• Has spread beyond the seminal vesicles to nearby tissue or organs, such as the rectum, bladder, or pelvic wall; or
• May have spread to the seminal vesicles or to nearby tissue or organs, such as the rectum, bladder, or pelvic wall. Cancer has spread to nearby lymph nodes; or
• Has spread to distant parts of the body, which may include lymph nodes or bones. Prostate cancer often spreads to the bones.

Stress incontinence can occur after surgery and mild urge incontinence can occur after radiation therapy. Prostate cancer and its treatment can affect sexual functioning. Sensation of orgasm is not usually affected, but smaller amounts of ejaculate will be produced or men may experience a “dry” ejaculate because of retrograde ejaculation.

Sexual Dysfunction

In males, the normal sexual response involves erection, emission, and ejaculation.
**Sexual dysfunction** is the impairment of any or all of these processes and can be caused by various physiologic, psychologic, and emotional factors.

Until the late 1970s, most cases of male sexual dysfunction were considered psychogenic. Now there is evidence that 89% to 90% of cases involve organic factors and include (1) vascular, endocrine, and neurologic disorders; (2) chronic disease, including renal failure and diabetes mellitus; (3) penile diseases and penile trauma; and (4) iatrogenic factors, such as surgery and pharmacologic therapies. Most of these disorders cause erectile dysfunction (ED).

**Pathophysiology**

Sexual dysfunction can have a specific physiologic cause, can be associated with many chronic diseases and their treatment, or may be related to low energy levels, stress, or depression. For example, vascular disease may cause impotence, and endocrine disorders or conditions that cause decreased testosterone levels or testicular atrophy can diminish sexual functioning or libido. In addition, neurologic disorders and spinal cord injuries can interfere with sympathetic, parasympathetic, and CNS mechanisms required for erection, emission, and ejaculation.

Drug-induced sexual dysfunction consists of decreased desire, decreased erectile ability, or decreased ejaculatory ability. Alcohol and other CNS depressants, antihypertensives, antidepressants, antihistamines, and hormonal preparations are commonly used drugs that affect sexual functioning. Other pharmacologic agents may diminish the quality or quantity of sperm or cause priapism.

**Clinical manifestations and treatment**

Evaluation of sexual dysfunction includes a thorough history and physical examination. Particular attention is given to drug history and examination of the genitalia, prostate, and nervous system. Basic laboratory tests are used to identify the presence of endocrinopathies or other underlying disorders that can cause dysfunction. Psychologic evaluation is indicated for younger men with a sudden onset of sexual dysfunction or for men of any age who can achieve but not maintain an erection. If no physiologic cause is found and the condition does not improve with psychotherapy, the man is referred for further investigation of organic causes.

Treatments for organic sexual dysfunction include both medical and surgical approaches. The advent of phosphodiesterase type 5 inhibitors (PDE5i) has revolutionized the erectile dysfunction (ED) treatment landscape and provided effective, minimally invasive therapies to restore male sexual function. The original PDE5i, Viagra (sildenafil), has created much enthusiasm over its ability to help a man maintain an erection. For a small percentage of men (1%), however, this improvement in sexual function is accompanied by heart attacks and death. Whether
these effects are the result of sexual performance or Viagra has been controversial. Research has shown that Viagra increases blood concentrations of the enzyme cGMP-dependent protein kinase G (PKG), which increases blood flow to the penis. PKG, however, plays a dual role: first, it increases platelet aggregation; and then, minutes later, it decreases clot size. The initial clot could cause some men with heart disease to experience cardiac arrest.

Currently available PDE5i medications in the United States include sildenafil, vardenafil, tadalafil, and avanafil, each of which has unique side effect profiles. For instance, sildenafil is associated with (in addition to the previously mentioned cardiac issues) an increased rate of visual changes, vardenafil with QT prolongation, and tadalafil with lower back pain.102 Nonsurgical approaches include correction of underlying disorders, particularly drug-induced dysfunction and endocrinopathy-related (e.g., reduced testosterone level associated with chronic renal failure) dysfunction. Use of vasodilators and cessation of smoking can benefit individuals with vasculogenic erectile dysfunction. Surgical approaches include penile implants, penile revascularization, and correction of other anatomic defects contributing to sexual dysfunction.

**Impairment of Sperm Production and Quality**

Spermatogenesis requires adequate secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by the pituitary and sufficient secretion of testosterone by the testes. Inadequate secretion of gonadotropins may be caused by numerous alterations (e.g., hypothyroidism, hyperadrenocortisolism, hyperprolactinemia, or hypogonadotropic hypogonadism). In the absence of adequate gonadotropin levels, the Leydig cells are not stimulated to secrete testosterone, and sperm maturation is not promoted in the Sertoli cells. Spermatogenesis also depends on an appropriate response by the testes. Defects in testicular response to the gonadotropins result in decreased secretion of testosterone and inhibit B and occur as a result of normal feedback mechanisms and high levels of circulating gonadotropins. In the absence of adequate testosterone levels, spermatogenesis is impaired. Newer studies demonstrate the importance of inhibit B as a valuable marker of the competence of Sertoli cells and spermatogenesis.25,103 Impaired spermatogenesis also can be caused by testicular trauma, infection, atrophy of the testes, systemic illness involving high fever, ingestion of various drugs, exposure to environmental toxins, and cryptorchidism.

