated with vascular disorders (common in stroke), trauma, tumors, degenerative disorders, infections, or metabolic disorders. People with apraxia have difficulty performing tasks requiring motor skills including speaking, writing, using tools or utensils, playing sports, following instructions, and focusing.\(^5^1\)

True apraxias occur when the connecting pathways between the left and right cortical areas are interrupted. Apraxias may result from any pathologic process that disrupts the cortical areas necessary for the conceptualization and execution of a complex motor act or the communication pathways within the left hemisphere or between the hemispheres.\(^5^1,5^2\)
Extrapyramidal Motor Syndromes

Because the extrapyramidal system encompasses all the motor pathways except the pyramidal system, two types of motor dysfunction make up the extrapyramidal motor syndromes: (1) the basal ganglia motor syndromes and (2) the cerebellar motor syndromes. Unlike pyramidal motor syndromes, both extrapyramidal motor syndromes result in movement or posture disturbance without significant paralysis, along with other distinctive symptoms (Table 15-19).

### TABLE 15-19
Pyramidal vs. Extrapyramidal Motor Syndrome

</table>

**Basal ganglia motor syndromes** are caused by an imbalance of dopaminergic and cholinergic activity in the corpus striatum. A relative excess of cholinergic activity produces akinesia and hypertonia. A relative excess of dopaminergic activity produces hyperkinesia and hypotonia. Symptoms associated with Parkinson and Huntington diseases are exemplary of disorders of the basal ganglia. **Cerebellar motor syndromes** are associated with ataxia and other symptoms affecting coordinated movement. Cerebellar disorders primarily influence the same side of the body, so that damage to the right cerebellum generally causes symptoms on the right side of the body.

**Quick Check 15-6**

1. Why are there so many causes of hypertonia?
2. How is chorea different from athetosis?
3. Why is paresis/paralysis a type of hypokinesia?
4. What structures are involved in alterations of complex motor performance?
Did You Understand?

Alterations in Cognitive Systems

1. Full consciousness is an awareness of oneself and the environment with an ability to respond to external stimuli with a wide variety of responses.

2. Consciousness has two components: arousal (level of awakenss) and awareness (content of thought).

3. An altered level of arousal occurs by diffuse bilateral cortical dysfunction, bilateral subcortical (reticular formation, brainstem) dysfunction, localized hemispheric dysfunction, and metabolic disorders.

4. An alteration in breathing pattern and the level of consciousness reflect the level of brain dysfunction.

5. Pupillary changes reflect changes in level of brainstem function, drug action, and response to hypoxia and ischemia.

6. Abnormal eye movements, including nystagmus and divergent gaze, reflect alterations in brainstem function.

7. Level of brain function manifests by changes in generalized motor responses or no responses.

8. Loss of cortical inhibition associated with decreased consciousness produces abnormal flexor and extensor movements.

9. Cerebral death or irreversible coma represents permanent brain damage, with an ability to maintain cardiac, respiratory, and other vital functions.

10. Brain death results from irreversible brain damage, with an inability to maintain internal homeostasis.

11. Arousal returns in vegetative states, but awareness is absent.

12. Alterations in awareness include alterations in executive attention (abstract reasoning, planning, decision making, judgment, error correction, and self-control) and memory.
13. With a deficit in selective attention, mediated by midbrain, thalamus, and parietal lobe structures, the individual cannot focus on selective stimuli and thus neglects those stimuli.

14. In amnesia, some past memories are lost and new memories cannot be stored.

15. Frontal areas mediate vigilance, detection, and working (short-term) memory.

16. With vigilance deficits, the person cannot maintain sustained concentration.

17. With detection deficits, the person is unmotivated and unable to set goals and plan.

18. Data processing deficits include agnosias, dysphasias, acute confusional states, and dementias.

19. Agnosias are defects of recognition and may be tactile, visual, or auditory. They are caused by dysfunction in the primary sensory area or the interpretive areas of the cerebral cortex.

20. Dysphasia (aphasia) is an impairment of comprehension or production of language. Dysphasia may be expressive or receptive.

21. Acute confusional states are characterized chiefly by a loss of detection and, in the case of delirium, intense autonomic nervous system hyperactivity.

22. Alzheimer disease is a chronic irreversible dementia that is related to altered production or failure to clear amyloid from the brain with plaque formation, formation of neurofibrillary tangles, and loss of basal forebrain cholinergic neurons.

23. Frontotemporal dementias are rare early-onset degenerative diseases similar to Alzheimer disease.

24. Seizures represent a sudden, chaotic discharge of cerebral neurons with transient alterations in brain function. Seizures may be generalized or focal and can result from cerebral lesions, biochemical disorders, trauma, or epilepsy.

**Alterations in Cerebral Hemodynamics**
1. Alterations in cerebral blood flow are related to changes in cerebral perfusion pressure, changes in cerebral blood volume, and cerebral blood oxygenation.

2. Increased intracranial pressure (IICP) may result from edema, excess cerebrospinal fluid, hemorrhage, or tumor growth. When intracranial pressure approaches arterial pressure, hypoxia and hypercapnia produce brain damage.

3. Cerebral edema is an increase in the fluid content of the brain resulting from infection, hemorrhage, tumor, ischemia, infarction, or hypoxia. Cerebral edema can cause IICP.

4. The shifting or herniation of brain tissue from one compartment to another disrupts the blood flow of both compartments and damages brain tissue.

5. Supratentorial herniation involves the temporal lobe and hippocampal gyrus shifting from the middle fossa to posterior fossa; transtentorial herniation involves a downward shift of the diencephalon through the tentorial notch; and shifting of the cingulate gyrus can occur under the falx cerebri.

6. The most common infratentorial herniation is a shift of the cerebellar tonsils through the foramen magnum.

7. Hydrocephalus comprises a variety of disorders characterized by an excess of fluid within the ventricles, subarachnoid space, or both. Hydrocephalus occurs because of interference with cerebrospinal fluid flow caused by increased fluid production or obstruction within the ventricular system or by defective reabsorption of the fluid.

**Alterations in Neuromotor Function**

1. Motor dysfunction may be characterized as alterations of motor tone, movement, and complex motor performance.

**Alterations in Muscle Tone**

1. Hypotonia and hypertonia are the main categories of altered tone.

2. Hypotonia is associated with pyramidal tract or cerebellar injury. Muscles are flaccid and weak with atrophy.
3. The four types of hypertonia are spasticity paratonia (gegenhalten), dystonia, and rigidity.

**Alterations in Muscle Movement**

1. Paresis, paraplegia, hyperkinesia, and hypokinesia are the main categories of altered movement.

2. Two subtypes of paresis/paralysis are described: upper motor neuron spastic paresis/paralysis and lower motor neuron flaccid paresis/paralysis.

3. An upper motor neuron syndrome is characterized by paresis/paralysis, hypertonia, and hyperreflexia.

4. Interruption of the pyramidal tract below the pons results in spinal shock.

5. Lower motor neuron syndromes manifest by impaired voluntary and involuntary movements and flaccid paralysis.

6. Partial paralysis occurs with only partial loss of alpha motor neurons, and total paralysis is complete loss of alpha motor neurons. Loss of gamma motor neurons impairs muscle tone and decreases tendon reflexes.

7. Included in the category of hyperkinesia are chorea, athetosis, ballism, akathisia, tremor, and myoclonus.

8. Huntington disease (chorea) is a rare hereditary disease involving the basal ganglia and cerebral cortex that commonly manifests between 25 and 45 years of age.

9. The major pathologic feature of Huntington disease is severe degeneration of the basal ganglia and the frontal cerebral cortex with an excess of dopaminergic activity that causes involuntary, fragmentary hyperkinetic movements.

10. Types of hypokinesia include akinesia, bradykinesia, and loss of associated movements.

11. Parkinson disease is a commonly occurring degenerative disorder of the basal ganglia (corpus striatum) involving degeneration of the dopamine-secreting nigrostriatal pathway.
12. Dopamine depletion in the basal ganglia and excess cholinergic activity in the cortex, basal ganglia, and thalamus cause tremor and rigidity in Parkinson disease. Progressive dementia may be associated with an advanced stage of the disease.

13. Upper motor neuron syndromes are the result of damage to descending motor pathways at cortical, brainstem, or spinal cord levels and result in spastic paralysis.

14. Spinal shock is temporary loss of all spinal cord functions below the lesion (below the level of the pons). It is characterized by complete flaccid paralysis, absence of reflexes, and marked disturbances of bowel and bladder function.

15. Lower (primary, alpha) motor neuron syndromes involve the large motor neurons in the anterior (or ventral) horn of the spinal cord and the motor nuclei of the brainstem and cause flaccid paralysis.

16. Amyotrophic lateral sclerosis involves degeneration of both upper and lower motor neurons with progressive muscle weakness and atrophy.

**Alterations in Complex Motor Performance**

1. Alterations in complex motor performance include disorders of posture (stance), disorders of gait, and disorders of expression.

2. Disorders of posture include dystonic posture, decerebrate posture/response, basal ganglion posture, and senile posture.

3. Disorders of gait include upper motor neuron gait, cerebellar (ataxic) gait, basal ganglion gait, and frontal lobe ataxic gait.

**Disorders of Expression**

1. Disorders of expression include hypermimesis, hypomimesis, and apraxia (dyspraxia).

2. Apraxia is an impairment of the conceptualization or execution of a complex motor act.

**Extrapyramidal Motor Syndromes**

1. Extrapyramidal motor syndromes include basal ganglia and cerebellar motor
syndromes.

2. Basal ganglia disorders manifest by alterations in muscle tone and posture, including rigidity, involuntary movements, and loss of postural reflexes.

3. Cerebellar motor syndromes result in loss of muscle tone, difficulty with coordination, and disorders of equilibrium and gait.

Alterations in central nervous system (CNS) function are caused by traumatic injury, vascular disorders, tumor growth, infectious and inflammatory processes, and metabolic derangements (including those arising from nutritional deficiencies and drugs or chemicals). Alterations in peripheral nervous system function involve the nerve roots, a nerve plexus or the nerves themselves, or the neuromuscular junction.
Central Nervous System Disorders

Traumatic Brain and Spinal Cord Injury

Traumatic Brain Injury

**Traumatic brain injury (TBI)** is an alteration in brain function or other evidence of brain pathology caused by an external force. Those at highest risk for TBI are children 14 years and younger and adults 65 years and older. The most common causes are motor vehicle accidents for children and falls for older adults. Males have the highest incidence in every age group. The incidence of traumatic brain injury is highest among American Indian/Alaska Natives and blacks and in lower- and median-income families.¹

In recent years, individuals with traumatic brain injury have shown improved survival outcomes. Advancements have been made in enhanced safety measures (e.g., passive seat restraints, air bags, protective head gear), reduced transport time to hospitals or trauma centers, improved on-scene medical management, and prevention and management of secondary brain injury.

TBI can be classified as primary or secondary. Primary brain injury is caused by direct impact and can be focal, affecting one area of the brain, or diffuse (diffuse axonal injury [DAI]), involving more than one area of the brain.² Focal brain injury and diffuse axonal injury each account for half of all injuries. Focal brain injury accounts for more than two thirds of head injury deaths. DAI accounts for less than one third of deaths. More severely disabled survivors, including those surviving in an unresponsive state or reduced level of consciousness, have DAI. Secondary injury is an indirect consequence of the primary injury and includes systemic responses and a cascade of cellular and molecular cerebral events. TBI can be mild, moderate, or severe. The Glasgow Coma Scale (GCS) is used to grade severity of injury (Table 16-1). Most TBIs are mild. The hallmark of a severe TBI is loss of consciousness for 6 hours or more.³

*The GCS is scored between 3 and 15, with 3 being the worst and 15 the best. It is composed of the sum of three parameters: Best Eye Response, Best Verbal Response, and Best Motor Response. Mild Brain Injury = 13 or higher; Moderate Brain Injury = 9 to 12; Severe Brain Injury = 8 or less.

**NOTE:** It is important to break the scoring report into its components, for example, E3V3M5 = GCS 11. A total score is meaningless without this information. Age affects the GCS. Elderly individuals with TBI have better GCS scores than younger individuals with TBI with similar TBI severity (i.e., elderly individuals have higher GCS scores than younger individuals with TBI with similar anatomic TBI severity).

---

**Primary brain injury**

**Focal brain injury.**

**Focal brain injury** can be caused by closed (blunt) trauma or **open (penetrating) trauma**. Closed injury is more common and involves either the head striking a hard surface or a rapidly moving object striking the head, or by blast waves. The dura remains intact, and brain tissues are not exposed to the environment. Blunt trauma may result in both focal brain injuries and diffuse axonal injuries, and they can occur at the same time (Table 16-2). Open injury occurs with penetrating trauma or skull fracture. A break in the dura results in exposure of the cranial contents to the environment.3

CBF, Cerebral blood flow; IICP, increased intracranial pressure.

**Closed brain injuries** are specific, grossly observable brain lesions that occur in a precise location; 75% to 90% of blunt trauma injuries are mild. Injury to the vault, vessels, and supporting structures can produce more severe damage, including contusions and epidural, subdural, and intracerebral hematomas. The injury may be **coup** (injury at site of impact) or **contrecoup** (injury from brain rebounding and hitting opposite side of skull) ([Figure 16-1](#)). Compression of the skull at the point of impact produces **contusions** or brain bruising from blood leaking from an injured vessel. The severity of contusion varies with the amount of energy transmitted by the skull to underlying brain tissue. The smaller the area of impact, the more severe the injury because of the concentration of force. Brain edema forms around and in damaged neural tissues, contributing to increasing intracranial pressure (see **Chapter 15**). Multiple hemorrhages, edema, infarction, and necrosis can occur within the contused areas. The tissue has a pulpy quality. The maximal effects of these injuries peak 18 to 36 hours after severe head injury.
Contusions are found most commonly in the frontal lobes, particularly at the poles and along the inferior orbital surfaces; in the temporal lobes, especially at the anterior poles and along the inferior surface; and at the frontotemporal junction.
They cause changes in attention, memory, executive attention functions (see Chapter 15), affect, emotion, and behavior. Less commonly, contusions occur in the parietal and occipital lobes. Focal cerebral contusions are usually superficial, involving just the gyri. Hemorrhagic contusions may coalesce into a large confluent intracranial hematoma. A contusion may be evidenced by immediate loss of consciousness (generally accepted to last no longer than 5 minutes), loss of reflexes (individual falls to the ground), transient cessation of respiration, brief period of bradycardia, and decrease in blood pressure (lasting 30 seconds to a few minutes). Increased cerebrospinal fluid (CSF) pressure and electrocardiogram (ECG) and electroencephalogram (EEG) changes occur on impact. Vital signs may stabilize to normal values in a few seconds; reflexes then return and the person regains consciousness over minutes to days. Residual deficits may persist and some persons never regain a full level of consciousness.

Evaluation is based on results of the health history, level of consciousness according to the Glasgow Coma Scale (see Table 16-1), outcomes of imaging studies (e.g., computed tomography [CT], magnetic resonance imaging [MRI], and positron emission tomography [PET] scans), and assessment of vital parameters (e.g., intracranial pressure [ICP] and EEG). Large contusions and lacerations with hemorrhage may be surgically excised. Treatment is otherwise directed at controlling intracranial pressure and managing symptoms.

**Epidural (extradural) hematomas** (bleeding between the dura mater and the skull) represent 1% to 2% of major head injuries and occur in all age groups, but most commonly in those 20 to 40 years old. An artery is the source of bleeding in 85% of epidural hematomas, usually accompanied by a skull fracture; 15% of these injuries result from injury to the meningeal vein or dural sinus (Figure 16-2). The temporal fossa is the most common site of epidural hematoma caused by injury to the middle meningeal artery or vein. The temporal lobe shifts medially, precipitating uncal and hippocampal gyrus herniation through the tentorial notch. Epidural hemorrhages are found occasionally in the subfrontal area, especially in the young and elderly populations, caused by injury to the anterior meningeal artery or a venous sinus; and in the occipital-suboccipital area, resulting in herniation of the posterior fossa contents through the foramen magnum (see Figure 15-10).
Individuals with temporal epidural hematomas lose consciousness at injury; one third of those affected then become lucid for a few minutes to a few days (if a vein is bleeding). As the hematoma accumulates, a headache of increasing severity, vomiting, drowsiness, confusion, seizure, and hemiparesis may develop. Because temporal lobe herniation occurs, the level of consciousness is rapidly lost, with ipsilateral pupillary dilation and contralateral hemiparesis. A CT scan or MRI usually is needed to diagnose epidural hematoma. The prognosis is good if intervention is initiated before bilateral dilation of the pupils occurs. Epidural hematomas are almost always medical emergencies requiring monitoring and evaluation or surgical evacuation of the hematoma.4

**Subdural hematomas** (bleeding between the dura mater and the brain) arise in 10% to 20% of persons with traumatic brain injury. *Acute subdural hematomas* develop rapidly, commonly within hours, and usually are located at the top of the skull (the cerebral convexities). Bilateral hematomas occur in 15% to 20% of persons. Subacute subdural hematomas develop more slowly, often over 48 hours to 2 weeks. *Chronic subdural hematomas* (commonly found in elderly persons and
persons who abuse alcohol and have some degree of brain atrophy with a subsequent increase in extradural space) develop over weeks to months. Bridging veins tear, causing both rapidly and subacutely developing subdural hematomas, although torn cortical veins or venous sinuses and contused tissue also may be the source. These subdural hematomas act like expanding masses, increasing intracranial pressure that eventually compresses the bleeding vessels (see Figure 16-2). Brain herniation can result. With a chronic subdural hematoma, the existing subdural space gradually fills with blood. A vascular membrane forms around the hematoma in approximately 2 weeks. Further enlargement may take place.

In acute, rapidly developing subdural hematomas, the expanding clots directly compress the brain. As intracranial pressure rises, bleeding veins are compressed. Thus, bleeding is self-limiting, although cerebral compression and displacement of brain tissue can cause temporal lobe herniation.

An acute subdural hematoma classically begins with headache, drowsiness, restlessness or agitation, slowed cognition, and confusion. These symptoms worsen over time and progress to loss of consciousness, respiratory pattern changes, and pupillary dilation (i.e., the symptoms of temporal lobe herniation). Homonymous hemianopia (defective vision in either the right or the left field [see Figure 14-8]), dysconjugate gaze, and gaze palsies also may occur.

Of those individuals affected by chronic subdural hematomas, 80% have chronic headaches and tenderness over the hematoma on palpation. Most persons appear to have a progressive dementia with generalized rigidity (paratonia). Chronic subdural hematomas require a craniotomy to evacuate the gelatinous blood. Percutaneous drainage for chronic subdural hematomas has proven successful. However, reaccumulation often occurs unless the surrounding membrane is removed.

**Intracerebral hematomas** (bleeding within the brain) occur in 2% to 3% of persons with head injuries, may be single or multiple, and are associated with contusions. Although most commonly located in the frontal and temporal lobes, they may occur in the hemispheric deep white matter. Penetrating injury or shearing forces traumatize small blood vessels. The intracerebral hematoma then acts as an expanding mass, increasing intracranial pressure, compressing brain tissues, and causing edema (see Figure 16-2). Delayed intracerebral hematomas may appear 3 to 10 days after the head injury. Intracerebral hematomas also can occur with nontraumatic brain injury, such as hemorrhagic stroke (see p. 404).

Intracerebral hematomas cause a decreasing level of consciousness. Coma or a confusional state from other injuries, however, can make the cause of this increasing unresponsiveness difficult to detect. Contralateral hemiplegia also may occur and, as intracranial pressure rises, temporal lobe herniation may appear. In delayed intracerebral hematoma, the presentation is similar to that of a hypertensive
brain hemorrhage—sudden, rapidly progressive decreased level of consciousness with pupillary dilation, breathing pattern changes, hemiplegia, and bilateral positive Babinski reflexes.

History and physical examination help to establish the diagnosis, and CT scan, MRI, and cerebral angiography confirm it. Evacuation of a singular intracerebral hematoma has only occasionally been helpful, mostly for subcortical white matter hematomas. Otherwise, treatment is directed at reducing the intracranial pressure and allowing the hematoma to reabsorb slowly.

**Open brain injury** (trauma that penetrates the dura mater) produces both focal and diffuse injuries and includes compound skull fractures and missile injuries (e.g., bullets, rocks, shell fragments, knives, and blunt instruments). A **compound skull fracture** opens a communication between the cranial contents and the environment and should be investigated whenever lacerations of the scalp, tympanic membrane, sinuses, eye, or mucous membranes are present. Such fractures may involve the cranial vault or the base of the skull (basilar skull fracture). Cranial nerve damage and spinal fluid leak may occur with a basilar skull fracture.

The mechanisms of open brain trauma are crush injury (laceration and crushing of whatever the missile touches) and stretch injury (blood vessels and nerves damaged without direct contact as a result of stretching). The tangential injury is to the coverings and the brain (scalp and brain lacerations) and may also include skull fractures and meningeal or cerebral lacerations from projectiles and debris driven into the brain substance.

Most persons lose consciousness with open brain injury. The depth and duration of the coma are related to the location of injury, extent of damage, and amount of bleeding. Open brain injury often requires débridement of the traumatized tissues to prevent infection and to remove blood clots, thereby reducing intracranial pressure. Intracranial pressure also is managed with steroids, dehydrating agents, osmotic diuretics, or a combination of these drugs. Broad-spectrum antibiotics are administered to prevent infection.

A compound fracture may be diagnosed through physical examination, skull x-ray films, or both. Basilar skull fracture is determined on the basis of clinical findings, such as spinal fluid leaking from the ear or nose. Skull x-rays often do not demonstrate the fracture, although intracranial air or air in the sinuses on x-ray film, CT scan, or MRI is indirect evidence of a basilar skull fracture. Bed rest and close observation for meningitis and other complications are prescribed for a basilar skull fracture.

**Diffuse brain injury.**

**Diffuse brain injury (diffuse axonal injury [DAI])** involves widespread areas of the
brain. Mechanical effects from high levels of acceleration and deceleration, such as whiplash, or rotational forces cause shearing of delicate axonal fibers and white matter tracts that project to the cerebral cortex (see Figure 16-1). The most severe axonal injuries are located more peripheral to the brainstem, causing extensive cognitive and affective impairments, as seen in survivors of traumatic brain injury from motor vehicle crashes. Axonal damage reduces the speed of information processing and responding and disrupts the individual's attention span.5

Pathophysiologically, axonal damage can be seen only with an electron microscope and involves numerous axons, either alone or in conjunction with actual tissue tears. Advanced imaging techniques assist in defining areas of injury. Areas where axons and small blood vessels are torn appear as small hemorrhages, particularly in the corpus callosum and dorsolateral quadrant of the rostral brainstem at the superior cerebellar peduncle. More damaged axons are visible 12 hours to several days after the initial injury. The severity of diffuse injury correlates with how much shearing force was applied to the brainstem. DAI is not associated with intracranial hypertension immediately after injury; however, acute brain swelling caused by increased intravascular blood flow within the brain, vasodilation, and increased cerebral blood volume is seen often and can result in death.

Several categories of diffuse brain injury exist: mild concussion, classic concussion, mild DAI, moderate DAI, and severe DAI.

**Mild concussion** (mild traumatic brain injury) is characterized by immediate but transitory clinical manifestations. CSF pressure rises, and ECG and EEG changes occur without loss of consciousness.6 Approximately 75% to 90% of blunt trauma injuries cause mild concussion. The Glasgow Coma Scale score for mild concussion is 13 to 15. The initial confusional state lasts for 1 to several minutes, possibly with amnesia for events preceding the trauma (retrograde amnesia). Anterograde amnesia (lack of memories) may also exist transiently. Persons may experience headache and complain of nervousness and “not being themselves” for up to a few days.

**Classic cerebral concussion** is any loss of consciousness lasting less than 6 hours accompanied by retrograde and anterograde amnesia with a confusional state lasting for hours to days. Transient cessation of respiration can occur with brief periods of bradycardia and a decrease in blood pressure lasting 30 seconds or less. Vital signs stabilize within a few seconds to within normal limits. Reflexes fail and are regained as responsiveness returns.

DAI is a severe brain injury and produces coma lasting more than 6 hours because of axonal disruption. Three forms of DAI exist: mild, moderate, and severe. In **mild diffuse axonal injury**, coma lasts 6 to 24 hours with 30% of persons...
displaying decerebrate or decorticate posturing (see Figure 15-6). They may experience prolonged periods of stupor or restlessness.

In **moderate diffuse axonal injury**, the score on the Glasgow Coma Scale (GCS) is 4 to 8 initially and 6 to 8 by 24 hours. Thirty-five percent of victims have transitory decerebration or decortication, with unconsciousness lasting days or weeks. On awakening, the person is confused and suffers a long period of posttraumatic anterograde and retrograde amnesia. There is often permanent deficit in memory, attention, abstraction, reasoning, problem solving, executive functions, vision or perception, and language. Mood and affect changes range from mild to severe.

In **severe diffuse axonal injury**, injury involves both hemispheres and the brainstem. Coma may last days to months. The person experiences immediate autonomic dysfunction (hypertension, tachycardia, tachypnea, extensor posturing) that disappears in a few weeks. Increased intracranial pressure appears 4 to 6 days after injury. Pulmonary complications occur often. Profound sensorimotor and cognitive system deficits are present, including spastic paralysis, dysarthria, dysphagia, memory loss, inability to learn and reason, and failure to modulate behavior. Irreversible coma and death can occur.

High-resolution CT scan and MRI assist in the diagnosis of focal and diffuse injuries. Medical management must address endocrine and metabolic derangements. The goal of treatment is to maintain cerebral perfusion and oxygenation, and promote neuroprotection. Implementation of traumatic brain injury guidelines decreases death and improves neurologic outcome. The Corticosteroid Randomization After Significant Head Injury (CRASH) trial showed corticosteroids increase mortality with acute TBI; consequently, these drugs are no longer used.\(^3,7\) Guidelines are available to direct treatment.\(^8\)

**Secondary brain injury.**

**Secondary brain injury** is an indirect result of primary brain injury, including trauma and stroke syndromes. Systemic and cerebral processes are contributing factors. Systemic processes include hypotension, hypoxia, anemia, hypercapnia, and hypocapnia. Cerebral contributions include inflammation, cerebral edema, increased intracranial pressure (IICP), decreased cerebral perfusion pressure, cerebral ischemia, and brain herniation. Cellular and molecular brain damage from the effects of primary injury develops hours to days later. Astrocyte swelling and proliferation alter the blood-brain barrier and cause IICP. Ischemia contributes to excitotoxicity with release of excitatory neurotransmitters, such as glutamate and aspartate. They cause cellular influx of calcium, damage mitochondria, and cause
neuronal hyperexcitability. A hypermetabolic state, poor perfusion, influx of inflammatory mediators, fluctuations in cellular sodium and potassium ion channels, and mitochondrial failure all contribute to cytotoxic edema, axonal swelling, and neuronal death.²

The management of secondary brain injury is related to prevention and includes removal of hematomas and management of hypotension, hypoxemia, anemia, intracranial pressure, fluid and electrolyte balance, body temperature, and ventilation. Thyrotropin-releasing hormone, statins, and other agents are under investigation and may be neuroprotective by decreasing excitotoxicity, neuroinflammation, and other mechanisms of secondary injury.²,⁹ Progress is difficult because of the lack of predictive biomarkers and drugs that can cross the blood-brain barrier. Fluid and nutrition management has emerged as critically important in the care of individuals with severe brain injury.¹⁰ Long-term recovery can be influenced by systemic complications, such as pneumonia, fever, infections, and immobility that contribute to further brain injury, and delays in repair and recovery.

Complications of Traumatic Brain Injury

Many complications are associated with TBI and are related to the severity of injury and the parts of the brain that are affected. Altered states of consciousness can range from confusion to deep coma (see Table 15-3). Cognitive deficits; hydrocephalus; sensory-motor disorders, including pain, paresis, and paralysis; and loss of coordination may be present. Three of the most common posttraumatic brain syndromes are summarized below.

Postconcussion syndrome, including headache, dizziness, fatigue, nervousness or anxiety, irritability, insomnia, depression, inability to concentrate, and forgetfulness, may last for weeks to months after a concussion. Treatment entails reassurance and symptomatic relief in addition to 24 hours of close observation after the concussion in the event bleeding or swelling in the brain occurs. Symptoms requiring further evaluation and treatment include drowsiness or confusion, nausea or vomiting, severe headache, memory deficit, seizures, drainage of cerebrospinal fluid from the ear or nose, weakness or loss of feeling in the extremities, asymmetry of the pupils, and double vision. Guidelines for the management of pediatric and adult concussion are available.¹¹⁻¹³ Guidelines have been published for the management of sports-related concussion.¹⁴

Posttraumatic seizures occur in about 2% to 16% of TBIs, with the highest risk among open brain injuries. Seizures can occur early, within days, and up to 2 to 5 years or longer after the trauma. Causal mechanisms are poorly understood and
cellular and molecular changes in the brain associated with injury and repair, such as sprouting of new neurons with hyperexcitability and decreases in GABAergic inhibition, may cause the hyperexcitable state that leads to epileptogenesis. Seizure prevention using drugs, such as phenytoin, is initiated for moderate to severe TBI at the time of injury. Clinical trials are ongoing to test drugs that prevent the development of posttraumatic seizures.¹⁵

**Chronic traumatic encephalopathy (CTE)** (previously called **dementia pugilistica**) is a progressive dementing disease that develops with repeated brain injury associated with sporting events, blast injuries in soldiers, or work-related head trauma. Tau neurofibrillary tangles are present in the brain and research is in progress to discover the mechanistic link between neurotrauma and CTE. It is diagnosed from history and clinical evaluation, and at autopsy.¹⁶,¹⁷

### Quick Check 16-1

1. How is a concussion different from a contusion?

2. Why do epidural, subdural, and intracerebral hematomas act like expanding masses?

3. Why is head motion the principal causative mechanism of diffuse brain injury?

### Spinal Cord and Vertebral Injury

Each year 12,000 persons experience serious spinal cord injury. Male gender and ages 16 to 30 years are strong risk factors. Motor vehicle accidents are the leading cause of injury (36.5%); falls are the next most common cause (28.5%) followed by violence, other events, and sports activities.¹⁸ Elderly people are particularly at risk for trauma that results in serious spinal cord injury because of preexisting degenerative vertebral disorders.

**Pathophysiology**

**Primary spinal cord injury** occurs with the initial mechanical trauma and immediate tissue destruction. Injuries to the cord are summarized in Table 16-3. Primary spinal cord injury occurs if an injured spine is not adequately immobilized immediately following injury. Primary spinal cord injury also may occur in the absence of vertebral fracture or dislocation from longitudinal stretching of the cord with or without flexion or extension of the vertebral column, or both. The stretching causes altered axon transport, edema, myelin degeneration, and retrograde or
wallerian degeneration (see Chapter 13).

**Secondary spinal cord injury** is a pathophysiologic cascade of vascular, cellular, and biochemical events that begins within a few minutes after injury and continues for weeks. Edema, ischemia, excitotoxicity (excessive stimulation by excitatory neurotransmitters such as glutamate), inflammation, oxidative damage, and activation of necrotic and apoptotic cell death signal events similar to those previously described for traumatic brain injury (see p. 390).³⁹

With secondary spinal cord injury, microscopic hemorrhages appear in the central gray matter and pia-arachnoid, increasing in size until the entire gray matter is hemorrhagic and necrotic. Edema in the white matter occurs, impairing the microcirculation of the cord. Hemorrhages and edema are followed by reduced vascular perfusion and development of ischemic areas, which are maximal at the level of injury and two cord segments above and below it. Cellular and subcellular alterations and tissue necrosis occur. Cord swelling increases the individual’s degree of dysfunction, making it difficult to distinguish functions permanently lost from those temporarily impaired. In the cervical region, cord swelling may be life-threatening. Diaphragm function may be impaired because phrenic nerves exit at C3 to C5. Cardiovascular and respiratory functions mediated by the medulla oblongata can be lost.

Circulation in the white matter tracts of the spinal cord returns to normal in about 24 hours, but gray matter circulation remains altered. Phagocytes appear 36 to 48 hours after injury, and microglia proliferate with altered astrocytes. Red blood cells then begin to disintegrate, and resorption of hemorrhages and edema begins. Degenerating axons are engulfed by macrophages in the first 10 days after injury.
The traumatized cord is replaced by acellular collagenous tissue, usually in 3 to 4 weeks. Meninges thicken as part of the scarring process.

**Vertebral injuries** result from acceleration, deceleration, or deformation forces occurring at impact. These forces cause vertebral fractures, dislocations, and bone fragments that can cause compression to the tissues, pull or exert traction (tension) on the tissues, or cause shearing of tissues so they slide into one another (Figures 16-3 to 16-6). Vertebral injuries can be classified as (1) simple fracture—a single break usually affecting transverse or spinous processes; (2) compressed (wedged) vertebral fracture—vertebral body compressed anteriorly; (3) comminuted (burst) fracture—vertebral body shattered into several fragments; and (4) dislocation.

![Hyperextension Injuries of the Spine](image-url)
FIGURE 16-4  Flexion Injury of the Spine. Hyperflexion produces translation (subluxation) of vertebrae that compromises the central canal and compresses spinal cord parenchyma or vascular structures.

FIGURE 16-5  Axial Compression Injuries of the Spine. In axial compression injuries of the spine, the spinal cord is contused directly by retropulsion of bone or disk material into the spinal canal.
The vertebrae fracture readily with both direct and indirect trauma. When the supporting ligaments are torn, the vertebrae move out of alignment and dislocations occur. A horizontal force moves the vertebrae straight forward; if the individual is in a flexed position at the time of injury, the vertebrae are then angulated. Flexion and extension injuries may result in dislocations. (Bone, ligament, and joint injuries are presented in Table 16-4.)

Vertebral injuries in adults occur most often at vertebrae C1 to C2 (cervical), C4 to C7, and T10 (thoracic) to L2 (lumbar) (see Figure 13-11), the most mobile portions of the vertebral column. The spinal cord occupies most of the vertebral canal in the cervical and lumbar regions, so it can be easily injured in these locations.

**Clinical manifestations**

*Spinal shock* develops immediately after injury because of loss of continuous tonic discharge from the brain or brainstem and inhibition of suprasegmental impulses
caused by cord hemorrhage, edema, or anatomic transection. Normal activity of spinal cord cells at and below the level of injury ceases with complete loss of reflex function, flaccid paralysis, absence of sensation, loss of bladder and rectal control, transient drop in blood pressure, and poor venous circulation. The condition also results in disturbed thermal control because the sympathetic nervous system is damaged. The hypothalamus cannot regulate body heat through vasoconstriction and increased metabolism; therefore the individual assumes the temperature of the air (poikilothermia). Spinal shock generally lasts 7 to 20 days, with a range of a few days to 3 months. It terminates with the reappearance of reflex activity, hyperreflexia, spasticity, and reflex emptying of the bladder. Table 16-5 summarizes the clinical manifestations of spinal cord injury.

</table>
| Complete spinal cord transection | 1. Quadriplegia with injuries of cervical spinal cord  
2. Paraplegia with injuries of thoracic spinal cord  
Muscle flaccidity  
Loss of all reflexes below level of injury  
Loss of pain, temperature, touch, pressure, and proprioception below level of injury  
Pain at site of injury caused by zone of hyperesthesia above injury  
Atonic bladder and bowel  
Paralytic ileus with distention  
Loss of vasomotor tone in lower parts; low and unstable blood pressure  
Loss of perspiration below level of injury  
Loss or extreme depression of genital reflexes such as penile erection and bulbocavernous reflex  
Dry and pale skin; possible ulceration over bony prominences  
Respiratory impairment |
| **Partial spinal cord transection** | Asymmetric flaccid motor paralysis below level of injury  
Asymmetric reflex loss  
Preservation of some sensation below level of injury  
Vasomotor instability less severe than that seen with complete cord transection  
Bowel and bladder impairment less severe than that seen with complete cord transection  
Preservation of ability to perspire in some portions of body below level of injury  
Brown-Séquard syndrome (associated with penetrating injuries, hyperextension and flexion, locked facets, and compression fractures)  
1. Ipsilateral paralysis or paresis below level of injury  
2. Ipsilateral loss of touch, pressure, vibration, and position sense below level of injury  
3. Contralateral loss of pain and temperature sensations below level of injury  
Central cervical cord syndrome (acute cord compression between bony bars or spurs anteriorly and thickened ligamentum flavum posteriorly associated with hyperextension)  
1. Motor deficits in upper extremities, especially hands, more dense than in lower extremities  
2. Varying degrees of bladder dysfunction  
Burning hand syndrome (variant of central cord syndrome; in 50% of cases an underlying spine fracture/dislocation is present)  
1. Severe burning paresthesias and dysesthesias in the hands or feet  
Anterior cord syndrome (compromise of anterior spinal artery by occlusion or pressure effect of disk)  
1. Loss of motor function below level of injury  
2. Loss of pain and temperature sensations below level of injury  
3. Touch, pressure, position, and vibration senses intact  
Posterior cord syndrome (associated with hyperextension injuries with fractures of vertebral arch)  
1. Impaired light touch and proprioception  
Conus medullaris syndrome (compression injury at T12 from disk herniation or burst fracture of body of T12)  
1. Flaccid paralysis of legs  
2. Flaccid paralysis of anal sphincter  
3. Variable sensory deficits  
Cauda equina syndrome (compression of nerve roots below L1 caused by fracture and dislocation of spine or large
posterocentral intervertebral disk herniation)

1. Lower extremity motor deficits
2. Variable sensorimotor dysfunction
3. Variable reflex dysfunction
4. Variable bladder, bowel, and sexual dysfunction

Syndrome of neuropraxia (postathletic injury, associated with congenital spinal stenosis)

1. Dramatic but transient neurologic deficits including quadriplegia

Horner syndrome (injury to preganglionic sympathetic trunk or postganglionic sympathetic neurons of superior cervical ganglion)

1. Ipsilateral pupil smaller than contralateral pupil
2. Sunken ipsilateral eyeball
3. Ptosis of affected eyeball
4. Lack of perspiration on ipsilateral side of face

**Neurogenic shock**, also called vasogenic shock, occurs with cervical or upper thoracic cord injury above T5 and may be seen in addition to spinal shock. Neurogenic shock is caused by the absence of sympathetic activity through loss of supraspinal control and unopposed parasympathetic tone mediated by the intact vagus nerve. Symptoms include vasodilation, hypotension, bradycardia, and failure of body temperature regulation. Neurogenic shock may be complicated by hypovolemic or cardiogenic shock if there is concurrent heart failure or blood loss (see Chapter 24).

**Autonomic hyperreflexia (dysreflexia)** is a syndrome of sudden, massive reflex sympathetic discharge associated with spinal cord injury at level T6 or above where descending inhibition is blocked (Figure 16-7). It may occur after spinal shock resolves and be a recurrent complication. Characteristics include paroxysmal hypertension (up to 300 mm Hg, systolic), a pounding headache, blurred vision, sweating above the level of the lesion with flushing of the skin, nasal congestion, nausea, piloerection caused by pilomotor spasm, and bradycardia (30 to 40 beats/min). The symptoms may develop singly or in combination. The condition can cause serious complications (stroke, seizures, myocardial ischemia, and death) and requires immediate treatment.
1. Visceral distention
   - Bowel
   - Bladder
   - Abdomen
   - Pain receptors
     - Skin
     - Glans penis
     - Uterus

2. Spinothalamic tracts carry the impulses to brain

3. Brain interprets sensory inputs; course of action determined
   - Empty bladder
   - Remove painful stimulus, etc.

4. Corticospinal tracts carry motor impulses to appropriate muscles

   **STIMULUS**

   - Spinal ganglion
   - Gray ramus
   - White ramus
   - Splanchnic nerve
   - Vagus nerve

5. Motor output
   - Empty bladder
   - Remove painful stimulus, etc.
   - Eliminates stimulus to sensory nerve
In autonomic hyperreflexia, sensory receptors below the level of the cord lesion are stimulated. The intact autonomic nervous system reflexively responds with an arteriolar spasm that increases blood pressure. Baroreceptors in the cerebral
vessels, the carotid sinus, and the aorta sense the hypertension and stimulate the parasympathetic system. The heart rate decreases, but the visceral and peripheral vessels do not dilate because efferent impulses cannot pass through the cord.

The most common cause is a distended bladder or rectum; however, any sensory stimulation (i.e., skin or pain receptors) can elicit autonomic hyperreflexia. Intravenous fluids may be required to maintain blood pressure. Drug therapy, may be required to lower blood pressure and reduce complications. Bladder, bowel, and skin care management are important preventive strategies. Education of the individual and family regarding triggers and acute management is important as is wearing a medic alert tag.20

**Evaluation and treatment**

Diagnosis of spinal cord injury is based on physical examination and imaging studies. Neurogenic shock must be differentiated from other kinds of shock (i.e., hypovolemic shock). For a suspected or confirmed vertebral fracture or dislocation, regardless of the presence or absence of spinal cord injury, the immediate intervention is immobilization of the spine to prevent further injury. Decompression and surgical fixation may be necessary. Corticosteroids may be given at the time of injury to decrease secondary cord injury from inflammation and thereafter for several days.21 Therapeutic hypothermia has shown some encouraging evidence for improved outcomes, particularly for cervical cord injuries; however, more research is needed.22 Clinical trials are in progress to treat acute spinal cord injury, including cell-based therapies, immune modulators, vasculature selective treatments, and functional electrical stimulation.23 Nutrition; lung function; skin integrity; prevention of pressure ulcers, in particular; and bladder and bowel management must be addressed. Plans for rehabilitation need early consideration.

**Degenerative Disorders of the Spine**

**Low Back Pain**

Low back pain (LBP) affects the area between the lower rib cage and gluteal muscles and often radiates into the thighs. The percentage of the population affected with LBP is about 29%, with a higher percentage among older individuals, particularly women older than age 60.24 LBP is the primary cause of disability worldwide.25 The burdens of disability include psychologic, financial, occupational, and social effects on the person and family members.

Risk factors include occupations that require repetitious lifting in the forward bent-and-twisted position; exposure to vibrations caused by vehicles or industrial
machinery; obesity; and cigarette smoking. Some people have a genetic predisposition for low back pain.

**Pathogenesis**

Most cases of LBP are idiopathic or nonspecific, and no precise diagnosis is possible. Acute LBP is often associated with muscle or ligament strain and is more common in individuals younger than 50 years of age without a history of cancer. Common causes of chronic LBP include degenerative disk disease, spondylolysis, spondylolisthesis (vertebra slides forward or slips in relation to a vertebra below), spinal osteochondrosis, spinal stenosis, and lumbar disk herniation. Other causes include tension caused by tumors or disk prolapse, bursitis, synovitis, rising venous and tissue pressures (found in degenerative joint disease), abnormal bone pressures, spinal immobility, inflammation caused by infection (as in osteomyelitis), and pain referred from viscera or the posterior peritoneum. Systemic causes of LBP include bone diseases, such as osteoporosis or osteomalacia, and hyperparathyroidism. Anatomically, low back pain must originate from innervated structures, but deep pain is widely referred and varies. The nucleus pulposus has no intrinsic innervation, but when extruded or herniated through a prolapsed disk, it irritates the spinal nerve dural membranes and causes pain referred to the segmental area (Figure 16-8).

![Herniated Nucleus Pulposus](image)

The interspinous bursae can be a source of pain between L3, L4, L5, and S1 but also may affect L1, L2, and L3 spinous processes. The anterior and posterior
longitudinal ligaments of the spine and the interspinous and supraspinous ligaments are abundantly supplied with pain receptors, as is the ligamentum flavum. All of these ligaments are vulnerable to traumatic tears (sprains) and fracture. Diskogenic pain also may be related to inflammation and nerve sprouting within the disk.\textsuperscript{27}

**Clinical manifestations**

About 1% of individuals with acute low back pain have pain along the distribution of a lumbar nerve root (radicular pain), most commonly involving the sciatic nerve (sciatica). Sciatica is often accompanied by neurosensory and motor deficits, such as tingling, numbness, and weakness in various parts of the leg and foot. Major or progressive motor or sensory deficit, \textit{cauda equina syndrome} (new-onset bowel or bladder incontinence or urinary retention, loss of anal sphincter tone, and saddle anesthesia), history of cancer metastasis to bone, and suspected spinal infection can be associated with chronic low back pain.

**Evaluation and treatment**

Diagnosis of low back pain is based on the history and physical examination. Imaging and nerve conduction studies are obtained with severe neurologic deficit or serious underlying disease. Diagnosis and treatment guidelines are available to plan therapy.\textsuperscript{28} Most individuals with acute low back pain benefit from a nonspecific short-term treatment regimen of bed rest, analgesic medications, exercises, physical therapy, and education. Surgical treatments, specifically diskectomy and spinal fusions, are used for individuals not responding to medical management or for emergency management of cauda equina syndrome. Individuals with chronic low back pain may benefit from anti-inflammatory and muscle relaxant medications, exercise programs, massage, topical heat, spinal manipulation, acupuncture, cognitive-behavioral therapies, and interdisciplinary care.\textsuperscript{29} There is scant evidence for efficacy of opioids for chronic low back pain, but a high risk for addiction.\textsuperscript{30} The complexity of causes contributes to the difficulty in defining pathogenesis and clearly defining the most effective therapies.

**Degenerative Joint Disease (DJD)**

**Degenerative disk disease.**

\textit{Degenerative disk disease (DDD)} is common in individuals 30 years of age and older. It is, in part, a process of normal aging as a response to continuous vertical compression of the spine (axial loading). DDD includes a genetic component, involving genes that code the cartilage intermediate layer protein (CILP).
Combination of environmental interactions and genetic predisposition increases susceptibility to lumbar disk disease by disrupting normal building and maintenance of cartilage. Causes include biochemical (e.g., inflammatory mediators) and biomechanical alterations (e.g., mechanical loading and compression) of the intervertebral disk tissue. For example, loss of disk proteoglycans and collagen with disk dehydration and loss of hydrostatic pressure alters disk structure and function. The annulus can tear and the disk can herniate, pinching nerves or placing strain on the spine. The pathologic findings in DDD include disk protrusion, spondylolysis and/or subluxation (spondylolysis), degeneration of vertebrae, and spinal stenosis. Lumbar disk disease causes one third of all back pain that affects 70% to 90% of adults at some point in their lives. However, only a small percentage of people with degenerative disk disease have any functional incapacity because of pain.

**Spondylolysis.**

*Spondylolysis* is a structural defect (degeneration, fracture, or developmental defect) in the pars interarticularis of the vertebral arch (the joining of the vertebral body to the posterior structures). The lumbar spine at L5 is affected most often. Mechanical pressure may cause an anterior or posterior displacement of the deficient vertebra (*spondylolisthesis*). Heredity plays a significant role, and spondylolysis is associated with an increased incidence of other congenital spinal defects. Symptoms include lower back and lower limb pain.

**Spondylolisthesis.**

*Spondylolisthesis*, an osseous defect of the pars interarticularis, allows a vertebra to slide anteriorly in relation to the vertebra below, commonly occurring at L5-S1. Spondylolisthesis is graded from 1 to 4 based on the percentage of slip that occurs. Grades 1 and 2 have symptoms of pain in the lower back and buttocks, muscle spasms in the lower back and legs, and tightened hamstrings. Conservative management includes exercise, rest, and back bracing. Vertebral slippage in grades 3 and 4 usually requires surgical decompression, stabilization, or both.

**Spinal stenosis.**

*Spinal stenosis* is a narrowing of the spinal canal that causes pressure on the spinal nerves or cord and can be congenital or acquired (more common) and associated with trauma or arthritis. It is categorized by the area of the spine affected: cervical, thoracic, or lumbar. Acquired conditions include a bulging disk, facet hypertrophy, or a thick ossified posterior longitudinal ligament. Symptoms are related to the area
of the spine affected and can produce pain; numbness; and tingling in the neck, hands, arms, or legs with weakness and difficulty walking. Surgical decompression is recommended for those with chronic symptoms and those who do not respond to medical management.

**Herniated Intervertebral Disk**

Herniation of an intervertebral disk is a displacement of the nucleus pulposus or annulus fibrosus beyond the intervertebral disk space (see Figure 16-8). Rupture of an intervertebral disk usually is caused by trauma, degenerative disk disease, or both. Risk factors are weight-bearing sports, light weight lifting, and certain work activities, such as repeated lifting. Men are affected more often than women, with the highest incidence in the 30- to 50-year age group. Most commonly affected are the lumbosacral disks L4-L5 and L5-S1. Herniation is typically at higher vertebrae in older persons. Disk herniation occasionally occurs in the cervical area, usually at C5-C6 and C6-C7. Herniations at the thoracic level are extremely rare. The herniation may occur immediately, within a few hours, or months to years after injury.

**Pathophysiology**

In a herniated disk, the ligament and posterior capsule of the disk are usually torn, allowing the nucleus pulposus to extrude and compress the nerve root. The vascular supply may be compromised and cause inflammatory changes in the nerve root (radiculitis). Occasionally, the injury tears the entire disk loose, causing the disk capsule and nucleus pulposus to protrude onto the nerve root or compress the spinal cord. Multiple nerve root compression may be found at the L5-S1 level, where the cauda equina may be compressed, causing cauda equina syndrome (see Table 16-5).

**Clinical manifestations**

The location and size of the herniation into the spinal canal, together with the amount of space in the canal, determine the clinical manifestations associated with the injury (Figure 16-9). Compression or inflammation, or both, of a spinal nerve resulting from disk herniation follows a dermatomal distribution called **radiculopathy** (Figure 16-10). A herniated disk in the lumbosacral area is associated with pain that radiates along the sciatic nerve course over the buttock and into the calf or ankle. The pain occurs with straining, including coughing and sneezing, and usually on straight leg raising. Other clinical manifestations include limited range of motion of the lumbar spine; tenderness on palpation in the sciatic notch and along the sciatic nerve; impaired pain, temperature, and touch sensations
in the L4-L5 or L5-S1 dermatomes of the leg and foot; decreased or absent ankle jerk reflex; and mild weakness of the foot. More rarely, there is development of cauda equine syndrome.

**FIGURE 16-9** Clinical Features of a Herniated Nucleus Pulposus.
With the herniation of a lower cervical disk, paresthesias and pain are present in the upper arm, forearm, and hand along the affected nerve root distribution. Neck motion and straining, including coughing and sneezing, may increase neck and nerve root pain. Neck range of motion is diminished. Slight weakness and atrophy of biceps or triceps muscles may occur; the biceps or triceps reflex may decrease. Occasionally, signs of corticospinal and sensory tract impairments appear, including motor weakness of the lower extremities, sensory disturbances in the lower extremities, and presence of a Babinski reflex.

**Evaluation and treatment**
Diagnosis of a herniated intervertebral disk is made through the history and physical examination, spinal x-ray films, electromyelography, CT scan, MRI, myelography, diskography, and nerve conduction studies. Evidenced-based practice guidelines have been published to guide treatment options. Most herniated disks heal spontaneously over time and do not require surgery. A surgical approach is indicated if there is evidence of severe compression (weakness or decreased deep tendon, bladder, or bowel reflexes) or if a conservative approach is unsuccessful. Cauda equina syndrome requires emergency surgical evaluation.

Cerebrovascular Disorders

Cerebrovascular disease is the most frequently occurring neurologic disorder, accounting for more than 50% of the persons admitted to general hospitals with neurologic problems. Any abnormality of the brain caused by a pathologic process in the blood vessels is referred to as a cerebrovascular disease. Included in this category are lesions of the vessel wall, occlusion of the vessel lumen by thrombus or embolus, rupture of the vessel, and alteration in blood quality such as increased blood viscosity.

The brain abnormalities induced by cerebrovascular disease are either (1) ischemia with or without infarction (death of brain tissues) or (2) hemorrhage. The common clinical manifestation of cerebrovascular disease is a cerebrovascular accident or stroke. The symptoms occur suddenly and are focal (i.e., slurred speech, difficulty swallowing, limb weakness, or paralysis). In its mildest form, a cerebrovascular accident is so minimal that it is almost unnoticed. In its most severe form, hemiplegia, coma, and death result.

Cerebrovascular Accidents (Stroke Syndromes)

Cerebrovascular accidents (CVAs) are the leading cause of disability and the third cause of death in women and the fifth leading cause of death in men in the United States (see Health Alert: Prevention of Stroke in Women). About 75% of CVAs occur among those older than 65 years. The incidence is about 150% greater in blacks than whites. Blacks between the ages of 55 and 64 who live in the southern states are about 50% more likely to die of stroke than blacks of the same age who live in the North. In addition, persons with both hypertension and type 2 diabetes mellitus have a fourfold increase in stroke incidence and an eightfold increase in stroke mortality. The incidence of stroke decreased 35.8% from 2000 to 2010 and is associated with hypertension, diabetes and high cholesterol control and smoking cessation.
Health Alert

Prevention of Stroke in Women

Stroke is the third leading cause of death in women and the fifth leading cause of death in men. The number of women with stroke will increasingly outnumber men in the future. Guidelines have been developed by the American Heart Association/American Stroke Association Council on Stroke to reduce stroke risk in women considering genetic differences in immunity, coagulation, hormonal factors, reproductive factors including pregnancy and childbirth, and social factors. A summary of these guidelines is presented below:

• Women should be informed about stroke risk factors (e.g., obesity, hypertension, and diabetes) at an early age.

• Women with a history of high blood pressure before pregnancy should be considered for low-dose aspirin or calcium supplement therapy, or both, to lower preeclampsia risks.

• Women who have preeclampsia have twice the risk of stroke and a fourfold increased risk of high blood pressure later in life. Therefore, preeclampsia should be recognized as a risk factor well after pregnancy and other risk factors such as smoking, high cholesterol, and obesity in these women should be treated early.

• Pregnant women with moderately high blood pressure (150-159 mm Hg/100-109 mm Hg) may be considered for safe and effective antihypertensive medication, whereas expectant mothers with severe high blood pressure (160/110 mm Hg or higher) should be treated.

• Women at risk for central venous thrombosis require prothrombotic screening, consideration for antithrombotic therapy, and careful management during pregnancy.

• Women should be screened for high blood pressure before taking birth control pills because the combination raises stroke risks.

• Hormone therapy (conjugated equine estrogen) with or without medroxyprogesterone should not be used for primary or secondary prevention of stroke in postmenopausal women.
Women who have migraine headaches with aura should stop smoking to avoid higher stroke risks.

Women with cardiovascular risk factors should engage in regular physical activity, moderate alcohol consumption (<1 drink per day for nonpregnant women), abstention from cigarette smoking, and a diet rich in fruit, vegetables, grains, nuts, olive oil, and low saturated fat.

Women older than age 75 should be screened for atrial fibrillation risks because of its link to higher stroke risk.

Cerebrovascular accidents (stroke syndromes) are classified pathophysiologically as ischemic, hemorrhagic, or associated with hypoperfusion. Risk factors for stroke include the following:

- Poorly or uncontrolled arterial hypertension
- Smoking, which increases the risk of stroke by 50%
- Insulin resistance and diabetes mellitus
- Polycythemia and thrombocythemia
- High total cholesterol or low high-density lipoprotein (HDL) cholesterol, elevated lipoprotein-a
- Congestive heart disease and peripheral vascular disease
- Hyperhomocysteinemia
- Atrial fibrillation
- *Chlamydia pneumoniae* infection

**Ischemic stroke.**

Ischemic stroke occurs when there is obstruction to arterial blood flow to the brain from thrombus formation, an embolus, or hypoperfusion related to decreased blood volume or heart failure. The inadequate blood supply results in ischemia (inadequate cellular oxygen) and can progress to infarction (death of tissue).

Transient ischemic attacks (TIAs) are episodes of neurologic dysfunction lasting no more than 1 hour and resulting from focal cerebral ischemia. The clinical manifestations of a TIA may include weakness, numbness, sudden confusion, loss of balance, or a sudden severe headache. The use of brain imaging modalities often
reveals a brain infarction. About 3% to 17% of individuals experiencing a TIA will have a stroke within 90 days.\textsuperscript{37}

**Thrombotic strokes (cerebral thromboses)** arise from arterial occlusions caused by thrombi formation in arteries supplying the brain or intracranial vessels. Conditions causing increased coagulation or inadequate cerebral perfusion (e.g., dehydration, hypotension, prolonged vasoconstriction from malignant hypertension) increase the risk of thrombosis. Cerebral thrombosis develops most often from atherosclerosis and inflammatory disease processes that damage arterial walls. It may take as long as 20 to 30 years for obstruction to develop at the branches and curvature found in the cerebral circulation (see \textit{Chapter 24} for a discussion of atherogenesis). The smooth stenotic area can degenerate, forming an ulcerated area of the vessel wall. Platelets and fibrin adhere to the damaged wall, and a clot forms, gradually occluding the artery. The clot may enlarge both distally and proximally. Thrombotic strokes also occur when parts of a clot detach, travel upstream, and obstruct blood flow, causing acute ischemia.

**Embolic stroke** involves fragments that break from a thrombus formed outside the brain, usually in the heart, aorta, or common carotid artery. Other sources of embolism include fat, air, tumor, bacterial clumps, and foreign bodies. The embolus usually involves small brain vessels and obstructs at a bifurcation or other point of narrowing, thus causing ischemia. An embolus may plug the lumen entirely and remain in place or shatter into fragments and become part of the vessel's blood flow. Risk factors for an embolic stroke include atrial fibrillation, left ventricular aneurysm or thrombus, left atrial thrombus, recent myocardial infarction, endocarditis, rheumatic valve disease, mechanical valvular prostheses, atrioseptal defects, patent foramen ovale, and primary cardiac tumors. In persons who experience an embolic stroke, a second stroke usually follows because the source of emboli continues to exist. Embolization is usually in the distribution of the middle cerebral artery (the largest cerebral artery). Ischemic strokes in children are associated with congenital heart disease, cerebral arteriovenous malformations, and sickle cell disease (see \textit{Chapter 17}).

**Lacunar strokes (lacunar infarcts or small vessel disease)** are usually caused by occlusion of a single, deep perforating artery that supplies small penetrating subcortical vessels, causing ischemic lesions (0.5 to 15 mm, or lacunes) predominantly in the basal ganglia, internal capsules, and pons. These strokes are rare and, because of the location and small area of infarction, they may have pure motor or sensory deficits.\textsuperscript{38}

**Hypoperfusion, or hemodynamic stroke**, is associated with \textit{systemic} hypoperfusion caused by cardiac failure, pulmonary embolism, or bleeding that results in inadequate blood supply to the brain. Stroke may occur more readily if
there is carotid artery occlusion. Symptoms are usually bilateral and diffuse.39

Pathophysiology

Cerebral infarction results when an area of the brain loses its blood supply because of vascular occlusion. Causes include (1) abrupt vascular occlusion (e.g., embolus or thrombi), (2) gradual vessel occlusion (e.g., atheroma), and (3) partial occlusion of stenotic vessels. Cerebral thrombi and cerebral emboli most commonly produce occlusion, but atherosclerosis and hypertension are the dominant underlying processes.

There is a central core of irreversible ischemia and necrosis with cerebral infarction. The central core is surrounded by a zone of borderline ischemic tissue, the ischemic penumbra. Ischemia in the penumbra is not severe enough to result in structural damage. Prompt restoration of perfusion in the penumbra by injection of thrombolytic agents promotes perfusion and may prevent necrosis and loss of neurologic function. The window of opportunity for protecting the penumbra is about 3 hours.

Cerebral infarctions are ischemic or hemorrhagic. In ischemic infarcts, the affected area becomes pale and softens 6 to 12 hours after the occlusion. Necrosis, swelling around the insult, and mushy disintegration appear by 48 to 72 hours after infarction. There is infiltration of macrophages and phagocytosis of necrotic tissue. The necrosis resolves by about the second week, ultimately leaving a cavity surrounded by glial scarring.

In hemorrhagic infarcts, bleeding occurs into the infarcted area through leaking vessels when the embolic fragments resolve and reperfusion begins to occur. Hemorrhagic transformation of ischemic stroke may be exacerbated by thrombolytic therapy.40

Clinical manifestations

Clinical manifestations of thrombotic and embolic stroke vary, depending on the artery obstructed. Different sites of obstruction create different occlusion syndromes (e.g., carotid artery, dysphasia and contralateral motor [i.e., paresis] sensory [i.e., numbness] deficits, conjugate ipsilateral eye deviation), middle cerebral artery syndromes (dysphasia and contralateral motor and sensory deficits), or vertebrobasilar system syndromes (dizziness and ataxia, can progress to quadriplegia and coma).41 Contralateral sensory and motor manifestations occur on the opposite side of the body from the location of the brain lesion because motor tracts originate in the cortex and most cross over in the medulla. Sensory tracts originate in the periphery and cross over in the spinal cord. Ipsilateral manifestations occur on the same side as the brain lesion.
Evaluation and treatment
Imaging is used to diagnose stroke. Treatment of ischemic stroke is focused on (1) restoring brain perfusion in a timeframe that does not contribute to reperfusion injury, (2) counteracting the ischemic cascade pathways, (3) lowering cerebral metabolic demand so that the susceptible brain tissue is protected against impaired perfusion, (4) preventing recurrent ischemic events, and (5) promoting tissue restoration. Thrombolysis, using tissue-type plasminogen activator (tPA), is given within 3 and up to 4.5 hours of onset of symptoms. Endovascular intraarterial thrombolysis may be used to treat those who cannot receive tPA. 

Supportive management is given to control cerebral edema and increased intracranial pressure and to provide neuroprotection. Arresting the disease process by control of risk factors is critical and antiplatelet therapy may be instituted. Scales and guidelines are available for the assessment and management of acute ischemic stroke.

In embolic strokes, treatment is directed at preventing further embolization by instituting anticoagulation therapy and correcting the primary problem. Rehabilitation is indicated for ischemic strokes and recovery of function is often possible.

Hemorrhagic stroke.
Hemorrhagic stroke (intracranial hemorrhage) is the third most common cause of cerebrovascular accident. They can occur within the brain tissue (intraparenchymal) or in the subarachnoid or subdural spaces. The primary cause of intraparenchymal hemorrhagic stroke is hypertension with other causes including tumors, coagulation disorders, trauma, or illicit drug use, particularly cocaine. Prevention or control of hypertension reduces the incidence of hemorrhagic stroke.

Subarachnoid hemorrhage is associated with ruptured aneurysms or arteriovenous malformations (see p. 405) or brain trauma. Subdural hemorrhage (hematoma) is usually associated with brain trauma (see p. 390). Hypertensive causes of hemorrhagic stroke involve primarily smaller arteries and arterioles, resulting in thickening of the vessel walls and increased cellularity of the vessels. Necrosis may be present. Microaneurysms in these smaller vessels or arteriolar necrosis may precipitate the bleeding.

Pathophysiology
A mass of blood is formed as bleeding continues into the brain tissue. Adjacent brain tissue is deformed, compressed, and displaced, producing ischemia, edema, and increased intracranial pressure and necrosis. Rupture or seepage of blood into the ventricular system often occurs and is associated with higher mortality.
Hemorrhages are described as massive, small, slit, or petechial. Massive hemorrhages are several centimeters in diameter, small hemorrhages are 1 to 2 cm in diameter, a slit hemorrhage lies in the subcortical area, and a petechial hemorrhage is the size of a pinhead bleed. The most common sites for hypertensive hemorrhages are in the putamen of the basal ganglia, the thalamus, the cortex and subcortex, the pons, the caudate nucleus, and the cerebellar hemispheres. Because neurons surrounding the ischemic or infarcted areas undergo changes that disrupt plasma membranes, cellular edema results, causing further compression of capillaries. Maximal cerebral edema develops in approximately 72 hours and takes about 2 weeks to subside. Most persons survive an initial hemispheric ischemic stroke unless there is massive cerebral edema, which is nearly always fatal. The cerebral hemorrhage resolves through reabsorption. Macrophages and astrocytes clear blood from the area. A cavity forms, surrounded by a dense gliosis (glial scar) after removal of the blood.

**Clinical manifestations**

The clinical manifestations of hemorrhagic stroke are similar to those for embolic and thrombotic stroke, and depend on the location and size of the bleed. Symptoms can occur suddenly and with activity. Once a deep unresponsive state occurs, the person rarely survives. The immediate prognosis is grave; however, if the person survives, recovery of function is often possible.

It is difficult to differentiate ischemic from hemorrhagic stroke based on symptoms. Individuals experiencing intracranial hemorrhage from a ruptured or leaking aneurysm have one of three sets of symptoms: (1) onset of an excruciating generalized headache with an almost immediate lapse into an unresponsive state, (2) headache but with consciousness maintained, and (3) sudden lapse into unconsciousness. If the hemorrhage is confined to the subarachnoid space, there may be no local signs. If bleeding spreads into the brain tissue, hemiparesis/paralysis, dysphasia, or homonymous hemianopia may be present. Warning signs of an impending aneurysm rupture include headache, transient unilateral weakness, transient numbness and tingling, and transient speech disturbance. However, such warning signs are often absent.

**Evaluation and treatment**

Treatment of an intracranial bleed, regardless of cause, focuses on stopping or reducing the bleeding, controlling the increased intracranial pressure, preventing a rebleed, and preventing vasospasm. There are some attempts to drain blood in a cerebral bleed but the benefit is not documented in studies. Microsurgical interventions are under investigation. Surgical treatments are options for ruptured
aneurysms, vascular malformations, and subarachnoid hemorrhage.

**Intracranial aneurysm.**

**Intracranial aneurysms** may result from arteriosclerosis, congenital abnormality, cocaine use, trauma, inflammation, and vascular sheer wall stress. The size may vary from 2 mm to 2 or 3 cm. Most aneurysms are located at bifurcations in or near the circle of Willis, in the vertebrobasilar arteries, or within the carotid system where there is higher wall sheer stress and flow turbulence (see Figures 13-19 and 13-20). Aneurysms may be single, but in 20% to 25% of the cases, more than one is present. In these instances, the aneurysms may be unilateral or bilateral. Peak incidence of rupture occurs in persons 50 to 59 years of age, with the incidence in postmenopausal women slightly higher than that in men.

**Pathophysiology**

No single pathologic mechanism exists. Aneurysms may be classified on the basis of shape and form. **Saccular aneurysms (berry aneurysms)** occur frequently (in approximately 2% of the population) and likely result from congenital abnormalities in the tunica media of the arterial wall and hemodynamic and molecular changes. The sac gradually grows over time. A saccular aneurysm may be (1) round with a narrow stalk connecting it to the parent artery, (2) broad-based without a stalk, or (3) cylindrical (Figure 16-11). Saccular aneurysms are rare in childhood; their highest incidence of rupturing or bleeding (subarachnoid hemorrhage) is among persons 20 to 50 years of age (Figure 16-12).
Fusiform aneurysms (giant aneurysms) are less common, occur as a result of diffuse arteriosclerotic changes, and are found most commonly in the basilar arteries or terminal portions of the internal carotid arteries (see Figure 16-11). They act as space-occupying lesions.
Aneurysms rupture through thin areas often at bifurcation sites, causing hemorrhage into the subarachnoid space that spreads rapidly, producing localized changes in the cerebral cortex and focal irritation of nerves and arteries (see the discussion of the Laplace law in Chapter 23). Bleeding ceases when a fibrin-platelet plug forms at the point of rupture and as a result of compression. Blood undergoes reabsorption through arachnoid villi within 3 weeks.

**Clinical manifestations**

Aneurysms often are asymptomatic. Of all persons undergoing routine autopsy, 5% are found to have one or more intracranial aneurysms. Clinical manifestations include dizziness or headache and cranial nerve compression, but the signs vary depending on the location and size of the aneurysm. Cranial nerves III, IV, V, and VI (see Table 13-6) are affected most often. Unfortunately, the most common first indication of the presence of an aneurysm is an acute subarachnoid hemorrhage, intracerebral hemorrhage, or combined subarachnoid-intracerebral hemorrhage (see Hemorrhagic Stroke, p. 404).

**Evaluation and treatment**

Diagnosis before a bleeding episode is made through arteriography. After a subarachnoid or intracerebral hemorrhage, a tentative diagnosis of an aneurysm is based on clinical manifestations, history, and imaging. Treatments for intracranial aneurysm are both medical (i.e., control of hypertension) and surgical (i.e., microvascular clipping or placement of endovascular coils).

**Vascular malformation.**

Vascular malformations are rare congenital vascular lesions. An arteriovenous malformation (AVM) is a mass of dilated vessels between the arterial and venous systems (arteriovenous fistula) without an intervening capillary bed, may occur in any part of the brain and vary in size from a few millimeters to large malformations extending from the cortex to the ventricle. AVMs occur equally in males and females and occasionally occur in families. Although AVMs are usually present at birth, symptoms exhibit a delayed age of onset and commonly occur before 30 years of age.

**Pathophysiology**

AVMs have abnormal blood vessel structure, are abnormally thin, and have complex growth and remodeling patterns. There is direct shunting of arterial blood into the venous vasculature without the dissipation of the arterial blood pressure with
increased risk for rupture. One or several arteries may feed the AVM and, over time, they become tortuous and dilated. With moderate to large AVMs, sufficient blood is shunted into the malformation to deprive surrounding tissue of adequate blood perfusion.

Clinical manifestations
Twenty percent of persons with an AVM have a characteristic chronic, nondescript headache, although some experience migraine. Fifty percent of persons experience seizures. The other 50% experience an intracerebral, subarachnoid, or subdural hemorrhage with progressive neurologic deficits. Bleeding from an AVM into the subarachnoid space causes symptoms identical to those associated with a ruptured aneurysm. If bleeding is into the brain tissue, focal signs that develop resemble a stroke that is progressing in severity. Ten percent of persons experience hemiparesis or other focal signs. At times, noncommunicating hydrocephalus (see Chapter 15) develops with a large AVM that extends into the ventricular lining.

Evaluation and treatment
A systolic bruit over the carotid artery in the neck, the mastoid process, or the eyeball in a young person is almost always diagnostic of an AVM. Confirming diagnosis is made by CT and MRI followed by MRA. Treatment options include direct surgical excision, endovascular embolization, or radiotherapy.49

Subarachnoid hemorrhage.
Subarachnoid hemorrhage (SAH) is the escape of blood from a defective or injured vessel into the subarachnoid space. Individuals at risk for a subarachnoid hemorrhage are those with intracranial aneurysm, intracranial arteriovenous malformation, hypertension, or a family history of SAH, and those who have sustained head injuries. Subarachnoid hemorrhages often recur, especially from a ruptured intracranial aneurysm.

Pathophysiology
When a vessel is leaking, blood oozes into the subarachnoid space. When a vessel tears, blood under pressure is pumped into the subarachnoid space. The blood increases the intracranial volume, and it is also extremely irritating to the neural tissues and produces an inflammatory reaction. In addition, the blood coats nerve roots, clogs arachnoid granulations (impairing CSF reabsorption), and obstructs foramina within the ventricular system (impairing CSF circulation). Intracranial pressure immediately increases to almost diastolic levels but returns to near
baseline in about 10 minutes. Cerebral blood flow and cerebral perfusion pressure decrease. Autoregulation of blood flow is impaired, and there is a compensatory increase in systolic blood pressure.\textsuperscript{50} The expanding hematoma acts like a space-occupying lesion, compressing and displacing brain tissue with increased intracranial pressure, decreased cerebral blood flow, blood-brain barrier breakdown, brain edema, inflammation, and cell death. Secondary brain injury can occur as described for traumatic brain injury (see p. 390). Granulation tissue is formed, and meningeal scarring with impairment of CSF reabsorption and secondary hydrocephalus often results. Mortality in subarachnoid hemorrhage is 50% at 1 month.

Delayed cerebral ischemia, a syndrome of progressive neurologic deterioration, is associated with cerebral artery vasospasm. From 40% to 60% of persons with a subarachnoid hemorrhage experience vasospasms in adjacent and, occasionally, in nonadjacent vessels. Vasospasm may occur because of leukocyte–endothelial cell interactions or the effects of vasoactive substances (e.g., calcium, prostaglandins, serotonin, catecholamines) on the arteries of the subarachnoid space. Edema, medial necrosis, and proliferation of the tunica intima in cerebral arterioles have been found. Vasospasm causes decreased cerebral blood flow, ischemia, and possibly infarct and can lead to delayed ischemic injury and death 3 to 14 days after the initial hemorrhage.\textsuperscript{51}

**Clinical manifestations**

Early manifestations associated with leaking vessels are episodic and include headache, changes in mental status or level of consciousness, nausea or vomiting, and focal neurologic defects. A ruptured vessel causes a sudden, throbbing, “explosive” headache, accompanied by nausea and vomiting, visual disturbances, motor deficits, and loss of consciousness related to a dramatic rise in intracranial pressure. Meningeal irritation and inflammation often occur, causing neck stiffness (nuchal rigidity), photophobia, blurred vision, irritability, restlessness, and low-grade fever. A positive **Kernig sign** (straightening the knee with the hip and knee in a flexed position produces pain in the back and neck regions) and a positive **Brudzinski sign** (passive flexion of the neck produces neck pain and increased rigidity) may appear. No localizing signs are present if the bleed is confined completely to the subarachnoid space.

The Hunt and Hess subarachnoid hemorrhage (SAH) grading system is based on description of the clinical manifestations (Table 16-6).\textsuperscript{52} Rebleeding is a significant risk with a high mortality (up to 70%). The period of greatest risk is during the first 72 hours and up to 2 weeks after the initial bleed. Rebleeding is manifested by a sudden increase in blood pressure and intracranial pressure, along with a
deteriorating neurologic status.\textsuperscript{53}

Seizures occur in 25% of persons with an SAH, and hydrocephalus after a bleed occurs in 20% of cases. Hypothalamic dysfunction, manifested by salt wasting, hyponatremia, and ECG changes, is common.

**Evaluation and treatment**

The diagnosis of an SAH is based on the clinical presentation, imaging, and cerebrospinal fluid evaluation. Treatment is directed at controlling intracranial pressure, improving cerebral perfusion pressure, preventing ischemia and hypoxia of neural tissues, and avoiding rebleeding episodes. Surgical intervention is common. Treatment guidelines are available to direct therapy.\textsuperscript{47}

**Quick Check 16-2**

1. Why is atherosclerosis a risk factor for thrombotic stroke?
2. Why do the signs and symptoms of a TIA resolve completely?
3. Why do lacunar strokes involve small infarcts?
4. How is an AVM different from an aneurysm?

**Headache**

*Headache* is a common neurologic disorder and is usually a benign symptom. However, it can be associated with serious disease such as brain tumor, meningitis, or cerebrovascular disease (e.g., giant cell arteritis, cerebral aneurysm, or cerebral bleeds). The headache syndromes discussed here are the chronic, recurring type not
associated with structural abnormalities or systemic disease and include migraine, cluster, and tension headaches. Characteristics of the major types of headache syndromes are summarized in Table 16-7.

**Migraine**

Migraine is an episodic neurologic disorder characterized by a headache lasting 4 to 72 hours. It is diagnosed when any two of the following features occur: unilateral head pain, throbbing pain, pain worsens with activity, moderate or severe pain intensity; and at least one of the following: nausea and/or vomiting, or photophobia and phonophobia. Migraine is broadly classified as (1) *migraine with aura* with visual, sensory, or motor symptoms; and, more commonly, (2) *migraine without aura*.

Migraine occurs in 18% of women and 6% of men in the United States and can occur in children. It is more common in those 25 to 55 years of age. There often is a family history of migraine. In susceptible women, migraine occurs most frequently before and during menstruation and is decreased during pregnancy and menopause. The cyclic withdrawal of estrogen and progesterone may trigger attacks of migraine.

Migraine is caused by a combination of multiple genetic and environmental factors. Persons with migraine have an increased risk for epilepsy, depression, anxiety disorders, cardiovascular disease, and stroke. Migraine may be precipitated by triggers. Individuals with migraine are likely to have a genetically determined reduced threshold for triggers. Triggers can include becoming tired or oversleeping, missed meals, overexertion, weather change, stress or relaxation from stress, hormonal changes (menstrual periods), excess afferent stimulation.
(bright lights, strong smells), and chemicals (alcohol or nitrates).

The pathophysiologic basis for migraine is complex and not clearly established. There is no identifiable pathology but there are associated changes in brain metabolism and blood flow. Current theories include neurologic, vascular, hormonal, and neurotransmitter components. Migraine aura is associated with cortical spreading depression (CSD). CSD is a spontaneous self-propagating wave of glial and neuronal depolarization resulting in hyperactivity that starts in the occipital region and spreads across the cortex. CSD initiates the release of neurotransmitters that activate the trigeminal vascular system (afferent projections from cranial nerve V), stimulating vasodilation of dural blood vessels, activation of inflammation, peripheral and central sensitization of pain receptors (hypersensitivity to pain), and activation of areas of the brainstem and forebrain that modulate pain. Release of inflammatory mediators with sterile meningeal inflammation and edema of blood vessels may be an important component of migraine pain. Vasodilation of blood vessels is not sufficient to account for the pain of migraine. Calcitonin gene–related peptide (CGRP) release by the trigeminal vascular system is related to migraine pain. The mechanism is not clear, but CGRP antagonists stop the headache. Glutamate (an excitatory neurotransmitter) concentration is increased and 5-hydroxytryptamine (5-HT, serotonin) concentration is decreased. 5-HT causes vasoconstriction and antagonizes CGRP. Consequently, 5-HT(1B/1D) receptor agonists (i.e., triptans) and CGRP receptor and glutamate receptor antagonists have been used for the acute treatment of migraine.

The clinical phases of a migraine attack are as follows:

1. **Premonitory phase**: Up to one third of persons have premonitory symptoms hours to days before onset of aura or headache. These symptoms may include tiredness, irritability, loss of concentration, stiff neck, and food cravings.

2. **Migraine aura**: Up to one third of persons have aura symptoms at least some of the time that may last up to 1 hour. Symptoms can be visual, sensory, or motor.

3. **Headache phase**: Throbbing pain usually begins on one side and spreads to include the entire head. Headache may be accompanied by fatigue, nausea, and vomiting or dizziness. There may be hypersensitivity to anything touching the head. Symptoms may last from 4 to 72 hours (usually about a day).

4. **Recovery phase**: Irritability, fatigue, or depression may take hours or days to resolve.
Differentiation of types of migraine headache is summarized in Table 16-7. The diagnosis of migraine is made from medical history and physical examination. Differential diagnosis is confirmed by imaging and EEG. Functional neuroimaging and genetic studies are advancing the understanding of the mechanisms involved in migraine attacks and individual variants involved with disease susceptibility. The management of migraine includes avoidance of triggers (e.g., darkening the room, applying ice). Sleeping can provide some relief with the onset of acute migraine. Pharmacologic management for the treatment and prevention of migraine is available. A transcutaneous electrical stimulation device providing trigeminal neurostimulation has been approved by the Food and Drug Administration for the prevention of migraine.

Chronic migraines usually begin as episodic migraines that increase in frequency over time. Chronic migraine occurs at least 15 days in a month (can occur daily or on a near-daily basis) for more than 3 months. Chronic migraines are associated with overuse of analgesic migraine medications (sometimes called rebound headaches), obesity, and caffeine overuse. Treatment is similar to that for episodic migraine. Individuals with chronic migraine unresponsive to medical treatment should be evaluated for intracranial hypertension without papilledema and the possibility of sinus venous stenosis.

Cluster Headache

Cluster headaches are one of a group of disorders referred to as trigeminal autonomic cephalagias (headaches involving the autonomic division of the trigeminal nerve). They occur in one side of the head primarily in men between 20 and 50 years of age. The pain may alternate sides with each headache episode and is severe, stabbing, and throbbing. These uncommon headaches occur in clusters (up to 8 attacks per day) and last for minutes to hours for a period of days, followed by a long period of spontaneous remission. Cluster headache has an episodic and a chronic form with extreme pain intensity and short duration. If the cluster of attacks occurs more frequently without sustained spontaneous remission, they are classified as chronic cluster headaches (10% to 20% of cases) (see Table 16-7). Triggers are similar to those that cause migraine headache.

Trigeminal activation occurs but the mechanism is unclear. Functional imaging indicates a role for concomitant posterior hypothalamic and pain neuromatrix activation with opioid system involvement. The pathogenic mechanism for pain is related to the release of vasoactive substances and the formation of neurogenic inflammation. Autonomic dysfunction is characterized by sympathetic underactivity and parasympathetic activation. There is unilateral trigeminal distribution of severe
pain with ipsilateral autonomic manifestations, including tearing on affected side, ptosis of the ipsilateral eye, and congestion of the nasal mucosa. Prophylactic drugs are used to treat cluster headache, as well as avoidance of triggers. Acute attacks are managed with oxygen inhalation, sumatriptan or inhaled ergotamine administration, and nerve stimulation. New drugs are under investigation.

**Tension-Type Headache**

**Tension-type headache (TTH)** is the most common type of headache. The average age of onset is during the second decade of life. It is a mild to moderate bilateral headache with a sensation of a tight band or pressure around the head with gradual onset of pain. The headache occurs in episodes and may last for several hours or several days. It is not aggravated by physical activity. Chronic tension-type headache (CTTH) evolves from episodic tension-type headache and represents headache that occurs at least 15 days per month for at least 3 months.

Both central and peripheral mechanisms operate in causing tension headache. The central pain mechanism is associated with chronic tension headache and a peripheral mechanism with episodic tension headache. The central mechanism probably involves hypersensitivity of pain fibers from the trigeminal nerve that leads to central sensitization. The peripheral sensitization of myofascial sensory nerves may contribute to muscular hypersensitivity and the development of chronic CTTH. Headache sufferers have more localized pain and tenderness of pericranial muscles. Many individuals have both tension-type and migraine headaches.

Mild tension-type headaches are treated with ice, and more severe forms are treated with aspirin or nonsteroidal anti-inflammatory drugs. CTTHs are best managed with a tricyclic antidepressant and behavioral and relaxation therapy. Some individuals benefit from injection of botulinum toxin A. Long-term use of analgesics or other drugs, such as muscle relaxants, antihistamines, tranquilizers, caffeine, and ergot alkaloids, should be avoided.

**Infection and Inflammation of the Central Nervous System**

The CNS may be infected by bacteria, viruses, fungi, parasites, and mycobacteria. The invading organisms enter the nervous system either by spreading through arterial blood vessels (Figure 16-13) or by directly invading the nervous tissue from another site of infection. Neurologic infections produce disease by several mechanisms: direct neuronal or glial infection, mass lesion formation, inflammation with subsequent edema, interruption of cerebrospinal fluid pathways,
neuronal or vascular damage, and secretion of neurotoxins. An immune process may initiate an inflammatory reaction.

Meningitis

Meningitis is inflammation of the brain or spinal cord. Infectious meningitis may be caused by bacteria, viruses, fungi, parasites, or toxins. The infection may be acute, subacute, or chronic with the pathophysiology, clinical manifestations, and
treatment differing for each type of microorganism.

**Fungal meningitis** is a chronic, much less common condition than bacterial or viral meningitis. The infection most often occurs in persons with impaired immune responses or alterations in normal body flora. It develops insidiously, usually over days or weeks. Fungi in the nervous system usually produce a granulomatous reaction, forming granulomata or gelatinous masses in the meninges at the base of the brain. Fungi also may extend along the perivascular sites in the subarachnoid space and into the brain tissue, producing arteritis with thrombosis, infarction, and communicating hydrocephalus. Meningeal fibrosis develops later in the inflammatory process. Cranial nerve dysfunction, caused by compression, often results from the granulomata and fibrosis. The first manifestations are often those of dementia (see Chapter 15) or communicating hydrocephalus (see Chapter 15). The individual is characteristically afebrile.

**Viral meningitis (aseptic or nonpurulent meningitis)** is thought to be limited to the meninges. An identifiable bacterium cannot be found in the cerebrospinal fluid. The most common viruses are enteroviral viruses (echovirus, coxsackievirus, and nonparalytic poliomyelitis), arboviruses, and herpes simplex type 2. Viruses enter the nervous system by crossing the blood-brain barrier, by direct spread along peripheral nerves, or through the choroid plexus epithelium. Recognition of viral antigens by immune cells activates the inflammatory response. The clinical manifestations of viral meningitis are similar to those of bacterial meningitis but milder. Viral meningitis is managed pharmacologically with antiviral drugs and steroids.

**Bacterial meningitis** is primarily an infection of the pia mater and arachnoid, the subarachnoid space, the ventricular system, and the CSF. Meningococci (*Neisseria meningitidis*) and pneumococci (*Streptococcus pneumoniae*) are the most common pathogens. An increase of drug-resistant strains of *S. pneumoniae* is an emerging problem worldwide. About 1 in 100,000 persons are affected annually. Meningococcus has been identified worldwide and there are six serogroups: A, B, C, W-135, X, and Y. Most cases are sporadic and occur predominantly in children younger than 1 year of age and adolescents. Local outbreaks may occur in dormitories, military bases, or sub-Saharan Africa. With pneumococcal meningitis, young persons and those more than 40 years of age are mostly affected. Predisposing conditions are otitis or sinusitis (25%), immunocompromised status (16%), and pneumonia (12%). The disease is spread by respiratory droplets and contact with contaminated saliva or respiratory tract secretions (kissing, coughing, sneezing, or sharing utensils, food, and drink). Carriers of the meningococcal bacteria do not develop meningitis but may pass it on to others.
Pathophysiology

Meningococci and pneumococci are inhaled and attach to epithelial cells in the nasopharynx where they cross the mucosal barrier, enter the bloodstream, travel to cerebral blood vessels, cross the blood-brain barrier, and infect the meninges. With bacterial infection, large numbers of neutrophils are recruited to the subarachnoid space. Release of cytotoxic inflammatory agents and bacterial toxins alter the blood-brain barrier, cause cerebral edema, and damage brain tissue. The inflammatory exudate thickens the CSF and interferes with normal CSF flow around the brain and spinal cord, possibly obstructing arachnoid villi and producing hydrocephalus. Meningeal cells become edematous, and the combined exudate and edematous cells increase intracranial pressure. Engorged blood vessels and thrombi can disrupt blood flow, causing further injury.\(^\text{72}\) Acute infectious purpura fulminans is a rare rapidly progressive syndrome of hemorrhagic infarction of the skin and disseminated intravascular coagulation that can lead to multiple organ failure, ischemic necrosis of digits and limbs with amputation required, and death. It is caused by bacterial endotoxin and inflammatory cytokines.

Clinical manifestations

The clinical manifestations of bacterial meningitis can be grouped into infectious signs, meningeal signs, and neurologic signs. The clinical manifestations of systemic infection include fever, tachycardia, and chills. The clinical manifestations of meningeal irritation are a severe throbbing headache, severe photophobia, nuchal rigidity, and positive Kernig and Brudzinski signs. The neurologic signs include a decrease in consciousness, cranial nerve palsies, focal neurologic deficits (such as hemiparesis/hemiplegia and ataxia), and seizures. Often there is projectile vomiting. As intracranial pressure increases, papilledema develops and delirium may progress to unconsciousness and death. With meningococcal meningitis, a petechial or purpuric rash covers the skin and mucous membranes.

Evaluation and treatment

Rapid diagnosis, antibiotic administration, and supportive treatment are important to prevent morbidity and mortality from bacterial meningitis. Diagnosis is based on physical examination, blood cultures, and the results of nasopharyngeal smear and antigen tests. CSF analysis and cultures are required for differential diagnosis.\(^\text{72,73}\) Serious complications, including septic shock, disseminated intravascular coagulation, purpura fulminans, limb damage, and multiple organ failure, require intensive multidisciplinary care.

Vaccinations are available to prevent meningococcal, pneumococcal, and
*Haemophilus influenzae* meningitis. Meningococcal vaccine promotes antibody protection within 7 to 14 days. Vaccination of children ages 11 or 12 years is recommended with a booster to be given between ages 16 and 18 years or older, particularly college students living in a dormitory.

**Brain or Spinal Cord Abscess**

Abscesses, localized collections of pus, may form within the parenchyma of the brain or spinal cord but are rare. Brain abscesses are classified as epidural, subdural, or intracerebral. Epidural brain abscesses (empyemas) are associated with osteomyelitis in a cranial bone. Subdural brain abscesses (empyemas) arise from a sinus infection or a vascular source. Intracerebral brain abscesses arise from a vascular source. Spinal cord abscesses are classified as epidural or intramedullary. Epidural spinal abscesses usually originate as osteomyelitis in a vertebra; the infection then spreads into the epidural space. (Osteomyelitis is discussed in Chapter 39.)

**Pathophysiology**

Microorganisms gain entrance to the CNS by direct extension or distribution along the wall of a vein. Infective emboli carry organisms from distant sites. Illegal drug users who share needles are at risk as are immunosuppressed persons. For example, *Toxoplasma gondii* is producing an ever-increasing number of CNS abscesses in persons with acquired immunodeficiency syndrome (AIDS). Streptococci, staphylococci, and *Bacteroides*, often combined with anaerobes, are the most common bacteria that cause abscesses; however, yeast and fungi also may be involved.

Brain abscesses progress from localized inflammation to a necrotic core with the formation of a connective tissue capsule, usually within 14 days or longer. Existing abscesses also tend to spread and form daughter abscesses.

**Clinical manifestations**

Early manifestations include low-grade fever, headache (most common symptom), nausea and vomiting, neck pain and stiffness, confusion, drowsiness, sensory deficits, and communication deficits. Later manifestations are associated with an expanding mass and include decreased attention span, memory deficits, decreased visual acuity and narrowed visual fields, papilledema, ocular palsy, ataxia, dementia, and seizures. The development of symptoms may be very insidious, often making an abscess difficult to diagnose.

Extradural brain abscesses are associated with localized pain, purulent drainage
from the nasal passages or auditory canal, fever, localized tenderness, and neck stiffness. Clinical manifestations of spinal cord abscesses have four stages: (1) spinal aching; (2) severe root pain, accompanied by spasms of the back muscles and limited vertebral movement; (3) weakness caused by progressive cord compression; and (4) paralysis.

**Evaluation and treatment**

The diagnosis is suggested by clinical features and confirmed by imaging studies. Antibiotics and surgical aspiration or excision is usually indicated. Intracranial pressure may have to be managed. Spinal cord abscesses are treated with surgical decompression or aspiration, antibiotic therapy, and supportive therapy.

**Encephalitis**

*Encephalitis* is an acute febrile illness, usually of viral origin, with nervous system involvement. The most common forms are caused by bites of mosquitoes, ticks, or flies. Herpes simplex type 1 is the most common sporadic cause of encephalitis. Viruses infect specific cell types in the CNS as shown in Figure 16-13. Referred to as infectious viral encephalitides, encephalitis may occur as a complication of systemic viral diseases such as poliomyelitis, rabies, or mononucleosis, or it may arise after recovery from viral infections such as rubella, varicella, rubeola, or yellow fever. Encephalitis also may follow vaccination with a live attenuated virus vaccine if the vaccine has an encephalitis component, for example, measles, mumps, and rubella. Typhus, trichinosis, malaria, and schistosomiasis also are associated with encephalitis. Toxoplasmosis may acutely reactivate in immunosuppressed persons when the once-dormant parasite in cyst form disseminates in brain tissues.

With the exception of the California viral encephalitis, which is endemic, the arthropod-borne encephalitides occur in epidemics, varying in geographic and seasonal incidence (Table 16-8 and Health Alert: West Nile Virus). Eastern equine encephalitis is the most serious but least common of the encephalitides.

**Health Alert**

**West Nile Virus**

*West Nile virus (WNV)*, a *Flavivirus* transmitted predominantly by the *Culex* mosquito, emerged in New York State in 1999. It is the most common cause of epidemic meningoencephalitis in North America and the leading cause of arboviral encephalitis in the United States. By the end of 2004, human cases had been found in
the 48 contiguous states. Humans and horses, as well as other mammals, are incidental hosts. Birds and mosquitoes are life cycle hosts. Summer and fall are peak times of infection incidence. The greatest amount of virus is carried by mosquitoes in early fall. Besides mosquito transmission, WN virus can be transmitted through blood transfusions and organ transplants. Health experts think that transmission from mother to unborn child and through breast milk is possible.

The human incubation period is 2 to 14 days. Most individuals develop no symptoms. About 20% of those infected have mild symptoms that last 4 to 6 days and generally include fever, headache, skin rash, and lymphadenopathy. Less than 1% of affected persons develop severe illness, including WN encephalitis marked by headache, disorientation, stupor, coma, seizures, and movement disorders including tremor, ataxia, extrapyramidal signs, and paralysis. WN meningitis is characterized by meningeal signs of severe headache, high fever, and nuchal rigidity. Myelitis and polyradiculitis also may be present. Abnormalities in the thalamus, basal ganglia, and cerebellum are often seen on MRI in people with severe infection. Identifiable risk factors are very young or advanced in age, immunocompromised, and pregnancy.

A preliminary diagnosis is made if IgM for the virus is found in serum or CSF. A rapid test became available in 2007. Plaque reduction neutralization assay (PRNA) is the confirmatory test. Treatment is supportive care. No West Nile vaccine has been developed for humans. Environmental control and prevention of mosquito bites is the best protection. Since 2003 all blood banks use blood-screening tests for West Nile virus.

### Pathophysiology

Viruses gain access to the CNS through the bloodstream, olfactory bulb, or choroid plexus, or through an intraneuronal route from peripheral nerves. Meningeal involvement is present in all encephalitides. The various encephalitides may cause widespread nerve cell degeneration. Edema, necrosis with or without hemorrhage, and increased intracranial pressure develop.

### Clinical manifestations

Encephalitis ranges from a mild infectious disease to a life-threatening disorder. Mild symptoms include malaise, headache, body aches, nausea, and vomiting. Dramatic clinical manifestations include fever, delirium or confusion progressing to unconsciousness, difficulty with word finding, seizure activity, cranial nerve palsies, paresis and paralysis, involuntary movement, and abnormal reflexes. Signs of marked intracranial pressure may be present.

### Evaluation and treatment

Diagnosis is made by history and clinical presentation aided by CSF examination and culture, serologic studies, white blood cell count, CT scan, or MRI. Empirical treatment is specific to the type of virus and may include antiviral agents, antibiotics, and steroids. Herpes encephalitis is treated with antiviral agents, such as acyclovir. Measures to control intracranial pressure are paramount.\(^1\)

### Neurologic Complications of Acquired Immunodeficiency
Syndrome (AIDS)

From 40% to 60% of all persons with AIDS (see Chapter 8) have neurologic complications. The most common neurologic disorder is HIV-associated neurocognitive disorder. Others are peripheral neuropathies, vacuolar (spongy softening) myelopathy, opportunistic infections of the CNS, neoplasms, and, less commonly, stroke syndromes.\(^{82}\)

**Human immunodeficiency virus–associated neurocognitive disorder (HAND).**

A variety of names have been used for HAND, including HIV-associated cognitive dysfunction, HIV encephalopathy, subacute encephalitis, HIV-associated dementia complex, HIV cognitive motor complex, AIDS encephalopathy, AIDS dementia complex, and AIDS-related dementia. Both adults and children may be affected by progressive cognitive dysfunction with motor and behavioral alterations. The syndrome typically develops later in the disease but may be an early or singular manifestation in some persons. The syndrome is more prevalent in drug users with HIV. Highly active antiretroviral therapy (HAART) with more efficient CNS drug penetration has reduced the prevalence and improved survival for severe HAND, but milder forms of the disease may persist because of longer life.

The neurologic syndromes develop from properties of the virus, genetic characteristics of the host, and interactions with the environment (including treatment). At the time of primary HIV infection, HIV infects the perivascular macrophages, microglial cells, and astrocytes, particularly the basal ganglia and deep white matter. Affected macrophages, macrophage-derived multinucleated cells, and microglia cause an immune-mediated demyelination process in white matter. Focal and diffuse demyelination of white matter and spongy changes of the spinal cord are present.

HAND is insidious in onset and unpredictable in its course. Most persons experience a steady progression of mental decline characterized by abrupt accelerations of signs over several months to more than 1 year. The triad of clinical manifestations are neurocognitive impairment, behavioral disturbance, and motor abnormalities. Specific manifestations can include an organic psychosis with agitation, inappropriate behavior, and hallucinosis. Motor signs include difficulty speaking; progressive loss of balance; gait ataxia; spastic paraparesis or paralysis; and generalized hyperreflexia sometimes accompanied by decreased writing ability, tremor, myoclonus, and seizure.

Diagnosis is difficult, especially in early stages, and CSF analysis, CT scan, and MRI data help establish the diagnosis. HIV antiretroviral treatment is continued.
Although CNS drug penetration is reduced there is decreased prevalence and improved survival for individuals with severe HAND. 

**HIV myelopathy.**

**HIV myelopathy** involves diffuse degeneration of the spinal cord in persons with HIV. **Vacuolar myelopathy** is thought to be a direct consequence of HIV. The lateral and posterior columns of the lumbar spinal cord are affected. Progressive spastic paraparesis with ataxia is the predominant clinical manifestation. Leg weakness, upper motor neuron signs, incontinence, and posterior column sensory loss may be present. Diagnosis is made on the basis of history, physical findings, and supporting data from diagnostic procedures. Treatment is supportive.

**HIV-associated peripheral neuropathy.**

HIV may directly infect nerves and cause **HIV distal symmetric polyneuropathy**, most commonly sensory neuropathy. Persons experience neuropathic pain including pain burning sensations and numbness commonly in the extremities. Weakness and decreased or absent distal reflexes may be present. Diagnosis is established through history and physical findings, laboratory data, and nerve conduction and electromyogram (EMG) studies.

**Viral meningitis and HIV.**

Some persons develop acute viral meningitis at approximately the time of seroconversion. This may represent the initial infection of the nervous system by the virus. Symptoms include headache, fever, and meningismus (headache, photophobia, nuchal rigidity). Cranial nerve involvement, especially V and VII, may appear, but the disease is self-limiting and requires only symptomatic treatment.

**Opportunistic infections and HIV.**

Opportunistic infections may be bacterial, fungal, or viral in origin and may produce neurologic disease. Typically, bacterial infections are caused by unusual microorganisms. Cryptococcal infection is the most common fungal disorder and the third leading cause of neurologic disease in persons with AIDS. The symptoms are vague, such as fever, headache, malaise, and meningismus. Herpes encephalitis and herpes varicella-zoster radiculitis may develop. Papovavirus may produce a demyelinating disorder. Cytomegalovirus encephalitis, toxoplasmosis (a protozoal infection), and tuberculosis meningitis have a high incidence in African countries.
CNS neoplasms and HIV.
The incidence of HIV-associated CNS neoplasms has declined significantly with HAART, particularly primary CNS lymphoma. Other neoplasms associated with HIV include systemic non-Hodgkin lymphoma and metastatic Kaposi sarcoma. Primary CNS lymphoma is a large-cell tumor that presents as rapidly developing and expanding multicentric intracranial mass lesions. The meninges and, possibly, the cranial nerves and spinal cord are invaded in systemic non-Hodgkin lymphoma. Metastasis of a Kaposi sarcoma to the CNS is uncommon.

Demyelinating Disorders
Demyelinating disorders result from damage to the myelin nerve sheath and affect neural transmission. They can occur in either the central (i.e., multiple sclerosis) or the peripheral (i.e., Guillain-Barré syndrome) nervous system. Contributing factors include genetics, infections, autoimmune reactions, environmental toxins, and unknown factors.

Multiple Sclerosis
Multiple sclerosis (MS) is a chronic inflammatory disease involving degeneration of CNS myelin, scarring (sclerosis or plaque formation), and loss of axons. MS is caused by an autoimmune response to self or microbial antigens in genetically susceptible individuals. The onset of MS is usually between 20 and 40 years of age and is more common in women. Men may have a more severe progressive course. The prevalence rate is higher in northern latitudes. Risk factors that may be involved include smoking, vitamin D deficiency, and Epstein-Barr virus infection. The etiology of MS is unknown.

Pathophysiology
MS is a diffuse and progressive disease with patches of damage that can occur throughout the brain and spinal cord. Autoreactive T and B cells cross the blood-brain barrier and recognize myelin and oligodendrocyte autoantigens, triggering inflammation and loss of oligodendrocytes (myelin producing cells). Activation of microglia cells (brain macrophages) contributes to inflammation and injury with plaque formation and axonal degeneration. Loss of myelin disrupts nerve conduction with subsequent death of neurons and brain atrophy. Normal appearing white matter can be microscopically very abnormal and gray matter lesions and atrophy have been documented during later stages of the disease process. These degenerative processes begin before symptom onset and progress throughout a
person's life (Figure 16-14). Myelin degeneration also can present as optic neuritis or involve the spinal cord. Spinal MS can occur concurrently or independently of brain lesions. The multifocal, multistaged features of MS lesions in established disease produce symptoms that are multiple and variable.
FIGURE 16-14  Pathogenesis of Multiple Sclerosis.
Clinical manifestations

The most common initial symptoms of MS are paresthesias of the face, trunk, or limbs; weakness; impaired gait; visual disturbances; or urinary incontinence, indicating diffuse CNS involvement. Cerebellar and corticospinal involvement presents as nystagmus, ataxia, and weakness with all four limbs involved. Intention tremor and slurred speech may also occur.

The onset, duration, and severity of symptoms are different for each person. Disease exacerbations (also known as relapses or flares) are the temporary occurrence or worsening of symptoms. The symptoms may be mild or serious, may last for several days or weeks, and may be followed by progressive symptoms, including include paresthesias, difficulty speaking, ataxia, or visual changes. The mechanism of these exacerbations is related to delayed or blocked conduction caused by inflammation and demyelination. Various events can occur immediately before the exacerbation of symptoms and are regarded as precipitating factors or triggers, including trauma, emotional stress, and pregnancy. Painful sensory events, spastic paralysis, and bowel and bladder incontinence are common with spinal involvement. Recovery from symptoms during remissions is caused by down-regulation of inflammation and the restoration of axonal function, either by remyelination, the resolution of inflammation, or the restoration of conduction to demyelinated axons.

The subtypes of MS are based on the clinical course: (1) remitting-relapsing, initial onset of symptoms followed by remission and exacerbations; (2) primary-progressive, a steady decline from onset; (3) secondary-progressive, initial remitting and relapsing symptoms with a steady decline in function; and (4) progressive-relapsing, a progressive course from onset with superimposed relapses. Initially, 85% to 90% of persons present with a remitting-relapsing course and without treatment transition to the progressive types with insidious neurologic decline. Early cognitive changes are common and may include poor judgment, apathy, emotional lability, and depression.

Evaluation and treatment

There is no single test available to diagnose or rule out MS. Diagnostic criteria include the history and clinical examination in combination with MRI (most sensitive test), CSF findings, and evoked potentials. Persistently elevated levels of CSF immunoglobulin G (IgG) are found in about two thirds of individuals with MS, and oligoclonal IgG bands on electrophoresis are found in more than 90% of MS patients. Evoked potential studies aid diagnosis by detecting decreased conduction velocity in visual, auditory, and somatosensory pathways. MRI is the most sensitive available method of detecting demyelinated plaques and monitoring disease.
The treatment goal in MS is prevention of exacerbations, prevention of permanent neurologic damage, and control of symptoms. Disease-modifying drugs are initiated with diagnosis and include corticosteroids, immunosuppressants, and immune system modulators. Continuous monitoring is important because of the increased risk for infection when taking these drugs. Plasma exchange may be used in persons who do not respond to steroids. Drugs are also available for symptom control. The long-term benefit of these drugs is under investigation. Supportive care includes participation in a regular exercise program, cessation of smoking, and avoidance of overwork, extreme fatigue, and heat exposure. The administration of vitamin D to prevent disease progression is being evaluated. Stem cell therapy is under investigation.

**Guillain-Barré Syndrome**

*Guillain-Barré syndrome* is a rare demyelinating disorder caused by a humoral and cell-mediated immunologic reaction directed at the peripheral nerves. It usually occurs after a respiratory tract or gastrointestinal infection. The clinical manifestations can vary from paresis of the legs to complete quadriplegia, respiratory insufficiency, and autonomic nervous system instability. Intravenous immunoglobulin or plasmapheresis is used during the acute phase and followed by aggressive rehabilitation. Recovery occurs within weeks to months or up to 2 years. About 30% of individuals have residual weakness.

**Quick Check 16-3**

1. What are two differences between the symptoms of migraine and cluster headaches?

2. How can bacterial meningitis lead to an amputation?

3. What are the autoimmune mechanisms that cause MS lesions?
Peripheral Nervous System and Neuromuscular Junction Disorders

Peripheral Nervous System Disorders

Disease processes may injure the axons traveling to and from the brainstem and spinal cord neuronal cell bodies. The injury may affect a distinct anatomic area on the axon, or the spinal nerves may be injured at the roots, at the plexus (plexus injuries) before peripheral nerve formation, or at the nerves themselves. The cranial nerves do not have roots or plexuses and are affected only within themselves. Autonomic nerve fibers may be injured as they travel in certain cranial nerves and emerge through the ventral root and plexuses to pass through the peripheral nerves of the body. Peripheral nervous system disorders are summarized in Table 16-9.

**TABLE 16-9**
Peripheral Nervous System Disorders

Neuromuscular Junction Disorders

Transmission of the nerve impulse at the neuromuscular junction requires the release of adequate amounts of neurotransmitter from the presynaptic terminals of the axon and effective binding of the released transmitter to the receptors on the membranes of muscle cells (see Figure 13-15). [Myasthenia gravis is the most...
prevailant of the neuromuscular junction disorders and is presented next.]

**Myasthenia Gravis**

*Myasthenia gravis* is an acquired chronic autoimmune disease mediated by antibodies against the acetylcholine receptor (AChR) at the postsynaptic membrane of the neuromuscular junction. The incidence is about 9 to 21 per million population and it is more common in women. Thymic tumors, pathologic changes in the thymus, and other autoimmune diseases are associated with the disorder. (Autoimmune mechanisms are discussed in Chapter 8.) **Ocular myasthenia**, more common in males, involves weakness of the eye muscles and eyelids, and may include swallowing difficulties and slurred speech.

**Pathophysiology**

Myasthenia gravis results from a defect in nerve impulse transmission at the neuromuscular junction. The postsynaptic AChRs on the muscle cell’s plasma membrane are no longer recognized as “self” and elicit T-cell–dependent formation of IgG autoantibodies. The autoantibodies fix onto ACh receptor sites, blocking the binding of acetylcholine. Eventually the antibody action destroys receptor sites. This loss of AChR sites causes diminished transmission of the nerve impulse across the neuromuscular junction and decreased muscle depolarization. Symptomatic individuals without anti-AChR antibodies may have antibodies against muscle-specific kinase (MuSK) with similar symptoms. Why this autosensitization occurs is unknown.

**Clinical manifestations**

Myasthenia gravis has an insidious onset. The variable distribution of ACh receptor sites or the number of and different isoforms of antibodies may determine when and which muscle groups are affected first. The muscles of the eyes, face, mouth, throat, and neck usually are affected first. There can be drooling and difficulty chewing and swallowing food. These problems can affect nutrition and put the person at risk for respiratory aspiration. The muscles of the neck, shoulder girdle, and hip flexors are less frequently affected but muscle fatigue is common after exercise and there can be progressive weakness. The respiratory muscles of the diaphragm and chest wall can become weak with impaired ventilation. Clinical manifestations may first appear during pregnancy, during the postpartum period, or in conjunction with the administration of certain anesthetic agents. The progression of myasthenia gravis varies, appearing first as a mild case that spontaneously remits, with a series of relapses and symptom-free intervals ranging from weeks to months. Over time, the
disease can progress. **Myasthenic crisis** can develop as the disease progresses and occurs when severe muscle weakness causes extreme quadripareisis or quadriplegia, respiratory insufficiency with shortness of breath, and extreme difficulty in swallowing. The individual in myasthenic crisis is in danger of respiratory arrest.

**Cholinergic crisis** may arise from anticholinesterase drug toxicity with increased intestinal motility, episodes of diarrhea and complaints of intestinal cramping, bradycardia, pupillary constriction, increased salivation, and diaphoresis. These symptoms are caused by the smooth muscle hyperactivity secondary to excessive accumulation of acetylcholine at the neuromuscular junctions and excessive parasympathetic-like activity. As in myasthenic crisis, the individual is in danger of respiratory arrest.

**Evaluation and treatment**

The diagnosis of myasthenia gravis is made on the basis of a response to edrophonium chloride (Tensilon), results of EMG studies, and detection of anti-AChR or MuSK antibodies. With the intravenous administration of the drug, immediate demonstrable improvement in muscle strength usually persists for several minutes. Mediastinal tomography and MRI help determine whether a thymoma is present. Current treatments for myasthenia gravis have improved prognosis, including in those who have ocular myasthenia.

Anticholinesterase drugs, steroids, and immunosuppressant drugs (e.g., azathioprine and cyclosporine) are used to treat myasthenia gravis and prevent myasthenic crisis. For individuals with cholinergic crisis, anticholinergic drugs are withheld until blood levels are nontoxic; in addition, ventilatory support is provided and respiratory complications are prevented. Plasmapheresis may be lifesaving. Thymectomy is the treatment of choice in individuals with a thymoma and those with anti-AChR antibodies because this terminates the production of self-reactive T cells and B cells that produce the antibodies. 98,99

**Quick Check 16-4**

1. Where in the peripheral nervous system can disease occur?

2. Why do antibodies contribute to the symptoms of myasthenia gravis?

3. How do myasthenic crisis and cholinergic crisis differ in terms of cause and treatment?
Tumors of the Central Nervous System

CNS tumors include both brain and spinal cord tumors. Primary CNS tumors had an estimated 22,850 new cases and 15,320 deaths in the United States in 2015.\textsuperscript{100} The incidence of CNS tumors increases to age 70 years and then decreases. CNS tumors are the second most common group of tumors occurring in children. Approximately 70% to 75% of all intracranial tumors in children are located infratentorially (see Chapter 17), and in adults 70% are located supratentorially. Peripheral nerve tumors are rare in children and common in adults. Carcinogenesis is discussed in Chapter 10, pituitary tumors are discussed in Chapter 19, and cerebral tumors in children are discussed in Chapter 17.

Brain Tumors

Tumors within the cranium can be either primary or metastatic. Primary brain tumors originate from brain substance, including neuroglia, neurons, cells of blood vessels, and connective tissue. Extracerebral tumors originate outside substances of the brain and include meningiomas, acoustic nerve tumors, and tumors of pituitary and pineal glands. Metastatic (secondary) brain tumors arise in organ systems outside the brain and spread to the brain. Sites of intracranial tumors are illustrated in Figure 16-15.

Local effects of cranial tumors are caused by the destructive action of the tumor...
itself on a particular site in the brain and by compression causing decreased cerebral blood flow. Generalized effects result from increased intracranial pressure caused by growth of the tumor, obstruction of the ventricular system, hemorrhages in and around the tumor, or cerebral edema (Figure 16-16). Manifestations include seizures, visual disturbances, unstable gait, and cranial nerve dysfunction.

Intracranial brain tumors do not metastasize as readily as tumors in other organs because there are no lymphatic channels within the brain substance. If metastasis does occur, it is usually through seeding of cerebral blood or CSF during cranial surgery or through artificial shunts.

**Primary Brain (Intracerebral) Tumors**

**Primary brain (intracerebral) tumors**, also called gliomas, include astrocytomas, oligodendrogliomas, and ependymomas. They make up 50% to 60% of all adult brain tumors and about 2% of all cancers in the United States (Table 16-10). The World Health Organization (WHO) divides gliomas into four grades based on histopathologic features, cellular density, atypia, mitotic activity, microvascular proliferation, and necrosis (Table 16-11). Grades I and II are generally benign or slow growing. Grades III and IV are malignant tumors. Etiology for primary brain tumors is not clearly known. Ionizing radiation is the only known environmental risk factor. There may be an association between mobile phone use and gliomas and acoustic neuromas.\(^{101,102}\)

*World Health Organization Grading of Central Nervous System Tumors.*

Surgical or radiosurgical excision, surgical decompression, chemotherapy, radiotherapy, and hyperthermia are treatment options for these tumors. Supportive treatment is directed at reducing edema. New treatment options are emerging. (Cancer treatment is discussed in Chapter 10.)

### Astrocytoma.

**Astrocytomas** are the most common glioma (about 35% to 50% of all tumors of the brain and spinal cord) and are graded by two classification systems (see Table 16-11). These tumor cells are thought to have lost normal growth restraint and thus proliferate uncontrollably. Astrocytomas are graded I through IV, with grades I and II being slow-growing tumors that are most common in children. Grade I and II astrocytomas commonly progress to a higher grade, faster growing tumor. They may occur anywhere in the brain or spinal cord, and are generally located in the cerebrum, hypothalamus, or pons. Low-grade astrocytomas tend to be located laterally or supratentorially in adults and in a midline or near-midline position in children.

Headache and subtle neurobehavioral changes may be early signs with other neurologic symptoms evolving slowly and increased intracranial pressure occurring late in the tumor's course. Onset of a focal seizure disorder between the second and sixth decade of life suggests an astrocytoma. Low-grade astrocytomas are treated with surgery or by external radiation, and at least 50% of persons survive 5 years when surgery is followed by radiation therapy (RT).

Grades III and IV astrocytomas are found predominantly in the frontal lobes and cerebral hemispheres, although they may occur in the brainstem, cerebellum, and
spinal cord. Men are twice as likely to have astrocytomas as women; in the 15- to 34-year-old age group they are the third most common brain cancer, whereas in the 35- to 54-year-old age group they are the fourth most common.

Grade IV astrocytoma, *glioblastoma multiforme*, is the most lethal and common type of primary brain tumor. They are highly vascular and extensively irregular and infiltrative, making them difficult to remove surgically. Fifty percent of glioblastomas are bilateral or at least occupy more than one lobe at the time of death. The typical clinical presentation for a glioblastoma multiforme is that of diffuse, nonspecific clinical signs, such as headache, irritability, and “personality changes” that progress to more clear-cut manifestations of increased intracranial pressure, including headache on position change, papilledema, vomiting, or seizure activity. Symptoms may progress to include definite focal signs, such as hemiparesis, dysphasia, dyspraxia, cranial nerve palsies, and visual field deficits.

Higher grade astrocytomas are treated surgically and with radiotherapy and chemotherapy. Recurrence is common and survival time is less than 5 years.\textsuperscript{104}

**Oligodendroglioma.**

*Oligodendrogliomas* constitute about 2% of all brain tumors and 10% to 15% of all gliomas. They are typically slow-growing tumors, and most oligodendrogliomas are macroscopically indistinguishable from other gliomas and may be a mixed type of oligodendroglioma and astrocytoma. Most are found in the frontal and temporal lobes, often in the deep white matter, but they are found also in other parts of the brain and spinal cord. Many are found in young adults with a history of temporal lobe epilepsy. Malignant degeneration occurs in approximately one third of persons with oligodendrogliomas, and the tumors are then referred to as oligodendroblastomas.

More than 50% of individuals experience a focal or generalized seizure as the first clinical manifestation. Only half of those with an oligodendroglioma have increased intracranial pressure at the time of diagnosis and surgery, and only one third develop focal manifestations. Treatment includes surgery, radiotherapy, and chemotherapy.

**Ependymoma.**

*Ependymomas* are nonencapsulated gliomas that arise from ependymal cells; they are rare in adults, usually occurring in the spinal cord.\textsuperscript{105} However, in children ependymomas are typically located in the brain. They constitute about 6% of all primary brain tumors in adults and 10% in children and adolescents. Approximately 70% of these tumors occur in the fourth ventricle, with others found in the third and
lateral ventricles and caudal portion of the spinal cord. Approximately 40% of infratentorial ependymomas occur in children younger than 10 years. Cerebral (supratentorial) ependymomas occur at all ages.

Fourth ventricle ependymomas present with difficulty in balance, unsteady gait, uncoordinated muscle movement, and difficulty with fine motor movement. The clinical manifestations of a lateral and third ventricle ependymoma that involves the cerebral hemispheres are seizures, visual changes, and hemiparesis. Blockage of the CSF pathway produces hydrocephalus and presents with headache, nausea, and vomiting.

The interval between first manifestations and surgery may be as short as 4 weeks or as long as 7 or 8 years. Ependymomas are treated with radiotherapy, radiosurgery, and chemotherapy. About 20% to 50% of persons survive 5 years. Some persons benefit from a shunting procedure when the ependymoma has caused a noncommunicating hydrocephalus.

**Primary Extracerebral Tumors**

**Meningioma.**

Meningiomas constitute about 34% of all intracranial tumors. These tumors usually originate from the arachnoidal (meningeal) cap cells in the dura mater and rarely from arachnoid cells of the choroid plexus of the ventricles. Meningiomas are located most commonly in the olfactory grooves, on the wings of the sphenoid bone (at the base of the skull), in the tuberculum sellae (next to the sella turcica), on the superior surface of the cerebellum, and in the cerebellopontine angle and spinal cord. Rarely, they can involve the optic nerve sheath with loss of visual acuity. The cause of meningiomas is unknown.

A meningioma is sharply circumscribed and adapts to the shape it occupies. It may extend to the dural surface and erode the cranial bones or produce an osteoblastic reaction. A few meningiomas exhibit malignant, invasive qualities.

Meningiomas are slow growing and clinical manifestations occur when they reach a certain size and begin to indent the brain parenchyma. Focal seizures are often the first manifestation and increased intracranial pressure is less common than with gliomas.

There is a 20% recurrence rate even with complete surgical excision. If only partial resection is possible, the tumor recurs. Radiation therapies also are used to slow growth.

**Nerve sheath tumors.**
Neurofibromas (benign nerve sheath tumors) are a group of autosomal dominant disorders of the nervous system. They include neurofibromatosis type 1 (NF1, previously known as von Recklinghausen disease) and neurofibromatosis type 2 (NF2); NF1 and NF2 are also known as peripheral and central neurofibromatosis, respectively.

Neurofibromatosis type 1 is the most prevalent with an incidence of about 1 in 3500 people and causes multiple cutaneous neurofibromas, cutaneous macular lesions (café-au-lait spots and freckles), and less commonly bone and soft tissue tumors. Inactivation of the NF1 gene results in loss of function of neurofibromin in Schwann cells and promotes tumorigenesis (neurofibromas). Learning disabilities are present in about 50% of affected individuals.\textsuperscript{107}

Neurofibromatosis type 2 is rare and occurs in about 1 in 60,000 people. The NF2 gene product is neurofibromin 2 (merlin), a tumor-suppressor protein, and mutations promote development of central nervous system tumors, particularly schwannomas, although other tumor types can occur (meningiomas, ependymomas, astrocytomas, and neurofibromas). Schwannomas of the vestibular nerves present with hearing loss and deafness. Other symptoms may include loss of balance and dizziness. Schwannomas also may develop in other cranial, spinal, and peripheral nerves, and cutaneous signs are less prominent.

Genetic testing is available for the management of families susceptible to NF, and prenatal diagnosis is possible. Diagnosis is based on clinical manifestations and neuroimaging studies, and diagnostic criteria have been established for NF1.\textsuperscript{109} Surgery is the major treatment. Individuals with NF2 have extensive morbidity and reduced life expectancy, particularly with early age of onset. Genetically tailored drugs are likely to provide personalized therapy for both of these devastating conditions.

**Metastatic brain tumors.**

Metastatic brain tumors from systemic cancers are 10 times more common than primary brain tumors and 20% to 40% of persons with cancer have metastasis to the brain.\textsuperscript{110} Common primary sites include lung, breast, and skin (e.g., melanomas), as well as kidney, colorectal, and other types of cancer. Metastasis to the brain is thought to be through vascular channels (see Chapter 10).

Metastatic brain tumors produce signs resembling those of glioblastomas, although several unusual syndromes do exist. Carcinomatous (metastatic cancer) encephalopathy causes headache, nervousness, depression, trembling, confusion, forgetfulness, and gait disorder. In carcinomatosis of the cerebellum, headache, dizziness, and ataxia are found. Carcinomatosis of the craniospinal meninges (also
called carcinomatous meningitis) manifests with headache, confusion, and symptoms of cranial or spinal nerve root dysfunction. Metastatic brain tumors carry a poor prognosis. Treatment is guided by the pathology of the original tumor; number, size and location of the brain metastasis; and prior cancer treatments. With the development of new drugs that cross the blood-brain barrier, chemotherapy is increasingly recommended. Survival is about 1 year.

**Spinal Cord Tumors**

Primary spinal cord tumors are rare and represent about 2% of CNS tumors. They may be extramedullary extradural, intradural extramedullary, or intradural intramedullary. Intramedullary tumors, originate within the neural tissues of the spinal cord. Extramedullary tumors, originate from tissues outside the spinal cord. Intramedullary tumors are primarily gliomas (astrocytomas and ependymomas). Gliomas are difficult to resect completely and radiotherapy is required. Spinal ependymomas may be completely resected and are more common in adults. Extramedullary tumors are either peripheral nerve sheath tumors (neurofibromas or schwannomas) or meningiomas. Neurofibromas are generally found in the thoracic and lumbar region, whereas meningiomas are more evenly distributed through the spine. Complete resection of these tumors can be curative. Other extramedullary tumors are sarcomas, vascular tumors, chordomas, and epidermoid tumors. Intramedullary tumors include ependymoma, astrocytoma and hemangioblastoma.

Metastatic spinal cord tumors are usually carcinomas (i.e., from breast, lung, or prostate cancer), lymphomas, or myelomas. Their location is often extradural, having proliferated to the spine through direct extension from tumors of the vertebral structures or from extraspinal sources extending through the interventricular foramen or bloodstream.

**Pathophysiology**

Intramedullary spinal cord tumors produce dysfunction by both invasion and compression. Extramedullary spinal cord tumors produce dysfunction by compressing adjacent tissue, not by direct invasion. Metastases from spinal cord tumors occur from direct extension or seeding through the CSF or bloodstream.

**Clinical manifestations**

An acute onset of clinical manifestations suggests a vascular occlusion of vessels supplying the spinal cord whereas gradual and progressive symptoms suggest compression. The **compressive syndrome (sensorimotor syndrome)** involves both
the anterior and the posterior spinal tracts, and motor function and sensory function are affected as the tumor grows. Pain is usually a presenting symptom.

The **irritative syndrome (radicular syndrome)** combines the clinical manifestations of a cord compression with radicular pain that occurs in the sensory root distribution and indicates root irritation. The segmental manifestations include segmental sensory changes, such as paresthesias and impaired pain and touch perception; motor disturbances, including cramps, atrophy, fasciculations, and decreased or absent deep tendon reflexes; and continuous spinal pain.

**Evaluation and treatment**

The diagnosis of a spinal cord tumor is made through bone scan, PET, CT-guided needle biopsy, or open biopsy. Involvement of specific cord segments is established. Any metastases also are identified. Treatment varies depending on the nature of the tumor and the person's clinical status, but surgery is essential for all spinal cord tumors.\(^{112}\)

### Quick Check 16-5

1. How is an encapsulated CNS tumor different from a nonencapsulated CNS tumor?
2. What are three types of spinal cord tumors?
3. What are some common signs and symptoms of compressive and irritative spinal cord tumor syndromes?
1. Motor vehicle crashes in children and falls in older adults are major risk factors for traumatic brain injury.

2. Causes of TBI include closed-head trauma (blunt) or open-head trauma (penetrating). Closed-head trauma is more common. Open-head trauma involves a skull fracture with exposure of the cranial vault to the environment.

3. Primary brain injury is caused by direct impact and involves neural injury, primary glial injury, and vascular responses.

4. Primary brain injuries can be focal or diffuse.

5. Focal brain injury includes contusion, laceration, extradural hematoma, subdural hematoma, intracerebral hematoma, and open-head trauma.

6. Diffuse brain injury (diffuse axonal injury [DAI]) results from shearing forces that result in axonal damage ranging from concussion to a severe DAI state.

7. Secondary brain injury develops from systemic and intracranial responses to primary brain trauma that result in further brain injury and neuronal death.

8. Spinal cord injury involves damage to neural tissues by compressing tissue, pulling or exerting tension on tissue, or shearing tissues so that they slide into one another. Vertebral fracture occurs with direct or indirect trauma.

9. Spinal cord injury may cause spinal shock with cessation of all motor, sensory, reflex, and autonomic functions below the transected area. Loss of motor and sensory function depends on the level of injury.

10. Neurogenic shock occurs with cervical or upper thoracic cord injury (above T5) and can occur concurrently with spinal shock.

11. Autonomic hyperreflexia (dysreflexia) is a syndrome of sudden, massive reflex sympathetic discharge associated with spinal cord injury at level T6 or above. Flexor spasms are accompanied by profuse sweating, piloerection, and automatic bladder emptying.
12. Complete cord transection results in paralysis. Paralysis of the lower half of the body with both legs involved is called *paraplegia*. Paralysis involving all four extremities is called *quadriplegia*.

13. Return of spinal neuron excitability occurs slowly. Reflex activity can return in 1 to 2 weeks in most persons with acute spinal cord injury. A pattern of flexion reflexes emerges, involving first the toes, then the feet and the legs. Eventually, reflex voiding and bowel elimination appear.

14. Low back pain is pain between the lower rib cage and gluteal muscles and often radiates into the thigh.

15. Most causes of low back pain are unknown; however, some secondary causes are disk prolapse, tumors, bursitis, synovitis, degenerative joint disease, osteoporosis, fracture, inflammation, and sprain.

16. Degenerative disk disease is an alteration in intervertebral disk tissue and can be related to normal aging.

17. Spondylolysis is a structural defect of the spine with displacement of the vertebra.

18. Spondylolisthesis involves forward slippage of the vertebra and can include a crack or fracture of the pars interarticularis, usually at the L5-S1 vertebrae.

19. Herniation of an intervertebral disk is a protrusion of part of the nucleus pulposus. Herniation most commonly affects the lumbosacral disks (L5-S1 and L4-5). The extruded pulposus compresses the nerve root, causing pain that radiates along the sciatic nerve course.

20. Cerebrovascular disease is the most frequently occurring neurologic disorder. Any abnormality of the blood vessels of the brain is referred to as a cerebrovascular disease.

21. Cerebrovascular disease is associated with two types of brain abnormalities: (1) ischemia with or without infarction and (2) hemorrhage.

22. Transient ischemic attacks (TIAs) are temporary decreases in brain blood flow.

23. Cerebrovascular accidents (stroke syndromes) are classified pathophysiologically as ischemic (thrombotic or embolic), hemorrhagic
(intracranial hemorrhage), or associated with hypoperfusion.

24. Intracranial aneurysms result from defects in the vascular wall and are classified on the basis of form and shape. They are often asymptomatic, but the signs vary depending on the location and size of the aneurysm.

25. An arteriovenous malformation (AVM) is a mass of dilated blood vessels. Although usually present at birth, symptoms are delayed and usually occur before age 30.

26. A subarachnoid hemorrhage occurs when blood escapes from defective or injured vasculature into the subarachnoid space. When a vessel tears, blood under pressure is pumped into the subarachnoid space. The blood produces an inflammatory reaction in these tissues and increased intracranial pressure.

27. Migraine headache is an episodic headache that can be associated with triggers, and may have an aura associated with a cortical spreading depression that alters cortical blood flow. Pain is related to overactivity in the trigeminal vascular system.

28. Cluster headaches are a group of disorders known as trigeminal autonomic cephalalgias and occur primarily in men. They occur in clusters over a period of days with extreme pain intensity and short duration, and are associated with trigeminal activation.

29. Tension-type headache is the most common headache. Episodic-type headaches involve a peripheral pain mechanism and the chronic type involves a central pain mechanism and may be related to hypersensitivity to pain in craniocervical muscles.

30. Infection and inflammation of the CNS can be caused by bacteria, viruses, fungi, protozoa, and rickettsiae. Bacterial infections are pyogenic or pus producing.

31. Meningitis (infection of the meninges) is classified as bacterial (i.e., meningococci), aseptic (viral or nonpurulent), or fungal. Bacterial meningitis primarily is an infection of the pia mater, the arachnoid, and the fluid of the subarachnoid space. Aseptic meningitis is thought to be limited to the meninges. Fungal meningitis is a chronic, less common type of meningitis.

32. Brain abscesses often originate from infections outside the CNS. Organisms gain access to the CNS from adjacent sites or spread along the wall of a vein. A localized inflammatory process develops with formation of exudate. After a few
days, the infection becomes delimited with a center of pus and a wall of granular tissue.

33. Encephalitis is an acute, febrile illness of viral origin with nervous system involvement. The most common encephalitides are caused by arthropod-borne (mosquito-borne) viruses and herpes simplex type 1. Meningeal involvement appears in all encephalitides.

34. Herpes encephalitis is treated with antiviral agents. No definitive treatment exists for the other encephalitides.

35. The common neurologic complications of AIDS are HIV-associated neurocognitive disorder, HIV myelopathy, opportunistic infections, cytomegalovirus infection, parasitic infection, and neoplasms. Pathologically, there may be diffuse CNS involvement, focal pathologic changes, and obstructive hydrocephalus.

Demyelinating Disorders

1. Multiple sclerosis (MS) is a relatively chronic inflammatory demyelinating disorder with scarring (sclerosis) and loss of axons. Although the pathogenesis is unknown, the demyelination is thought to result from an immunogenetic-viral cause in genetically susceptible individuals.

2. Guillain-Barré syndrome is a demyelinating disorder caused by a humoral and cell-mediated immunologic reaction directed at the peripheral nerves.

Peripheral Nervous System and Neuromuscular Junction Disorders

1. With disorders of the roots of spinal cord nerves, the roots may be compressed, inflamed, or torn. Clinical manifestations include local pain or paresthesias in the sensory root distribution. Treatment may involve surgery, antibiotics, steroids, radiation therapy, and chemotherapy.

2. Plexus injuries involve the plexus distal to the spinal roots. Paralysis can occur with complete plexus involvement.

3. When peripheral nerves are affected, axon and myelin degeneration may be
present. These syndromes are classified as sensorimotor, sensory, or motor and are characterized by varying degrees of sensory disturbance, paresis, and paralysis. Secondary atrophy may be present.

4. Myasthenia gravis is a disorder of voluntary muscles characterized by muscle weakness and fatigability. It is considered an autoimmune disease and is associated with an increased incidence of other autoimmune diseases.

5. Myasthenia gravis results from a defect in nerve impulse transmission at the postsynaptic membrane of the neuromuscular junction. IgG antibody is secreted against the “self” AChR receptors and blocks the binding of acetylcholine. The antibody action destroys the receptor sites, causing decreased transmission of the nerve impulse across the neuromuscular junction.

**Tumors of the Central Nervous System**

1. Two main types of tumors occur within the cranium: primary and metastatic. Primary tumors are classified as intracerebral tumors (astrocytomas, oligodendrogliaomas, and ependymomas) or extracerebral tumors (meningioma or nerve sheath tumors). Metastatic tumors can be found inside or outside the brain substance.

2. CNS tumors cause local and generalized manifestations. The effects are varied, and local manifestations include seizures, visual disturbances, loss of equilibrium, and cranial nerve dysfunction.

3. Spinal cord tumors are classified as intramedullary tumors (within the neural tissues) or extramedullary tumors (outside the spinal cord). Metastatic spinal cord tumors are usually carcinomas, lymphomas, or myelomas.

4. Extramedullary spinal cord tumors produce dysfunction by compression of adjacent tissue, not by direct invasion. Intramedullary spinal cord tumors produce dysfunction by both invasion and compression.
Key Terms

Arteriovenous malformation (AVM), 405
Astrocytomas, 416

Neurologic disorders in children can occur from infancy through adolescence and include congenital malformations, genetic defects in metabolism, brain injuries, infection, tumors, and other disorders that affect neurologic function.
Development of the Nervous System in Children

The nervous system develops from the embryonic ectoderm through a complex, sequential process that can be arbitrarily divided into stages. These include (1) formation of the neural tube (3 to 4 weeks' gestation), (2) development of the forebrain from the neural tube (2 to 3 months' gestation), (3) neuronal proliferation and migration (3 to 5 months' gestation), (4) formation of network connections and synapses (5 months' gestation to many years postnatally), and (5) myelination (birth to many years postnatally). Many different events happen simultaneously and critical periods must pass uninterrupted if the vulnerable fetus is to develop normally. Genetic and environmental factors (e.g., nutrition, hormones, oxygen levels, toxins, alcohol, drugs, maternal infections, maternal disease) can have a significant effect on neural development1,2 (see Health Alert: Alcohol-Related Neurodevelopmental Disorder [ARND]).

Health Alert

Alcohol-Related Neurodevelopmental Disorder (ARND)

ARND is a type of alcohol spectrum disorder with long-lasting neurobehavioral and cognitive deficiencies as a result of fetal alcohol exposure. It is among the most common causes of mental deficits that persist throughout adulthood. ARND is 100% preventable and there is no known amount of alcohol that is safe to consume while pregnant. Rates of alcohol consumption by women during pregnancy range from 5% to 15%.1-3 Alcohol crosses the placenta and the blood-brain barrier and exerts teratogenic effects on the developing brain throughout fetal development. Alcohol exposure during the first trimester can lead to fetal brain volume reduction and can be related to apoptosis, neurodegeneration, and suppression of neurogenesis.4 Fetal alcohol exposure during the second trimester is associated with dilation of the lateral ventricles, a reflection of decreased brain growth.5 Regions shown to be particularly susceptible to third-trimester binge drinking–induced neurodegeneration include the cerebellum; hippocampus; olfactory bulb; corpus callosum; occipital, cingulate, and parietal cortices; caudate nucleus; nucleus accumbens; and anterior thalamic nuclei.6 MRI imaging reveals delayed white matter development during childhood and adolescence in ARND and may underlie persistent or worsening behavioral and cognitive deficits during this critical period of development.7 Screening, education, and prevention programs...
promote alcohol-free pregnancies.\textsuperscript{8-10}

References

The growth and development of the brain occur rapidly from the third month of gestation through the first year of life, reflecting the proliferation of neurons and glial cells. Although basically all of the neurons that an individual will ever have are present at birth, development of skills, such as walking, talking, and thinking, depends on these cells making correct connections with other cells and on myelination of the axons making those connections. The head is the fastest growing body part during infancy. One half of postnatal brain growth is achieved by the first year and is 90% complete by age 6 years. The cortex thickens with maturation, and the sulci deepen as a result of rapid expansion of the surface area of the brain. Cerebral blood flow and oxygen consumption during these years are about twice those of the adult brain.

The bones of the infant's skull are separated at the suture lines, forming two \textbf{fontanelles}, or “soft spots”: one diamond-shaped anterior fontanelle and one triangular-shaped posterior fontanelle. The sutures allow for expansion of the rapidly growing brain. The posterior fontanelle may be open until 2 to 3 months of age; the anterior fontanelle normally does not fully close until 18 months of age (Figure 17-1). Head growth almost always reflects brain growth. Monitoring the fontanelles and careful measurement and plotting of the head circumference on standardized growth charts are essential elements of the pediatric examination. A
common cause of accelerating head growth and macrocephaly is hydrocephalus, a condition in which the cerebrospinal fluid (CSF) compartment (ventricles) is enlarged. Increased intracranial pressure, with distention or bulging of the fontanelles, and separation of the sutures are key signs of hydrocephalus. Microcephaly (head circumference below the 2nd percentile for age) can be the result of prenatal infection, toxin exposure, or malnutrition, or have a primary genetic etiology (see p. 427).

Because of the immaturity of much of the human forebrain at birth, neurologic examination of the infant detects mostly reflex responses that require an intact spinal cord and brainstem. Some of these reflex patterns are inhibited as cerebral cortical function matures, and these patterns disappear at predictable times during infancy (Table 17-1).

Absence of expected reflex responses at the appropriate age indicates general depression of central or peripheral motor functions. Asymmetric responses may indicate lesions in the motor cortex or peripheral nerves, or may occur with fractures of bones after traumatic delivery or postnatal injury. As the infant matures, the neonatal reflexes disappear in a predictable order as voluntary motor functions supersede them. Abnormal persistence of these reflexes is seen in infants with developmental delays or with central motor lesions.

**Quick Check 17-1**

1. When does development of neuronal myelination occur?
2. What is a major function of the fontanelles?
3. Why do many of the reflexes of infancy disappear by 1 year of age?
Structural Malformations

Central nervous system (CNS) malformations are responsible for 75% of fetal deaths and 40% of deaths during the first year of life. CNS malformations account for 33% of all apparent congenital malformations, and 90% of CNS malformations are defects of neural tube closure.

Defects of Neural Tube Closure

Neural tube defects (NTDs) are caused by an arrest of the normal development of the brain and spinal cord during the first month of embryonic development. They occur in about 3000 pregnancies in the United States each year, although there are significant regional prevalence variations. Fetal death often occurs in the more severe forms, thereby reducing the actual prevalence of neural defects at birth. Defects of neural tube closure are divided into two categories: (1) anterior midline defects (ventral induction) and (2) posterior defects (dorsal induction). Anterior midline defects may cause brain and face abnormalities with the most extreme form being cyclopia, in which the child has a single midline orbit and eye with a protruding noselike proboscis above the orbit. Spina bifida (split spine) is the most common neural tube defect and includes anencephaly (an, “without”; enkephalos, “brain”), encephalocele, meningocele, and myelomeningocele. Vertebrae fail to close in spina bifida. Myelomeningocele is a form of spina bifida with incomplete development of the spine and protrusion of both the spinal cord and the meninges through the skin. Meningocele is a form of spina bifida in which there is protrusion of the meninges but the spinal cord remains in the spinal canal. Disorders of embryonic neural development are summarized in Figure 17-2.
The cause of neural tube defects is believed to be multifactorial (a combination of genes and environment). No single gene has been found to cause neural tube defects but there can be associated mutations in folate-responsive/folate-dependent pathways. Folic acid deficiency during preconception and early stages of pregnancy increases the risk for neural tube defects, and supplementation (400 mcg of folic acid per day) ensures adequate folate status. Other risk factors include a
previous NTD pregnancy, maternal diabetes or obesity, use of anticonvulsant drugs (particularly valproic acid), and maternal hyperthermia.\textsuperscript{7,8}

Anencephaly is an anomaly in which the soft, bony component of the skull and part of the brain are missing. This is a relatively common disorder, with an incidence of approximately 1 per 4859 total live births in the United States each year.\textsuperscript{9} These infants are stillborn or die within a few days after birth. The pathologic mechanism is unknown. Diagnosis is often made prenatally by using ultrasound or evaluating maternal serum alpha fetoprotein (AFP).

Encephalocele refers to a herniation or protrusion of the brain and meninges through a defect in the skull, resulting in a saclike structure. The incidence is approximately 1.0 in 10,000 live births in the United States each year.\textsuperscript{10}

Meningocele is a saclike cyst of meninges filled with spinal fluid and is a mild form of spina bifida (Figure 17-3). It develops during the first 4 weeks of pregnancy when the neural tube fails to close completely. The cystic dilation of meninges protrudes through the vertebral defect but does not involve the spinal cord or nerve roots and may produce no neurologic deficit or symptoms. Meningoceles occur with equal frequency in the cervical, thoracic, and lumbar spine areas.
A. Normal

B. Spina bifida

C. Meningocele

D. Myelomeningocele

E. Myelomeningocele with an intact sac
Myelomeningocele (meningomyelocele; spina bifida cystica) is a hernial protrusion of a saclike cyst (containing meninges, spinal fluid, and a portion of the spinal cord with its nerves) through a defect in the posterior arch of a vertebra. Eighty percent of myelomeningoceles are located in the lumbar and lumbosacral regions, the last regions of the neural tube to close. Myelomeningocele is one of the most common developmental anomalies of the nervous system, with an incidence rate ranging from 0.5 to 1.0 per 1000 pregnancies.\textsuperscript{11}

Meningocele and myelomeningoceles are evident at birth as a pronounced skin defect on the infant's back (see Figure 17-3). The bony prominences of the unfused neural arches can be palpated at the lateral border of the defect. The defect usually is covered by a transparent membrane that may have neural tissue attached to its inner surface. This membrane may be intact at birth or may leak cerebrospinal fluid (CSF), thereby increasing the risks of infection and neuronal damage.

The spinal cord and nerve roots are malformed below the level of the lesion, resulting in loss of motor, sensory, reflex, and autonomic functions. A brief neurologic examination concentrating on motor function in the legs, reflexes, and sphincter tone is usually sufficient to determine the level above which spinal cord and nerve root function is preserved (Table 17-2). This is useful to predict if the child will ambulate, require bladder catheterization, or be at high risk for developing scoliosis (see Chapter 40).

Hydrocephalus occurs in 85% of infants with myelomeningocele.\textsuperscript{12} Seizures also occur in 30% of those with myelodysplasia. Visual and perceptual problems, including ocular palsies, astigmatism, and visuoperceptual deficits, are common. Motor and sensory functions below the level of the lesions are altered. Often these problems worsen as the child grows and the cord ascends within the vertebral canal,
pulling primary scar tissue and tethering the cord. Several musculoskeletal deformities are related to this diagnosis, as are spinal deformities.

Myelomeningoceles are almost always associated with the **Chiari II malformation (Arnold-Chiari malformation)**. This is a complex malformation of the brainstem and cerebellum in which the cerebellar tonsils are displaced downward into the cervical spinal canal; the upper medulla and lower pons are elongated and thin; and the medulla is also displaced downward and sometimes has a “kink” (Figure 17-4). The Chiari II malformation is associated with hydrocephalus from pressure that blocks the flow of cerebrospinal fluid; syringomyelia, an abnormality causing cysts at multiple levels within the spinal cord; and cognitive and motor deficits.
Other types of Chiari malformations are not associated with spina bifida. Type I Chiari malformation does not involve the brainstem and may be asymptomatic. In type III, the brainstem or cerebellum extends into a high cervical myelomeningocele. Type IV is characterized by lack of cerebellar development.

Most cases of meningocele and myelomeningocele are diagnosed prenatally by a combination of maternal serologic testing (alpha fetoprotein) and prenatal ultrasound. In these cases, the fetus is usually delivered by elective cesarean section to minimize trauma during labor. Surgical repair is critical and can be performed by in utero fetal surgery or during the first 72 hours of life.\textsuperscript{15,16}

It is possible for a defect to occur without any visible exposure of meninges or neural tissue and the term \textit{spina bifida occulta} is then used. The defect is common and occurs to some degree in 10\% to 25\% of infants. Spina bifida occulta usually causes no neurologic dysfunction because the spinal cord and spinal nerves are normal. \textbf{Tethered cord syndrome} may develop after surgical correction for myelomeningocele. The cord becomes abnormally attached or tethered as a result of scar tissue as the cord transcends the vertebral canal with growth.\textsuperscript{17}

**Craniosynostosis**

Skull malformations range from minor, insignificant defects to major defects that are incompatible with life. \textbf{Craniosynostosis} (craniostenosis) is the premature closure of one or more of the cranial sutures (sagittal, coronal, lambdoid, metopic) during the first 18 to 20 months of the infant's life. The incidence of craniosynostosis is 1 per 1800 to 2200 live births.\textsuperscript{18} Males are affected twice as often as females. Fusion of a cranial suture prevents growth of the skull perpendicular to the suture line, resulting in an asymmetric shape of the skull. The general term \textit{plagiocephaly}, meaning “misshapen skull,” is used to describe deformities that result from craniosynostosis or from asymmetric head posture (positional). When a single coronal suture fuses prematurely, the head is flattened on that side in front. When the sagittal suture fuses prematurely, the head is elongated in the anteroposterior direction (scaphocephaly).\textsuperscript{19} Single suture craniosynostosis is usually only a cosmetic issue. Rarely, when multiple sutures fuse prematurely, brain growth may be restricted, and surgical repair may prevent neurologic dysfunction (\textbf{Figure 17-5}). Syndromic craniosynostosis involves deformities in other systems (i.e., the heart, limbs, and central nervous system).
Malformations of Brain Development

Reduced proliferation or accelerated apoptosis causes congenital microcephaly (microencephaly—small brain) and increased proliferation causes megalencephaly (abnormally large brain).

Microcephaly is a defect in brain growth as a whole (see Figure 17-5). Cranial size is significantly below average for the infant's age, gender, race, and gestation. The small size of the skull reflects a small brain (microencephaly), which is caused
by reduced proliferation or accelerated apoptosis (Table 17-3). True (primary) microcephaly is usually caused by an autosomal recessive genetic or chromosomal defect. Secondary (acquired) microcephaly is associated with various causes including infection, trauma, metabolic disorders, maternal anorexia experienced during the third trimester of pregnancy, and the presence of other genetic syndromes. Children with microcephaly are usually developmentally delayed.

**Cortical dysplasias** are a heterogeneous group of disorders caused by defects in brain development. These disorders may range from a small area of abnormal tissue (e.g., heterotopia, which are pieces of gray matter that did not migrate to their normal position in the cortex of the brain; and focal cortical dysplasias, where brain organization in one small area is abnormal) to an entire brain that is smooth without the normal configuration of gyri and sulci of a developed brain (lissencephaly). The malformation occurs during brain formation. There is a specific genetic defect for some of these disorders; others are multifactorial or acquired (e.g., intrauterine trauma or infection). Cortical dysplasias increase the risk for seizures that are difficult to control, and cause developmental delay and motor dysfunction. Genetic testing assesses risk in other family members and guides therapy.

**Congenital hydrocephalus** is present at birth and characterized by increased cerebrospinal fluid (CSF) pressure. It may be caused by blockage within the ventricular system where the CSF flows, an imbalance in the production of CSF, or a reduced reabsorption of CSF. The increased pressure within the ventricular system dilates the ventricles and pushes and compresses the brain tissue against the skull cavity (Figure 17-6) When hydrocephalus develops before fusion of the cranial sutures, the skull can expand to accommodate this additional space-occupying volume and preserve neuronal function. The overall incidence of hydrocephalus is approximately 1 to 3 per 1000 live births. The incidence of hydrocephalus that is not associated with myelomeningocele is approximately 0.5 to
1 per 1000 live births.\textsuperscript{22} (Types of hydrocephalus are discussed in Chapter 15.)

Congenital hydrocephalus may cause fetal death in utero, or the increased head circumference may require cesarean delivery of the infant. Symptoms depend directly on the cause and rate of hydrocephalus development. When there is separation of the cranial sutures, a resonant note sounds when the skull is tapped, a manifestation termed \textbf{Macewen sign} or \textbf{“cracked pot” sign}. The eyes may assume a
staring expression, with sclera visible above the cornea, called *sunsetting*. Cognitive impairment in children with hydrocephalus is often related to associated brain malformations, or episodes of shunt failure or infection. Approximately 30% to 40% of children with uncomplicated congenital hydrocephalus complete schooling and are employed when treated successfully with shunting or endoscopic third ventriculostomy and choroid plexus cauterization.\(^{23-25}\)

The **Dandy-Walker malformation (DWM)** is a congenital defect of the cerebellum characterized by a large posterior fossa cyst that communicates with the fourth ventricle and an atrophic, upwardly rotated cerebellar vermis.\(^{26}\) DWM is commonly associated with hydrocephalus caused by compression of the aqueduct of Sylvius. Other causes of obstructions within the ventricular system that can result in hydrocephalus include brain tumors, cysts, trauma, arteriovenous malformations, blood clots, infections, and the Chiari malformations (see p. 425).

Alterations in Function: Encephalopathies

**Encephalopathy**, meaning brain pathology, is a general category that includes a number of syndromes and diseases (see Chapter 16). These disorders may be acute or chronic, as well as static or progressive.

**Static Encephalopathies**

Static or nonprogressive encephalopathy describes a neurologic condition caused by a fixed lesion without active and ongoing disease. Causes include brain malformations (disorders of neuronal migration) or brain injury that may occur during gestation or birth, or at any time during childhood. The degree of neurologic impairment is directly related to the extent of the injury or malformation. Anoxia, trauma, and infections are the most common factors that cause injury to the nervous system in the perinatal period. Infections, metabolic disturbances (acquired or genetic), trauma, toxins, and vascular disease may injure the nervous system in the postnatal period.

Cerebral palsy is a disorder of movement, muscle tone, or posture that is caused by injury or abnormal development in the immature brain, before, during, or after birth up to 1 year of age. Cerebral palsy is one of the most common crippling disorders of childhood, affecting nearly 500,000 children in the United States alone. Although the exact incidence is unknown, studies suggest that the prevalence is approximately 1 in 323 children in the United States.

Risk factors include prenatal or perinatal cerebral hypoxia, hemorrhage, infection, genetic abnormalities, or low birth weight. It can be classified on the basis of neurologic signs and motor symptoms, with the major types involving spasticity, dystonia, ataxia, or a combination of these symptoms (mixed). Diplegia, hemiplegia, or tetraplegia may be present.

Pyramidal/spastic cerebral palsy results from damage to corticospinal pathways (upper motor neurons) and is associated with increased muscle tone, persistent primitive reflexes, hyperactive deep tendon reflexes, clonus, rigidity of the extremities, scoliosis, and contractures. This accounts for approximately 70% to 80% of cerebral palsy cases. Extrapyramidal/nonspasitic cerebral palsy is caused by damage to cells in the basal ganglia, thalamus, or cerebellum and includes two subtypes: dystonic and atactic. Dystonic cerebral palsy is associated with extreme difficulty in fine motor coordination and purposeful movements. Movements are stiff, uncontrolled, and abrupt, resulting from injury to the basal ganglia or extrapyramidal tracts. This form of cerebral palsy accounts for approximately 10% to 20% of cases. Ataxic cerebral palsy is caused by damage to the cerebellum with
alterations in coordination and movement. There is a broad based gait in an attempt to maintain balance and tremor is common with intentional movements. This form of cerebral palsy accounts for approximately 5% to 10% of cases. A child may have symptoms of each of these cerebral palsy types, which leads to a mixed disorder accounting for approximately 13% of cases.29

Children with cerebral palsy often have associated neurologic disorders, such as seizures (about 50%), and intellectual impairment ranging from mild to severe (about 67%). Other complications include visual impairment, communication disorders, respiratory problems, bowel and bladder problems, and orthopedic disabilities.30

**Inherited Metabolic Disorders of the Central Nervous System**

A large number of inherited metabolic disorders have been identified, typically leading to diffuse brain dysfunction. Early diagnosis and treatment is vital if these infants are to survive without severe neurologic problems. Newborn metabolic screening for 28 metabolic conditions (in most states) has led to most of these children being identified before symptoms develop. Table 17-4 lists some of these inherited metabolic disorders. Inborn errors of metabolism are present at birth and most cause disturbances of the nervous system, although they may not manifest until childhood or even adulthood. Defects in amino acid and lipid metabolism are among the most common.

Defects in Amino Acid Metabolism

Biochemical defects in amino acid metabolism include (1) those in which the transport of an amino acid is impaired, (2) those involving an enzyme or cofactor deficiency, and (3) those encompassing certain chemical components, such as branched-chain or sulfur-containing amino acids. Most of these disorders are caused by genetic defects resulting in lack of a normal protein and absence of enzymatic activity.

Phenylketonuria.

Phenylketonuria (PKU) is an example of an inborn error of metabolism characterized by phenylalanine hydroxylase deficiency and the inability of the body to convert the essential amino acid phenylalanine to tyrosine (Figure 17-7). PKU is an autosomal recessive inborn error of metabolism characterized by mutations of the phenylalanine hydroxylase (PAH) gene. PKU has an incidence of 1 per 15,000 live births in the United States.\(^{31,32}\)
Most natural food proteins contain about 15% phenylalanine, an essential amino acid. Phenylalanine hydroxylase controls the conversion of this essential amino acid to tyrosine in the liver. The body uses tyrosine in the biosynthesis of proteins, melanin, thyroxine, and the catecholamines in the brain and adrenal medulla. Phenylalanine hydroxylase deficiency causes an accumulation of phenylalanine in the serum. Elevated phenylalanine levels result in developmental abnormalities of the cerebral cortical layers, defective myelination, and cystic degeneration of the gray and white matter. Unfortunately, brain damage occurs before the metabolites can be detected in the urine, and damage continues as long as phenylalanine levels remain high. Nonselective newborn screening is used to detect PKU in the United States and in more than 30 other countries. Treatment, consisting of reduction of dietary phenylalanine (PKU diet), is effective and allows for normal development. Mutations in the PAH gene are by far the most common cause of PKU, although...
there are other types of PKU as well. In one such variation, there is impaired synthesis of cofactors (e.g., tetrahydrobiopterin \([\text{BH}_4]\)), which contributes to elevated levels of phenylalanine. Individuals with impaired synthesis of \(\text{BH}_4\) have a positive response when sapropterin, a synthetic form of tetrahydrobiopterin, is included in their treatment.\(^{33}\)

**Storage Diseases**

Disorders of lipid metabolism are termed **lysosomal storage diseases** because each disorder in this group can be traced to a missing lysosomal enzyme. Lysosomal storage disorders include more than 50 known genetic disorders. The incidence of lysosomal storage disorders is approximately 1 in 7500 live births.\(^{34}\) These disorders cause an excessive accumulation of a particular cell product, occurring in the brain, liver, spleen, bone, and lung, and thus involving several organ systems. Generally, these disorders are not included in newborn screening. Some of these disorders may be treated with enzyme replacement therapy.\(^{35}\) Perhaps the best known of the lysosomal storage disorders is **Tay-Sachs disease** (GM\(_2\) gangliosidosis), an autosomal recessive disorder (\(\text{HexA}\) gene on chromosome 15) caused by deficiency of the lysosomal enzyme hexosaminidase A (\(\text{HexA}\)), an enzyme that degrades GM\(_2\) gangliosides (fatty acids) within nerve cell lysosomes. Approximately 80% of individuals diagnosed are of Jewish ancestry, although sporadic cases appear in the non-Jewish population. Onset of this disease usually occurs when the infant is 4 to 6 months old. Symptoms of Tay-Sachs include an exaggerated startle response to loud noise, seizures, developmental regression, dementia, and blindness. Death from this disease is almost universal and occurs by 5 years of age. Screening for carriers of the gene defect concomitant with counseling to prevent disease transmission is possible.\(^{36}\)

**Acute Encephalopathies**

**Intoxications of the Central Nervous System**
Drug-induced encephalopathies must always be considered a possibility in the child with unexplained neurologic changes. Such encephalopathies may result from accidental ingestion, therapeutic overdose, intentional overdose, or ingestion of environmental toxins (the most commonly ingested poisons are listed in Table 17-5). Approximately 1.4 million children were exposed to poisons and approximately 185 children died in the United States in 2012 as a result of poisoning.\textsuperscript{37,38}

</table>

**Lead poisoning** results in high blood levels of lead. If lead poisoning is untreated, lead encephalopathy results and is responsible for serious and irreversible neurologic damage. Those at greatest risk are children ages 2 to 3 years and children prone to the practice of pica—the habitual, purposeful, and compulsive ingestion of non-food substances, such as clay, soil, and paint chips or paint dust. Lead intoxication also may occur from chronic exposure to lead in cosmetics, inhalation of gasoline vapors, and ingestion of airborne lead.\textsuperscript{39}

An estimated 535,000 children 1 to 5 years of age in the United States (2.2% of children 1 month to 5 years of age) have excessive amounts of lead in their blood.\textsuperscript{40} The incidence in black children is greater than that in white children. Most lead exposures are preventable.\textsuperscript{41} The American Academy of Pediatrics has published recommendations for the treatment of lead poisoning depending on blood lead levels.\textsuperscript{42} Fetal neurotoxicity occurs with maternal lead exposure, particularly during the first trimester.\textsuperscript{43}
Infections of the Central Nervous System

**Meningitis** is an infection of the meninges and subarachnoid space of the brain and spinal cord, whereas the word **encephalitis** reflects inflammation within the brain. In many infections of the meninges, encephalitis also is present and the term **meningoencephalitis** is used. The origin of such inflammation and acute encephalopathy can be caused by bacteria, viruses, or other microorganisms. **Aseptic meningitis** has no evidence of bacterial infection but may be associated with viral infection, systemic disease, or drugs.

**Bacterial Meningitis**

**Acute bacterial meningitis** is one of the most serious infections to which infants and children are susceptible. In the United States approximately 4100 cases of bacterial meningitis occurred each year between 2003 and 2007, including 500 deaths. Approximately half of these cases occurred in children younger than 18 years of age. The introduction of conjugate vaccines against *Haemophilus influenzae* type B, *Streptococcus pneumoniae*, and *Neisseria meningitidis* (meningococcus) has decreased the incidence of bacterial meningitis. Vaccines for serogroup B *N. meningitidis* are not yet available but clinical trials are in progress.

Group B *Streptococcus* causes lethal meningitis and sepsis in neonates and is transmitted to the child from the mother's birth canal. *S. pneumoniae* is the most common microorganism in children 1 to 23 months of age. Staphylococcal or streptococcal meningitis can occur in children of any age but shows a predilection for children who have had neurosurgery, skull fracture, or a complication of systemic bacterial infection. Infections that originate in the middle ear, sinuses, or mastoid cells also may lead to *S. pneumoniae* infection in children. Children with sickle cell disease or who have had a splenectomy are particularly at high risk for infection.

*Escherichia coli* and group B beta-hemolytic streptococci are the most common causes of meningitis in the newborn period. The second most common microorganism causing bacterial meningitis, particularly in children younger than 4 years, is *Neisseria meningitidis* (meningococcus) and it has the potential to occur in epidemics. Approximately 2% to 5% of healthy children are carriers of *N. meningitidis*. As the incidence of *N. meningitidis* infection increases in adolescence and with crowded environments, such as in dormitories and among military personnel, it is recommended that all individuals 11 to 18 years of age receive two immunizations against this pathogen.

Pathogens enter the nervous system by direct extension from a contiguous source (e.g., paranasal sinuses or mastoid cells) or, more commonly, by hematogenous
spread (e.g., infective endocarditis, pneumonia, neurosurgical procedures, severe burns). Pathogens then cross the blood-brain barrier, enter the cerebrospinal fluid, and multiply. Bacterial toxins increase cerebrovascular permeability, causing alterations in blood flow and edema. Increased ICP may be increased further by obstruction to the CSF circulation. Herniation of the brainstem causes death.

Acute bacterial meningitis often is preceded by an upper respiratory tract or a gastrointestinal infection. Inflammation leads to the general symptoms of fever, headache, vomiting, and irritability and the CNS symptoms of photophobia, nuchal and spinal rigidity, decreased level of consciousness, and seizures. Irritation of the meninges and spinal roots causes pain and resistance to neck flexion (nuchal rigidity), a positive Kernig sign (resistance to knee extension in the supine position with the hips and knees flexed against the body), and a positive Brudzinski sign (flexion of the knees and hips when the neck is flexed forward rapidly). With severe meningeal irritation the child may demonstrate opisthotonic posturing (rigid arching of the back with the head extended). Infants may have bulging fontanelles. Meningococcal meningitis can produce a characteristic petechial rash.

**Viral meningitis** may result from a direct infection of a virus or it may be secondary to disease, such as measles, mumps, herpes, or leukemia. The hallmark of viral meningitis, or aseptic meningitis, is a mononuclear response in the CSF and the presence of normal glucose levels as well. The clinical manifestations are similar to those in bacterial meningitis, although usually milder.

**Viral encephalitis** in children is similar to viral encephalitis in adults (see Chapter 16, Figure 16-13 and Table 16-8) and can be difficult to distinguish from viral meningitis. Viruses can directly invade the brain, causing inflammation; or postinfectious encephalitis can develop as a result of an autoimmune response. Encephalopathy resulting from human immunodeficiency virus (HIV) is discussed in Chapter 8 and Chapter 16.
Cerebrovascular Disease in Children

Perinatal Stroke

Perinatal arterial ischemic stroke is estimated at 1 in 4000 live births and is a leading cause of perinatal brain injury, cerebral palsy, and lifelong disability. Although a cause for perinatal stroke is usually not found, clotting abnormalities may make the child prone to further vascular events.

Childhood Stroke

Childhood stroke occurs in 1.3 to 1.6 per 100,000 children per year and may be divided into two categories: ischemic and hemorrhagic.\(^{50,51}\)

**Ischemic (occlusive) stroke** is rare in children and may result from embolism, sinovenous thrombosis, or congenital or iatrogenic narrowing of vessels leading to decreased flow of blood and oxygen to areas of the brain. Children with arterial ischemic stroke do not have the typical adult risk factors of atherosclerosis and hypertension. Risk factors include cardiac diseases, hematologic and vascular disorders, and infection. Approximately 40% of children with acute ischemic stroke have no identifiable risk factors.\(^{52}\) Sickle cell disease, cerebral arteriopathies, and cardiac anomalies are the common disorders associated with arterial ischemic stroke.\(^{53}\)

**Hemorrhagic stroke** is most commonly caused by bleeding from congenital cerebral arteriovenous malformations and is rare in children younger than 19 years. Intraventricular hemorrhage associated with premature birth is related to immature blood vessels and unstable blood pressure. There is a high risk of developing posthemorrhagic hydrocephalus.\(^{54}\)

**Moyamoya disease** is a rare, chronic, progressive vascular stenosis of the circle of Willis. There is obstruction of arterial flow to the brain and the development of basal arterial collateral vessels that vascularize hypoperfused brain distal to the occluded vessels.\(^{55}\) Moyamoya means a “puff of smoke” in Japanese. The disease is idiopathic or associated with other disorders (moyamoya syndrome).

Clinical presentation varies according to the vessels involved, the cause of the disease, and the age of the individual. Symptoms include hemiplegia, weakness, seizures, headaches, high fever, nuchal rigidity, hemianopia, sensory changes, facial palsy, and temporary aphasia. Obtaining a thorough history of evolving symptoms and risk factors is important for diagnosis. Laboratory studies may be indicated. Neuroimaging studies assist in determining the cause of the disease. Surgery is an option for treatment and anticoagulants and antithrombotics may be used in selected
Epilepsy and Seizure Disorders in Children

The incidence of epilepsy varies greatly with age, geographic location, and study design. The incidence is highest younger than age 2 years and older than age 65 years. Approximately 150,000 persons in the United States are newly diagnosed each year.\textsuperscript{56}

Seizures are the abnormal discharge of electrical activity within the brain. When a sufficient number of neurons become overexcited, they discharge abnormally, which sometimes results in clinical manifestations (seizures) with alterations in motor function, sensation, autonomic function, behavior, and consciousness. The manifestations depend on the site and spread of abnormal electrical activity. If a child has more than one unprovoked seizure, that child is said to have epilepsy, although there are a few exceptions—one example being febrile seizures. Seizures may result from diseases that are primarily neurologic (CNS) or are systemic and affect CNS function secondarily (such as diabetes). Seizures can be caused by structural abnormalities of the brain, hypoxia, intracranial hemorrhage, CNS infection, traumatic injury, electrolyte imbalance, or inborn metabolic disturbances. Febrile seizures occur in about 2% to 5% of children between ages 6 months and 5 years; they are benign and the most common type of childhood seizure. Seizures are sometimes clearly familial. Often the cause of epilepsy is unknown and presumed to have a genetic basis. Table 17-6 summarizes the major types of seizures (also see Chapter 15 and Table 15-14).
## TABLE 17-6
### Major Types of Seizure Disorders Found in Children

<table>
<thead>
<tr>
<th>Disorder</th>
<th>Manifestations</th>
</tr>
</thead>
<tbody>
<tr>
<td>Generalized Seizure</td>
<td>First clinical manifestations indicate that seizure activity starts in or involves both cerebral hemispheres; consciousness may be impaired; bilateral manifestations; may be preceded by an aura</td>
</tr>
<tr>
<td>Tonic-clonic</td>
<td>Musculature stiffens, then intense jerking as trunk and extremities undergo rhythmic contraction and relaxation</td>
</tr>
<tr>
<td>Atomic</td>
<td>Sudden, momentary loss of muscle tone; drop attacks</td>
</tr>
<tr>
<td>Myoclonic</td>
<td>Sudden, brief contractures of a muscle or group of muscles</td>
</tr>
<tr>
<td>Absence seizure</td>
<td>Brief loss of consciousness with minimal or no loss of muscle tone; may experience 20 or more episodes a day lasting approximately 5 to 10 sec each; may have minor movement, such as lip smacking, twitching of eyelids</td>
</tr>
<tr>
<td>Partial (Focal) Seizure</td>
<td>Seizure activity that begins and usually is limited to one part of left or right hemisphere; an aura is common</td>
</tr>
<tr>
<td>Simple</td>
<td>Seizure activity that occurs without loss of consciousness</td>
</tr>
<tr>
<td>Complex</td>
<td>Seizure activity that occurs with impairment of consciousness</td>
</tr>
<tr>
<td>Epilepsy Syndromes</td>
<td>Seizure disorders that display a group of signs and symptoms that occur collectively and characterize or indicate a particular condition</td>
</tr>
<tr>
<td>Infantile spasms (West syndrome)</td>
<td>Form of epilepsy with episodes of sudden flexion or extension involving neck, trunk, and extremities; clinical manifestations range from subtle head nods to violent body contractions (jackknife seizures); onset between 3 and 12 months of age; may be idiopathic, genetic, result of metabolic disease, or in response to CNS insult; spasms occur in clusters of 5 to 150 times per day; EEG shows large-amplitude, chaotic, and disorganized pattern called “hypsarrhythmia”</td>
</tr>
<tr>
<td>Lennox-Gastaut syndrome</td>
<td>Epileptic syndrome with onset in early childhood, 1 to 5 years of age; includes various generalized seizures—tonic-clonic, atonic (drop attacks), akinetic, absence, and myoclonic; EEG has characteristic “slow spike and wave” pattern; results in mental retardation and delayed psychomotor developments</td>
</tr>
<tr>
<td>Juvenile myoclonic epilepsy</td>
<td>Onset in adolescence; multifocal myoclonus; seizures often occur early in morning, aggravated by lack of sleep or after excessive alcohol intake; occasional generalized convulsions; require long-term medication treatment</td>
</tr>
<tr>
<td>Benign rolandic epilepsy</td>
<td>Epileptic syndrome typically occurring in the preadolescent age (6 to 12 years); strong association with sleep (seizures typically occur few hours after sleep onset or just before waking in morning); complex partial seizures with orofacial signs (drooling, distortion of facial muscles); characteristic EEG with centrotemporal (Rolandic fissure) spikes</td>
</tr>
<tr>
<td>Status Epilepticus</td>
<td>Continuing or recurring seizure activity in which recovery from seizure activity is incomplete; unrelenting seizure activity can last 30 min or more; medical emergency that requires immediate intervention</td>
</tr>
</tbody>
</table>
Childhood Tumors

Brain Tumors

Brain tumors are the most common solid tumor and second most common primary neoplasm in children. Overall, brain tumors account for nearly 20% of all childhood cancers, with an annual incidence of 5.42 per 100,000 for primary malignant tumors and nonmalignant tumors for ages 0 to 19 years in the United States; approximately 43,620 brain tumors are expected to be diagnosed in 2015.\(^5^7\) Five-year survival for childhood brain tumors is about 73%, varying significantly by tumor type, although there is often significant morbidity.

Primary brain tumors arise from brain tissue and do not metastasize outside the brain. The cause of brain tumors is unknown, although genetic, environmental, and immune factors have been investigated. Exposure to radiation therapy has been the only environmental factor consistently related to the development of brain tumors.\(^5^8\)

Brain tumors can arise from any CNS cell, and tumors are classified by cell type. The types and characteristics of childhood brain tumors are summarized in Table 17-7. Medulloblastoma, ependymoma, astrocytoma, brainstem glioma, craniopharyngioma, and optic nerve glioma constitute approximately 75% to 80% of all pediatric brain tumors. Germ cell tumors are rare. Two thirds of all pediatric brain tumors in children are located in the posterior fossa (Figure 17-8) Treatment strategies and prognoses are listed in Table 17-8.

</table>
Cranioopharyngiomas
- Located adjacent to the sella turcica (structure containing the pituitary gland), often considered to lie supratentorial
- Considered to have benign properties but is life threatening because of its location near vital structures
- 4.9% of brain tumors in children

Optic nerve gliomas
- Most often a low-grade astrocytoma
- 6%

Brain stem gliomas
- Arise from pons or medulla
- 10% of childhood brain tumors
- Slow growing
- May involve cranial nerves V-X
- 10%

Infratentorial ependymomas
- Arise from lining tissue of fourth ventricle
- Comprise 13% of childhood brain tumors together with supratentorial ependymomas
- 13%

Cerebellar astrocytomas
- Most common brain tumor of childhood (20%)
- Slow growing
- Grading system I to IV with I and II less malignant than III and IV
- 20%

Cerebral tumors
- Astrocytomas invade surrounding structures but grow slowly
- 8%
- Ependymomas arise from lining tissue of lateral ventricle
- 6%

Medulloblastomas
- Arise from cerebellum
- Can invade fourth ventricle, subarachnoid space, and cerebrospinal fluid pathways
- 18% of brain tumors in children
- Fast growing
- Arise from embryonic cerebellum
- 18%

Signs and symptoms of brain tumors in children vary from generalized and vague to localized and related specifically to an anatomic area. Signs of increased intracranial pressure may occur, including headache, vomiting, lethargy, and irritability. If a young child complains of repeated and worsening headache, a thorough investigation should take place because headache is an uncommon complaint in young children. Headache caused by increased intracranial pressure usually is worse in the morning and gradually improves during the day when the child is upright and venous drainage is enhanced. The frequency of headache and other symptoms increases as the tumor grows. Irritability or possible apathy and increased somnolence also may result. Like headache, vomiting occurs more commonly in the morning. Often it is not preceded by nausea and may become projectile, differing from a gastrointestinal disturbance in that the child may be ready to eat immediately after vomiting. Other signs and symptoms include increased head circumference with bulging fontanelles in the child younger than 2
years, cranial nerve palsies, and papilledema (Box 17-1).

**Box 17-1**

**Clinical Manifestations of Brain Tumors**

**Headache**

Recurrent and progressive

In frontal or occipital area

Worse on arising; pain lessens during the day

Intensified by lowering head and straining, such as when defecating, coughing, sneezing

**Vomiting**

With or without nausea or feeding

Progressively more projectile

More severe in morning

Relieved by moving and changing position

**Neuromuscular Changes**

Uncoordination or clumsiness

Loss of balance (use of wide-based stance, falling, tripping, banging into object)

Poor fine motor control

Weakness

Hyporeflexia or hyperreflexia

Positive Babinski sign
Spasticity
Paralysis

**Behavioral Changes**

Irritability
Decreased appetite
Failure to thrive
Fatigue (frequent naps)
Lethargy
Coma
Bizarre behavior (staring, automatic movements)

**Cranial Nerve Neuropathy**

Cranial nerve involvement varies according to tumor location
Most common signs:

**Head tilt**

Visual defects (nystagmus, diplopia, strabismus, episodic “graying out” of vision, and visual field defects)

**Vital Sign Disturbances**

Decreased pulse and respiratory rates
Increased blood pressure
Decreased pulse pressure
Hypothermia or hyperthermia

Other Signs

Seizures

Cranial enlargement*

Tense, bulging fontanelle at rest*

Separating suture*

Nuchal rigidity

Papilledema (edema of optic nerve)

*Present only in infants and young children.

From Hockenberry MN: Wong’s essentials of pediatric nursing, ed 7, St Louis, 2007, Mosby.

Localized findings relate to the degree of disturbance in physiologic functioning in the area where the tumor is located. Children with infratentorial tumors exhibit localized signs of impaired coordination and balance, including ataxia, gait difficulties, truncal ataxia, and loss of balance. Medulloblastoma occurs as an invasive malignant tumor that develops in the vermis of the cerebellum and may extend into the fourth ventricle. Ependymoma develops in the fourth ventricle and arises from the ependymal cells that line the ventricular system. Because both tumors are located in the posterior fossa region along the midline, presenting signs and symptoms are similar and are usually related to hydrocephalus and increased intracranial pressure. In contrast, cerebellar astrocytomas are located on the surface of the right or left cerebellar hemisphere and cause unilateral symptoms (occurring on the same side as the tumor), such as head tilt, limb ataxia, and nystagmus.

Brainstem gliomas often cause a combination of cranial nerve involvement (facial weakness, limitation of horizontal eye movement), cerebellar signs of ataxia, and corticospinal tract dysfunction. Increased intracranial pressure generally does not occur.

The area of the sella turcica, the structure containing the pituitary gland, is the site of several childhood brain tumors; most common of this group is the
**craniopharyngioma.** This tumor originates from the pituitary gland or hypothalamus. Usually slow growing, it may be quite large by the time of diagnosis. Symptoms include headache, seizures, diabetes insipidus, early onset of puberty, and growth delay. Other tumors located in this region of the brain include **optic gliomas.** Optic nerve gliomas are associated with neurofibromatosis type 1, a neurocutaneous condition characterized by café-au-lait macules on the skin and benign tumors of the skin. Tumors that involve the optic tract may cause complete unilateral blindness and hemianopia of the other eye. Optic atrophy is another common finding. Supratentorial tumors of the cerebral hemispheres are more common in neonates and adolescents.  

**Embryonal Tumors**

**Neuroblastoma**

**Neuroblastoma** is an embryonal tumor originating outside the CNS in the developing sympathetic nervous system (sympathetic ganglia and the adrenal medulla). Because neuroblastoma involves a defect of embryonic tissue and is the most common cancer in infants less than 1 year of age, 75% of neuroblastomas are found before the child is 5 years old and is rare after 10 years of age. Occasionally, these tumors have been diagnosed at birth with metastasis apparent in the placenta. It is seen more commonly in white children (9.6 per million) than in black children (7 per million). Although it accounts for only about 6% of pediatric malignancies, neuroblastoma causes about 15% of cancer deaths in children.  

Neuroblastoma is the most common and immature form of the sympathetic nervous system tumors. Areas of necrosis and calcification often are present in the tumor. More than with any other cancer, neuroblastoma has been associated with spontaneous remission, commonly in infants. Prognosis is worse for children older than 2 years of age with disseminated disease.  

Although familial tendency has been noted in individual cases, a nonfamilial or sporadic pattern is found in most children with neuroblastoma. Familial cases of neuroblastoma are considered to have an autosomal dominant pattern of inheritance (mechanisms of inheritance are discussed in Chapter 2).  

The most common location of neuroblastoma is in the retroperitoneal region (65% of cases), most often the adrenal medulla. The tumor is evident as an abdominal mass and may cause anorexia, bowel and bladder alteration, and sometimes spinal cord compression. The second most common location of neuroblastoma is the mediastinum (15% of cases), where the tumor may cause dyspnea or infection related to airway obstruction. Less commonly, neuroblastoma may arise from the cervical sympathetic ganglion (3% to 4% of cases). Cervical
neuroblastoma often causes Horner syndrome, which consists of miosis (pupil contraction), ptosis (drooping eyelid), enophthalmos (backward displacement of the eyeball), and anhidrosis (sweat deficiency). Neuroblastoma rarely presents with a cerebellar neurologic syndrome called opsoclonus-myoclonus syndrome. Children develop conjugate chaotic eye movements, jerky movements of the limbs, and ataxia.

A number of systemic signs and symptoms are characteristic of neuroblastoma, including weight loss, irritability, fatigue, and fever. Intractable diarrhea occurs in 7% to 9% of children and is caused by tumor secretion of a hormone called vasoactive intestinal polypeptide (VIP).

More than 90% of children with neuroblastoma have increased amounts of catecholamines and associated metabolites in their urine. High levels of urinary catecholamines and serum ferritin are associated with a poor prognosis.

Retinoblastoma

Retinoblastoma is a rare congenital eye tumor of young children that originates in the retina of one or both eyes (Figure 17-9). Two forms of retinoblastoma are exhibited: inherited and acquired. The inherited form of the disease generally is diagnosed during the first year of life. The acquired disease most commonly is diagnosed in children 2 to 3 years of age and involves unilateral disease.

Approximately 40% of retinoblastomas are inherited as an autosomal dominant trait with incomplete penetrance (see Figure 2-22). The remaining 60% are acquired. In the early 1970s, Knudson proposed the “two-hit” hypothesis to explain the occurrence of both hereditary and acquired forms of the disease. This hypothesis predicts that two separate transforming events or “hits” must occur in a normal retinoblast cell to cause the cancer. Further, it proposes that in the inherited
form, the first hit or mutation occurs in the germ cell (inherited from either parent), and the mutation is contained in every cell of the child's body. Only a second, random mutation in a retinoblast cell is needed to transform that cell into cancer. Multiple tumors are observed in the inherited form because these second mutations are likely to occur in several of the approximately 1 to 2 million retinoblast cells. In contrast, the acquired form of retinoblastoma requires two independent hits or mutations to occur in the same somatic cell (after the egg is fertilized) for the transformation to cancer. This is much less likely to happen. Figure 17-10 illustrates the two-mutation model for these two patterns of mutation.
In inherited retinoblastoma, the first mutation is transmitted through the germline of an affected parent. The second mutation occurs somatically in a retinal cell, leading to development of the tumor. In sporadic retinoblastoma, development of a tumor requires two somatic mutations.

The primary sign of retinoblastoma is leukocoria, a white pupillary reflex (white reflex) also called cat's eye reflex, which is caused by the mass behind the lens (see Figure 17-9). This easy to identify sign can be missed. Other signs and symptoms include strabismus; a red, painful eye; and limited vision.

Because retinoblastoma is a treatable tumor, dual priorities are saving the child's
life and restoring useful vision. The prognosis for most children with retinoblastoma is excellent, with a greater than 90% long-term survival.

Quick Check 17-4

1. Why are the principal symptoms of brain tumors in children related to brainstem function?
Did You Understand?

Development of the Nervous System in Children

1. Growth and development of the brain occur most rapidly during fetal development and during the first year of life.

2. The bones of the skull are joined by sutures, and the wide, membranous junctions of the sutures (known as **fontanelles**) allow for brain growth and close by 18 months of age.

3. At birth neurologic function is primarily at the subcortical level with transition in reflexes as motor development progresses during the first year.

Structural Malformations

1. Spina bifida (failure of vertebral closure) is the most common disorder of neural tube closure and includes anencephaly (absence of part of the skull and brain), encephalocele (herniation of the meninges and brain through a skull defect), meningocele (a saclike meningeal cyst that protrudes through a vertebral defect), and myelomeningocele.

2. Premature closure of the cranial sutures causes craniosynostosis and prevents normal skull expansion, resulting in compression of growing brain tissue.

3. Microcephaly is lack of brain growth with retarded mental and motor development.

4. Congenital hydrocephalus results from overproduction, impaired absorption, or blockage of circulation of cerebrospinal fluid. Dandy-Walker deformity is caused by cystic dilation of the fourth ventricle and aqueductal compression.

Alterations in Function: Encephalopathies

1. Static encephalopathies are nonprogressive disorders of the brain that can occur during gestation, birth, or childhood and can be caused by endogenous or exogenous factors.

2. Cerebral palsy can be caused by prenatal cerebral hypoxia or perinatal trauma,
with symptoms of motor dysfunction (including increased muscle tone, increased reflexes, and loss of fine motor coordination), mental retardation, seizure disorders, or developmental disabilities.

3. Inherited metabolic disorders that damage the nervous system include defects in amino acid metabolism (phenylketonuria) and lipid metabolism (Tay-Sachs disease) and result in abnormal behavior, seizures, and deficient psychomotor development.

4. Seizure disorders are abnormal discharges of electrical activity within the brain. They are associated with numerous nervous system disorders and more often are a generalized rather than a partial type of seizure.

5. Generalized forms of seizures include tonic-clonic, myoclonic, atonic, akinetic, and infantile spasms.

6. Partial seizures suggest more localized brain dysfunction.

7. Febrile seizures usually are limited to children ages 6 months to 6 years, with a pattern of one seizure per febrile illness.

8. Accidental poisonings from a variety of toxins can cause serious neurologic damage.

9. Bacterial meningitis is commonly caused by *Neisseria meningitidis* or *Streptococcus pneumoniae* and may result from respiratory tract or gastrointestinal infections; symptoms include fever, headaches, photophobia, seizures, rigidity, and stupor.

10. Viral meningitis may result from direct infection or be secondary to a systemic viral infection (e.g., measles, mumps, herpes, or leukemia).

**Cerebrovascular Disease in Children**

1. Ischemic (occlusive) cerebrovascular disease is rare in children but can occur from embolism, sickle cell disease, cerebral arteriopathies, and cardiac anomalies.

2. Hemorrhagic stroke can occur in association with immature blood vessel associated with prematurity or cerebral arteriovenous malformations.

3. Moyamoya is a rare, progressive vascular stenosis of the circle of Willis that
obstructs arterial blood flow to the brain.

Childhood Brain Tumors

1. Brain tumors are the most common tumors of the nervous system and the second most common type of childhood cancer.

2. Tumors in children most often are located below the tentorial plate (infratentorial tumors).

3. Fast-growing tumors produce symptoms early in the disease, whereas slow-growing tumors may become very large before symptoms appear.

4. Symptoms of brain tumors may be generalized or localized. The most common general symptoms are the result of increased intracranial pressure and include headache, irritability, vomiting, somnolence, and bulging of fontanelles.

5. Localized signs of infratentorial tumors in the cerebellum include impaired coordination and balance. Cranial nerve signs occur with tumors in or near the brainstem.

6. Supratentorial tumors may be located near the cortex or deep in the brain. Symptoms depend on the specific location of the tumor.

7. Neuroblastoma is an embryonal tumor of the sympathetic nervous system and can be located anywhere there is sympathetic nervous tissue. Symptoms are related to tumor location and size of metastasis.

8. Retinoblastoma is a congenital eye tumor that has two forms: inherited and acquired.

GERIATRIC CONSIDERATIONS: Aging & Its Effects on Specific Endocrine Glands, 457
The endocrine system is composed of various glands located throughout the body (Figure 18-1). These glands can synthesize and release special chemical messengers called hormones. The endocrine system has five general functions: (1) differentiation of the reproductive and central nervous systems in the developing fetus; (2) stimulation of sequential growth and development during childhood and adolescence; (3) coordination of the male and female reproductive systems, which makes sexual reproduction possible; (4) maintenance of an optimal internal environment throughout life; and (5) initiation of corrective and adaptive responses when emergency demands occur. The endocrine, nervous, and immune systems work together to regulate responses to the internal and external environments. Hormones convey specific regulatory information among cells and organs and are integrated with the nervous system to maintain communication and control. The mechanisms of communication and control occur within a cell (autocrine), between local cells (paracrine), and between cells located remotely from each other (endocrine). Changes in the structure and function of the endocrine glands occur with aging and are summarized in the Geriatric Considerations box.
FIGURE 18-1 Major Endocrine Glands. (From Applegate E: The anatomy and physiology learning system, ed 4, St Louis, 2011, Saunders.)
Mechanisms of Hormonal Regulation

Endocrine glands respond to specific signals by synthesizing and releasing hormones into the circulation, which then trigger intracellular responses. All hormones share certain general characteristics:

1. Hormones have specific rates and rhythms of secretion. Three basic patterns of secretion are (a) diurnal patterns, (b) pulsatile and cyclic patterns, and (c) patterns that depend on levels of circulating substrates (e.g., calcium, sodium, potassium, or the hormones themselves).

2. Hormones operate within feedback systems, either negative or positive, to maintain an optimal internal environment.

3. Hormones affect only target cells with specific receptors for the hormone and then act on these cells to initiate specific cell functions or activities.

4. Steroid hormones are either excreted directly by the kidneys or metabolized by the liver, which inactivates them and renders the hormone more water soluble for renal excretion. Peptide hormones are catabolized by circulating enzymes and eliminated in the feces or urine.

Hormones may be classified according to structure, gland of origin, effects, or chemical composition. (Table 18-1 categorizes known hormones based on structure.) The secretion and mechanisms of action of hormones represent an extremely complex system of integrated responses. The endocrine and nervous systems work together to regulate responses to the internal and external environments.

### Regulation of Hormone Release

Hormones are released either to respond to an altered cellular environment or to maintain the level of another hormone or substance. One or more of the following mechanisms regulates hormone release: (1) chemical factors (such as blood glucose or calcium levels), (2) endocrine factors (a hormone from one endocrine gland controlling another endocrine gland), and (3) neural control. For example, insulin is secreted by the chemical stimulation of increased plasma glucose levels, cortisol from the adrenal cortex is an endocrine factor that regulates and stimulates insulin secretion, and direct stimulation of the insulin-secreting cells of the pancreas by the autonomic nervous system is a form of neural control.

Feedback systems provide precise monitoring and control of the cellular environment. Both negative and positive feedback systems are important for
maintaining hormone levels within physiologic ranges. **Negative feedback** is the most common and occurs when a changing chemical, neural, or endocrine response to a stimulus decreases the synthesis and secretion of a hormone. **Positive feedback** occurs when a neural, chemical, or endocrine response increases the synthesis and secretion of a hormone. For example, Figure 18-2, *A*, illustrates negative feedback within the hypothalamus-pituitary axis and the thyroid gland. Decreased serum levels of the thyroid hormones thyroxine (T₄) and triiodothyronine (T₃) stimulate secretion of **thyrotropin-releasing hormone (TRH)** from the hypothalamus, which stimulates the secretion of **thyroid-stimulating hormone (TSH)**. Secretion of TSH stimulates the synthesis and secretion of T₃ and T₄. Increasing levels of T₄ and T₃ then generate negative feedback on the pituitary and hypothalamus to inhibit TSH and TRH synthesis and decrease the synthesis and production of thyroid hormones. The lack of negative feedback inhibition on hormonal release often results in pathologic excessive hormone production (see Chapter 19).
An example of positive feedback is found in the female reproductive cycle. The cyclic rise of estradiol levels provides positive feedback on the anterior pituitary and hypothalamus, causing a subsequent increase in gonadotropin-releasing hormone and follicle-stimulating hormone. These changes result in ovulation (see Chapter 32).

**Hormone Transport**

Once hormones are released into the circulatory system, they are distributed throughout the body. The protein (peptide) hormones (see Table 18-1) are water soluble and generally circulate in free (unbound) forms. Water-soluble hormones generally have a half-life of seconds to minutes because they are catabolized by circulating enzymes. For example, insulin has a half-life of 3 to 5 minutes and is catabolized by insulinases. Lipid-soluble hormones (see Table 18-1), such as cortisol and adrenal androgens, are transported bound to a water-soluble carrier or
transport protein and can remain in the blood for hours to days. Only free hormones (those not bound to a carrier protein) can signal a target cell. Because there is an equilibrium between the concentrations of free hormones and hormones bound to plasma proteins, a significant change in the concentration of binding proteins can affect the concentration of free hormones in the plasma (Table 18-2). (Mechanisms of hormone binding are discussed in Chapter 1.)

**Mechanisms of Hormone Action**

Although a hormone is distributed throughout the body, only those cells with appropriate receptors, termed **target cells**, for that hormone are affected. **Hormone receptors** of the target cell have two main functions: (1) to recognize and bind specifically and with high affinity to their particular hormones and (2) to initiate a signal to appropriate intracellular effectors.

The sensitivity of the target cell to a particular hormone is related to the total number of receptors per cell or the affinity (binding) for the receptors to the hormone: the more receptors or the higher the affinity of the receptors, the more sensitive the cell to the stimulating effects of the hormone. Low concentrations of hormone increase the number or affinity of receptors per cell; this is called **up-regulation**. High concentrations of hormone decrease the number or affinity of receptors; this is called **down-regulation** (Figure 18-3). Thus the cell can adjust its sensitivity to the concentration of the signaling hormone. The receptors on the plasma membrane are continuously synthesized and degraded, so that changes in receptor concentration or affinity may occur within hours. The regulation of hormone receptors is of particular importance in type 2 diabetes, in which there is a
decrease in insulin receptor sensitivity and hyperglycemia (see Chapter 19). Various physiochemical conditions can affect both the receptor number and the affinity of the hormone for its receptor. Some of these physiochemical conditions are the fluidity and structure of the plasma membrane, pH, temperature, ion concentration, diet, and the presence of other chemicals (e.g., drugs).

Hormones affect target cells directly or permissively. Direct effects are the obvious changes in cell function that result specifically from stimulation by a particular hormone. Permissive effects are less obvious hormone-induced changes that facilitate the maximal response or functioning of a cell. For example, insulin via insulin receptors has a direct effect on skeletal muscle cells, causing increased glucose transport into these cells. Insulin also has a permissive effect on mammary cells, facilitating the response of these cells to the direct effects of prolactin.

Some hormones have biphasic effects that are dependent on the concentration or secretion pattern of the hormone. For example, in primary hyperparathyroidism,
continuous hypersecretion of parathyroid hormone (PTH) leads to bone destruction by osteoclasts. Conversely, bone formation is stimulated when recombinant PTH is given in low doses at intermittent intervals, as a treatment for osteoporosis with high risk for fracture1 (see Chapter 39). Methods of hormone measurement are summarized in Box 18-1.

**Box 18-1**

**Methods of Hormone Measurement**

**Radioimmunoassay (RIA)**

In this immunologic technique, known amounts of antibody and radiolabeled hormone are placed in an assay tube with the unlabeled hormone. The radiolabeled hormone competes chemically with the nonlabeled hormone molecules for binding sites on the antibodies. When increasing amounts of unlabeled hormones are added to the assay, the limited binding sites of the antibody can bind less of the radiolabeled hormone. Therefore, the higher the concentration of unlabeled hormone, the fewer the number of radioactive counts, or labeled hormone, that bind with the fixed concentration of antibody. A quantitative value is established by use of standard reference curves.

**Enzyme-Linked Immunosorbent Assay (ELISA)**

This assay is used to determine circulating hormone levels. The method is similar to that of radioimmunoassay (RIA) but is less expensive and easier to conduct. Instead of radiolabeled hormones, an enzyme-labeled hormone is used. The enzyme activity in either the bound or the unbound fraction is determined and related to the concentration of the unlabeled hormone.

**Bioassay**

This assay uses graded doses of hormone in a reference preparation and then compares the results with an unknown sample. Bioassays are used more commonly in investigative endocrinology than in clinical laboratories.

**Hormone Receptors**

Hormone receptors may be located in the plasma membrane or in the intracellular compartment of the target cell (Figure 18-4). Water-soluble (peptide) hormones, which include the protein hormones and the catecholamines, have a high molecular weight and cannot diffuse across the cell membrane. They interact or bind with
receptors located in or on the cell membrane. Fat-soluble steroids, vitamin D, retinoic acid, and thyroid hormones diffuse freely across the plasma and nuclear membranes and bind with cytosolic or nuclear receptors. The hormone-receptor complex binds to a specific region in the deoxyribonucleic acid (DNA) and stimulates the expression of a specific gene. Some fat-soluble hormones (e.g., estrogen [see Chapter 32]) may also bind with plasma membrane receptors and can have rapid cellular effects.

**First and Second Messengers**

All water-soluble hormones and some steroid hormones have hormone-specific receptors located in the plasma membranes of cells. Hormone binding with the plasma membrane receptor initiates a complex cascade of intracellular effects. In this cascade, the hormone is termed the **first messenger**. The hormone-receptor interaction initiates a signal that generates a small molecule inside the cell, called the **second messenger**. Second messengers include cyclic adenosine
monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), calcium, inositol trisphosphate (IP₃), and the tyrosine kinase system (Table 18-3). The second messenger conveys the signal from the receptor to the cytoplasm and nucleus of the cell and mediates the effect of the hormone on the target cell (e.g., membrane permeability alterations, protein synthesis, inhibition of specific metabolic pathways, enzyme activation, or cellular growth).

When first messengers from the anterior pituitary gland, adrenocorticotropic hormone (ACTH) and thyroid-stimulating hormone (TSH), bind to a cell membrane receptor, intracellular levels of cAMP increase. Second-messenger cAMP activates protein kinases, leading to phosphorylation of cellular proteins. This either activates or deactivates intracellular enzymes, thus directing the actions or products of specific cells (Figure 18-5).
FIGURE 18-5  Mechanism of First and Second Messenger Action. The hormone acts as a “first messenger,” delivering its message via the bloodstream to a membrane receptor in the target cell much like a key fits into a lock. The “second messenger” causes the cell to respond and perform its specialized function. (From Patton KT, Thibodeau GA: Structure & function of the body, ed 15, St Louis, 2016, Mosby)

- cGMP functions as a second messenger following receptor binding of first messengers (e.g., atrial natriuretic peptide and nitric oxide). These hormones play crucial roles in cardiovascular and pulmonary health and disease. Drugs such as phosphodiesterase inhibitors that target cGMP are being explored for treatment of various diseases.\(^5,6\)

- Hormone-receptor binding of first-messenger angiotensin II and antidiuretic hormone (ADH) results in generation of the second messenger, inositol triphosphate. Inositol triphosphate triggers a release of intracellular calcium, another second messenger. Increased intracellular calcium levels can lead to the formation of the calcium-calmodulin complex, which mediates the effects of calcium on intracellular activities that are crucial for cell metabolism and growth. For example, calmodulin-dependent protein kinases control intracellular contractile components (myosin and actin, which cause muscle contraction), alter plasma membrane permeability to calcium, and regulate the intracellular enzyme activity that promotes hormone secretion.

- Some hormone first messengers, such as insulin, growth hormone, and prolactin, bind to surface receptors that directly activate second messengers of the tyrosine
kinase family. These tyrosine kinases include the Janus family of tyrosine kinases (JAK) and signal transducers and activators of transcription (STAT). They regulate a wide range of intracellular processes that contribute to cellular metabolism and growth, and are being targeted in emerging treatments for diabetes and cancer. 7-9

**Lipid-Soluble (Steroid) Hormone-Receptor Binding**

With the exception of thyroid hormones, the lipid-soluble hormones are synthesized from cholesterol (giving rise to the term “steroid”). These include androgens, estrogens, progestins, glucocorticoids, mineralocorticoids, vitamin D, and retinoid. Because these are relatively small, lipophilic, hydrophobic molecules, lipid-soluble hormones can cross the lipid plasma membrane by simple diffusion (see Chapter 1). Receptors for lipid-soluble hormones are in the cytosol and nucleus and direct gene expression (Figure 18-6). Modulation of gene expression can take hours to days. Studies also reveal that receptors for lipid-soluble hormones are in the plasma membrane and are associated with rapid responses (seconds to minutes) as shown in Figure 18-6.10,11

Steroid hormone molecules detach from the carrier protein (1) and pass through the plasma membrane (2). Hormone molecules then diffuse into the nucleus, where they bind to a receptor to form a hormone-receptor complex (3). This complex then binds to a specific site on a deoxyribonucleic acid (DNA) molecule (4), triggering transcription of the genetic information encoded there (5). The resulting messenger ribonucleic acid (mRNA) molecule moves to the cytosol, where it associates with a ribosome, initiating synthesis of a new protein (6). This new protein—usually an enzyme or channel protein—produces specific effects on the target cell (7). The classic genomic action is typically slow (red arrows). Steroids also may exact rapid effects (green arrows) by binding to receptors on the plasma membrane (A) and activating an intercellular second messenger (B). (From Patton KT, Thibodeau GA: Anatomy & physiology, ed 9, St Louis, 2016, Mosby.)
Structure and Function of the Endocrine Glands

Hypothalamic-Pituitary System

The hypothalamic-pituitary axis (HPA) forms the structural and functional basis for central integration of the neurologic and endocrine systems, creating what is called the neuroendocrine system. The HPA produces several hormones that affect a number of diverse body functions (Figure 18-7), including thyroid, adrenal, and reproductive functions.
The hypothalamus is located at the base of the brain. It is connected to the pituitary gland by the pituitary stalk (Figure 18-8). The hypothalamus is connected to the anterior pituitary through hypophysial portal blood vessels (Figure 18-9) and to the posterior pituitary via a nerve tract referred to as the hypothalamohypophysial tract (Figure 18-10). These connections are vital to the functioning of the hypothalamic-pituitary system. The hypothalamus contains special neurosecretory cells that are like other neurons in that they have similar electrical properties, organelles, membranes, and synapses. Hypothalamic neurosecretory cells, however, can synthesize and secrete the hypothalamic-releasing hormones that regulate the
release of hormones from the anterior pituitary. In addition, these cells synthesize the hormones antidiuretic hormone (ADH) and oxytocin that are released from the posterior pituitary gland. These hormones are summarized in Table 18-4.

</table>
The pituitary gland is located in the sella turcica (a saddle-shaped depression of the sphenoid bone at the base of the skull). It weighs approximately 0.5 g, except during pregnancy when its weight increases by about 30%. It is composed of two distinctly different lobes: (1) the anterior pituitary, or adenohypophysis, and (2) the posterior pituitary, or neurohypophysis (see Figure 18-7). These two lobes differ in their embryonic origins, cell types, and functional relationship to the hypothalamus.

**The Anterior Pituitary**

The anterior pituitary (adenohypophysis) accounts for 75% of the total weight of the pituitary gland. It is composed of three regions: (1) the pars distalis, (2) the pars tuberalis, and (3) the pars intermedia. The pars distalis is the major component of the anterior pituitary and is the source of the anterior pituitary hormones. The pars tuberalis is a thin layer of cells on the anterior and lateral portions of the pituitary stalk. The pars intermedia lies between the two and secretes melanocyte-stimulating hormone in the fetus. In the adult, the distinct pars intermedia disappears and the individual cells are distributed diffusely throughout the pars distalis and pars nervosa (neural lobe) of the posterior pituitary.

The anterior pituitary is composed of two main cell types: (1) the chromophobes, which appear to be nonsecretory, and (2) the chromophils, which are considered the secretory cells of the adenohypophysis. The chromophils are subdivided into seven secretory cell types, and each cell type secretes a specific hormone or hormones. In general, the anterior pituitary hormones are regulated by (1) secretion of hypothalamic peptide hormones or releasing factors, (2) feedback effects of the hormones secreted by target glands, and (3) direct effects of other mediating neurotransmitters. (These are summarized in Figure 18-2.)

The anterior pituitary secretes tropic hormones that affect the physiologic function of specific target organs (see Figure 18-7 and Table 18-5). Melanocyte-stimulating hormone (MSH) promotes the pituitary secretion of melanin, which darkens skin color. The glycoprotein hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH) influence reproductive function and are discussed in Chapter 32. Adrenocorticotropic hormone (ACTH) regulates the release of cortisol from the adrenal cortex. Thyroid-stimulating hormone (TSH) regulates the activity of the thyroid gland. The roles of ACTH and TSH are discussed later in this chapter. Growth hormone (GH) and prolactin are called the somatotropic hormones and have diverse effects on body tissues. GH secretion is controlled by two hormones from the hypothalamus: growth hormone–releasing hormone (GHRH), which increases GH secretion; and somatostatin, which inhibits GH secretion. GH is essential to normal tissue growth and maturation and also
impacts aging, sleep, nutritional status, stress, and reproductive hormones. Many of the anabolic functions of GH are mediated, at least in part, by the insulin-like growth factors (IGFs), which are also known as the somatomedins.\textsuperscript{12}

There are two primary forms of IGF: IGF-1 and IGF-2, of which IGF-1 is the most biologically active. They both circulate bound to a group of IGF-binding proteins (IGFBPs) modulating their availability. IGF-1 binds to IGF-1 receptors mediating the anabolic effects of GH. IGF-1 also binds to insulin receptors, providing an insulin-like effect on skeletal muscle. IGF-2 has important effects on fetal growth, but suppresses GH in the adult. Because of the anabolic effects of GH and IGF-1, they can be used to treat growth disorders, increase muscle mass, and potentially slow the aging process; but their use has also been linked to increased rates of cancer\textsuperscript{13,14} (see **Health Alert: Growth Hormone [GH] and Insulin-like Growth Factor [IGF] in Aging**).

---

**Health Alert**

**Growth Hormone (GH) and Insulin-like Growth Factor (IGF) in**
Aging is a multifactorial process that is influenced by genetic and environmental factors. The aging process is associated with many hormonal and metabolic changes. The amounts of GH and IGF decline with aging, a process that has been called the “somatopause.” Clinical findings related to somatotropic hormone changes with aging include increased visceral fat, decreased lean body mass, decreased bone density, and changes in reproductive and cognitive function. The underlying mechanisms of aging and its relationship to GH and IGF are complex. For example, not only do these hormones promote bone and muscle growth, but also a recent study suggests that the brain IGF-1 receptor may be a significant factor in determining overall life span and ability to respond to physiologic stress. GH and IGF effects on inflammation and immunity also are important in the aging process. Unfortunately, there remains much confusion and controversy over the role of these hormones. Although most studies suggest that it is a deficiency of these hormones that leads to an acceleration of the aging process, there are several studies suggesting that lower lifetime levels of these hormones may confer longevity by providing protection from cancer and other age-related diseases. As these hormones are used to treat a wider range of disorders and for different age groups, more information about their safety is emerging. Despite the initial enthusiasm for the use of therapeutic doses of recombinant human growth hormone (rhGH) as a way to slow the aging process, studies have not been consistently positive and the relationship between GH and IGF supplementation and increased cancer risk is being explored.

Prolactin primarily functions to induce milk production during pregnancy and lactation. It has immune stimulatory effects and modulates immune and inflammatory responses with both physiologic and pathologic reactions. Its synthesis is stimulated by vasoactive intestinal polypeptide, serotonin, and growth factors. Release of prolactin is inhibited by dopamine.

The Posterior Pituitary

The embryonic posterior pituitary (neurohypophysis) is derived from the hypothalamus and is comprised of three parts: (1) the median eminence, located at the base of the hypothalamus; (2) the pituitary stalk; and (3) the infundibular
process, also known as the pars nervosa or neural lobe. The median eminence is composed largely of the nerve endings of axons from the ventral hypothalamus. It often is designated as part of the posterior pituitary but contains at least 10 biologically active hypothalamic-releasing hormones, as well as the neurotransmitters dopamine, norepinephrine, serotonin, acetylcholine, and histamine. The pituitary stalk contains the axons of neurons that originate in the supraoptic and paraventricular nuclei of the hypothalamus and connects the pituitary gland to the brain. Axons originating in the hypothalamus terminate in the pars nervosa, which secretes the hormones of the posterior pituitary (see Figure 18-10).

The posterior pituitary secretes two polypeptide hormones: (1) antidiuretic hormone (ADH), also called arginine vasopressin, and (2) oxytocin. These hormones differ by only two amino acids. They are synthesized—along with their binding proteins, the neurophysins—in the supraoptic and paraventricular nuclei of the hypothalamus (see Figure 18-10). They are packaged in secretory vesicles and are moved down the axons of the pituitary stalk to the pars nervosa for storage. The posterior pituitary thus can be seen as a storage and releasing site for hormones synthesized in the hypothalamus. The release of ADH and oxytocin is mediated by cholinergic and adrenergic neurotransmitters. The major stimulus to both ADH and oxytocin release is glutamate, whereas the major inhibitory input is through gamma-aminobutyric acid (GABA). Before release into the circulatory system, ADH and oxytocin are split from the neurophysins and are secreted in unbound form.

**Antidiuretic hormone.**

The major homeostatic function of the posterior pituitary is the control of plasma osmolality as regulated by ADH (see Chapter 5). At physiologic levels, ADH increases the permeability of the distal renal tubules and collecting ducts (see Chapter 29). This increased permeability leads to increased water reabsorption into the blood, thus concentrating the urine and reducing serum osmolality. Hypercalcemia, prostaglandin E, and hypokalemia can inhibit this water reabsorption.

The secretion of ADH is regulated primarily by the osmoreceptors of the hypothalamus, located near or in the supraoptic nuclei. As plasma osmolality increases these osmoreceptors are stimulated, the rate of ADH secretion increases, more water is reabsorbed by the kidney, and the plasma is diluted back to its set-point osmolality. ADH has no direct effect on electrolyte levels, but by increasing water reabsorption, serum electrolyte concentrations may decrease because of a dilutional effect.
ADH secretion also is increased by changes in intravascular volume, as monitored by baroreceptors in the left atrium, in the carotid arteries, and in the aortic arches. A volume loss of 7% to 25% acts on these receptors to stimulate ADH secretion. Stress, trauma, pain, exercise, nausea, nicotine, exposure to heat, and drugs such as morphine also increase ADH secretion. ADH secretion decreases with decreased plasma osmolality, increased intravascular volume, hypertension, alcohol ingestion, and an increase in estrogen, progesterone, or angiotensin II levels.

Physiologic levels of ADH do not significantly impact vessel tone. However, ADH was originally named *vasopressin* because, in extremely high levels, it causes vasoconstriction and a resulting increase in arterial blood pressure. For example, high doses of ADH (given as the drug vasopressin) may be administered to achieve hemostasis during hemorrhage and to raise blood pressure in shock states.\(^{17,18}\)

**Oxytocin.**

Oxytocin is responsible for contraction of the uterus and milk ejection in lactating women and may affect sperm motility in men. In both genders, oxytocin has an antidiuretic effect similar to that of ADH. In women, oxytocin is secreted in response to sucking and mechanical distention of the female reproductive tract. Oxytocin binds to its receptors on myoepithelial cells in the mammary tissues and causes contraction of those cells, which increases intramammary pressure and milk expression ("let-down" reflex). Oxytocin also acts on the uterus to stimulate contractions. Oxytocin functions near the end of labor to enhance the effectiveness of contractions, promote delivery of the placenta, and stimulate postpartum uterine contractions, thereby preventing excessive bleeding. The function of this hormone is discussed in detail in Chapter 32.

**Quick Check 18-2**

1. What is the relationship between the hypothalamus and the pituitary?

2. What is the action of antidiuretic hormone (ADH)?

**Pineal Gland**

The pineal gland is located near the center of the brain and is composed of photoreceptive cells that secrete *melatonin*. It is innervated by noradrenergic sympathetic nerve terminals controlled by pathways within the hypothalamus. Melatonin release is stimulated by exposure to dark and inhibited by light exposure.
It is synthesized from tryptophan, which is first converted to serotonin and then to melatonin. Melatonin regulates circadian rhythms and reproductive systems, including the secretion of the gonadotropin-releasing hormones and the onset of puberty. It also plays an important role in immune regulation and is postulated to impact the aging process. Further effects of melatonin include increasing nitric oxide release from blood vessels, removing toxic oxygen free radicals, and decreasing insulin secretion. Melatonin has been used therapeutically in humans to help with sleep disturbances, jet lag, psychological and inflammatory disorders. Its utility for numerous other disorders is being explored.

**Thyroid and Parathyroid Glands**

The thyroid gland, located in the neck just below the larynx, produces hormones that control the rates of metabolic processes throughout the body. The four parathyroid glands are near the posterior side of the thyroid and function to control serum calcium levels (Figure 18-11).

**Thyroid Gland**

Two lobes of the thyroid gland lie on either side of the trachea, inferior to the thyroid cartilage and joined by a small band of tissue termed the isthmus. The
pyramidal lobe is superior to the isthmus (see Figure 18-11). The normal thyroid gland is not visible on inspection, but it may be palpated on swallowing, which causes it to be displaced upward.

The thyroid gland consists of follicles that contain follicular cells surrounding a viscous substance called colloid (Figure 18-12). The follicular cells synthesize and secrete the thyroid hormones. Neurons terminate on blood vessels within the thyroid gland and on the follicular cells themselves, so neurotransmitters (acetylcholine, catecholamines) may directly affect the secretory activity of follicular cells and thyroid blood flow. Approximately, a 2-month supply of thyroid hormone is stored in the gland.

![FIGURE 18-12 Thyroid Follicle Cells.](image)

Also found in the thyroid are parafollicular cells, or C cells (see Figure 18-12). C cells secrete various polypeptides, including calcitonin. At high levels, calcitonin, also called thyrocalcitonin, lowers serum calcium levels by inhibiting bone-resorbing osteoclasts (Table 18-6). However, in humans the metabolic consequences of calcitonin deficiency or excess do not appear to be significant. (Bone resorption is explained in Chapter 38.) Calcitonin can be used therapeutically to treat a number of bone disorders, including osteogenesis imperfecta, osteoporosis, and Paget bone disease, among others. Parafollicular cells can give rise to medullary thyroid carcinoma.

**Regulation of thyroid hormone secretion.**

**Thyroid hormone (TH)** is regulated through a negative-feedback loop involving the hypothalamus, the anterior pituitary, and the thyroid gland (see Figure 18-2). This loop is initiated by thyrotropin-releasing hormone (TRH), which is synthesized and stored within the hypothalamus. TRH is released into the hypothalamic-pituitary portal system and circulates to the anterior pituitary, where it stimulates the release of thyroid-stimulating hormone (TSH). TRH levels increase with exposure to cold or stress and from decreased levels of thyroxine (T\(_4\)).

TSH is a glycoprotein synthesized and stored within the anterior pituitary. When TSH is secreted by the anterior pituitary, it circulates to bind with receptors on the plasma membrane of the thyroid follicular cells. The primary effect of TSH on the thyroid gland is to cause an immediate release of stored TH and an increase in TH synthesis. TSH also increases growth of the thyroid gland by stimulating thymocyte hyperplasia and hypertrophy. As TH levels rise, there is a negative-feedback effect on the HPA to inhibit TRH and TSH release, which then results in decreased TH synthesis and secretion. TH synthesis is also controlled by serum iodide levels and by circulating selenium-dependent enzymes, called deiodinases, which inactivate the
precursor molecule thyroxine. Thyroid gland hormones and their regulation and function are summarized in Table 18-6.

**Synthesis of thyroid hormone.**

Thyroid hormone synthesis is summarized in the following steps:

1. Uniodinated thyroglobulin (a large glycoprotein) is produced by the endoplasmic reticulum of the thyroid follicular cells.

2. Tyrosine is incorporated into the thyroglobulin as it is synthesized.

3. Iodide (the inorganic form of iodine) is actively transferred (pumped) from the blood into the colloid by carrier proteins located in the outer membrane of the follicular cells. This active transport system is called the iodide trap and is very efficient at accumulating the trace amounts of iodide from the blood.

4. Iodide is oxidized and quickly attaches to tyrosine within the thyroglobulin molecule.

5. Coupling of iodinated tyrosine forms thyroid hormones. Triiodothyronine ($T_3$) is formed from coupling of monoiodotyrosine (one iodine atom and tyrosine) and diiodotyrosine (two iodine atoms and tyrosine). Tetraiodothyronine ($T_4$), commonly known as thyroxine, is formed from coupling of two diiodotyrosines.

6. Thyroid hormones are stored attached to thyroglobulin within the colloid until they are released into the circulation.

The thyroid gland normally produces 90% $T_4$ and 10% $T_3$. Once released into the circulation, $T_3$ and $T_4$ are primarily transported bound to thyroxine-binding globulin, though some TH is transported by thyroxine-binding prealbumin (transthyretin), albumin, or lipoproteins. The bound form serves as a reservoir while the unbound form is active. In the body tissues, most of the $T_4$ is converted to $T_3$, which acts on the target cell.

**Actions of thyroid hormone.**

TH has a significant effect on the growth, maturation, and function of cells and tissues throughout the body. TH is essential for normal growth and neurologic development in the fetus and infant and affects metabolic, neurologic, cardiovascular, and respiratory functioning across the lifespan. In addition, TH is
required for the metabolism and function of blood cells as well as normal muscle functioning and the integrity of skin, nails, and hair. Similar to some steroid hormones, TH binds to intracellular receptor complexes and then influences the genetic expression of specific proteins. TH also affects cell metabolism by altering protein, fat, and glucose metabolism and, as a result, increasing heat production and oxygen consumption. Additionally, TH has permissive effects throughout the body by optimizing the actions of other hormones and neurotransmitters (see Table 18-6). Use of TH and its analogs is being explored for the therapy of many metabolic disorders such as obesity and type 2 diabetes mellitus.²³

**Parathyroid Glands**

Normally two pairs of small parathyroid glands are present behind the upper and lower poles of the thyroid gland (see Figure 18-11). However, their number may range from two to six.

The parathyroid glands produce **parathyroid hormone (PTH)**, which is the single most important factor in the regulation of serum calcium concentration. The overall effect of PTH secretion is to increase serum calcium concentration and decrease the level of serum phosphate. A decrease in serum-ionized calcium level stimulates PTH secretion. PTH acts directly on the bone to release calcium by stimulating osteoclast activity. PTH also acts on the kidney to increase calcium reabsorption while phosphate reabsorption is decreased. The resultant increase in serum calcium concentration inhibits PTH secretion. Paradoxically, when PTH is administered intermittently and at a low dose, it stimulates bone formation. This observation led to the use of PTH for treatment of osteoporosis. **1,25-Dihydroxy-vitamin D₃** (the active form of vitamin D) works as a cofactor with PTH to promote calcium and phosphate absorption in the gut and enhance bone mineralization. Vitamin D also plays an important role in metabolic processes and controlling inflammation. It has been found to be deficient in the majority of individuals in the United States (see **Health Alert: Vitamin D**).

**Health Alert**

**Vitamin D**

Vitamin D is essential for bone health and is widely used for the prevention and treatment of postmenopausal osteoporosis and renal osteodystrophy. More recently, vitamin D deficiency has been found to affect more than 75% of all Americans, and more than 90% of Americans with pigmented skin. Inadequate serum levels of
vitamin D have been linked to infections, cancer, heart disease, dementia, diabetes, chronic pain syndromes, and autoimmune disorders. Controversies continue as to whether these associations indicate a direct cause and effect between low levels of vitamin D and the pathophysiology of these diseases, and whether vitamin D supplementation reduces risk or improves outcomes. However, many health organizations recommend increased intake of vitamin D–containing foods (seafood, vitamin D–fortified juices, and milk products), increased exposure to sunlight, and supplementation with vitamin D. The Institute of Medicine currently recommends 400 to 600 units of vitamin D per day for adults with a goal of achieving a serum level of 35 to 50 ng/mL.

Phosphate and magnesium concentrations also affect PTH secretion. An increase in serum phosphate level decreases serum calcium level by causing calcium-phosphate precipitation into soft tissue and bone, which indirectly stimulates PTH secretion. Hypomagnesemia in persons with normal calcium levels acts as a mild stimulant to PTH secretion; however, in persons with hypocalcemia, hypomagnessemia decreases PTH secretion.24

Quick Check 18-3

1. How does the anterior pituitary regulate the thyroid gland?
2. What form of thyroid hormone is biologically active?
3. What two organs are the sites of action of parathyroid hormone (PTH)?

Endocrine Pancreas

The pancreas is both an endocrine gland that produces hormones and an exocrine gland that produces digestive enzymes. (The exocrine function of the pancreas is discussed in Chapter 35.) The pancreas is located behind the stomach, between the spleen and the duodenum, and houses the islets of Langerhans. The islets of Langerhans have four types of hormone-secreting cells: alpha cells, which secrete glucagon; beta cells, which secrete insulin and amylin; delta cells, which secrete gastrin and somatostatin; and F (or PP) cells, which secrete pancreatic polypeptide.
These hormones regulate carbohydrate, fat, and protein metabolism. (The pancreas is illustrated in Figure 18-13.) Nerves from both the sympathetic and the parasympathetic divisions of the autonomic nervous system innervate the pancreatic islets.