Fertility is adversely affected if spermatogenesis is normal but the sperm are chromosomally or morphologically abnormal or are produced in insufficient quantities. Chromosomal abnormalities are caused by genetic factors and by
external variables, such as exposure to radiation or toxic substances. Because the Y chromosome plays a key role in testis determination and control of spermatogenesis, understanding how the genes interact can elucidate exact causes of infertility. The most common mutations are microdeletion of the Y chromosome (AZ [azoospermia] a, b, and c).\textsuperscript{104} Research related to mapping the critical genes and gene pathways is the current focus of male infertility. Common mechanisms may be involved in infertility and testicular cancer. In utero environmental exposure to endocrine disruptors modulates the genetic makeup of the gonad and may result in both infertility and testicular cancer.\textsuperscript{25}

Sperm motility also may affect fertility. Motility appears to be affected by the characteristics of the semen. Dysfunction of the prostate, excessive viscosity of the semen, presence of drugs or toxins in the semen, and presence of antisperm antibodies are associated with impaired sperm motility. However, new data show that motile density may not be a good indicator of infertility.\textsuperscript{105} Approximately 17% of infertile males have antisperm antibodies in their semen. These antibodies may be (1) cytotoxic antibodies, which attack sperm and reduce their number in the semen; or (2) sperm-immobilizing antibodies, which impair sperm motility and reduce their ability to traverse the endocervical canal.

Treatment for impaired spermatogenesis involves correcting any underlying disorders, avoiding radiation and possibly electromagnetic radiation (hypothesis from cell phones) and toxins, and using hormones to enhance spermatogenesis. In addition, semen can be modified to improve sperm motility; modifications are followed by artificial insemination.

Quick Check 34-4

1. What is the current understanding of hormones in the pathophysiology of prostate cancer?

2. Why is the worldwide variation of prostate cancer incidence important?

3. Describe what is meant by prostate cancer cell and stromal interactions for carcinogenesis.

4. What causes impaired spermatogenesis?
Disorders of the Male Breast

Gynecomastia

Gynecomastia is the overdevelopment of breast tissue in a male. Gynecomastia accounts for approximately 85% of all masses that develop in the male breast and affects 32% to 40% of the male population. If only one breast is involved, it is typically the left. Incidence is greatest among adolescents and men older than 50 years.

Gynecomastia results from hormonal alterations, which may be idiopathic or caused by systemic disorders, drugs, or neoplasms. Gynecomastia usually involves an imbalance of the estrogen/testosterone ratio. The normal estrogen/testosterone ratio can be altered in one of two ways. First, estrogen levels may be excessively high, although testosterone levels are normal. This is the case in drug-induced and tumor-induced hyperestrogenism. Second, testosterone levels may be extremely low, although estrogen levels are normal, as is the case in hypogonadism. Gynecomastia also can be caused by alterations in breast tissue responsiveness to hormonal stimulation. Breast tissue may have increased responsiveness to estrogen or decreased responsiveness to androgen. Alterations of responsiveness may cause many cases of idiopathic gynecomastia.

Besides puberty and aging, estrogen/testosterone imbalances are associated with hypogonadism, Klinefelter syndrome, and testicular neoplasms. Hormone-induced gynecomastia is usually bilateral. Pubertal gynecomastia is a self-limiting phenomenon that usually disappears within 4 to 6 months. Senescent gynecomastia usually regresses spontaneously within 6 to 12 months.

Systemic disorders associated with gynecomastia include cirrhosis of the liver, infectious hepatitis, chronic renal failure, chronic obstructive lung disease, hyperthyroidism, tuberculosis, and chronic malnutrition. It may be that these disorders ultimately alter the estrogen/testosterone ratio, initiating the gynecomastia.

Gynecomastia is often seen in males receiving estrogen therapy, either in preparation for a gender-change operation or in the treatment of prostatic carcinoma. Other drugs that can cause gynecomastia include digitalis, cimetidine, spironolactone, reserpine, thiazide, isoniazid, ergotamine, tricyclic antidepressants, amphetamines, vincristine, and busulfan. Gynecomastia is usually unilateral in these instances.

Malignancies of the testes, adrenals, or liver can cause gynecomastia if they alter the estrogen/testosterone ratio. Pituitary adenomas and lung cancer also are associated with gynecomastia.
**Pathophysiology**

The enlargement of the breast consists of hyperplastic stroma and ductal tissue. Hyperplasia results in a firm, palpable mass that is at least 2 cm in diameter and located beneath the areola.

**Evaluation and treatment**

The diagnosis of gynecomastia is based on physical examination. Identification and treatment of the cause are likely to be followed by resolution of the gynecomastia. The man should be taught to perform breast self-examination and is reexamined at 6- and 12-month intervals if the gynecomastia persists.

**Carcinoma**

Breast cancer in males accounts for 0.26% of all male cancers and 1.1% of all breast cancers. About 2350 new cases of breast cancer in men were estimated in 2015.¹ Global incidence rates were generally less than 1 per 100,000 man-years, in contrast to much higher rates in females.¹⁰⁶ The highest incidence rate for male breast cancer (MBC) was Israel (1.24 per 100,000), and the lowest incidence rates for males (0.16 per 100,000) and females (18.0 per 100,000) were observed in Thailand.¹⁰⁶ It is seen most commonly after the age of 60 years, with the peak incidence between 60 and 69 years (men tend to be diagnosed at an older age than women). It has, however, been reported in males as young as 6 years old and in adolescents. Klinefelter syndrome is the strongest risk factor for developing male breast carcinoma. Other risk factors include germline mutation in *BRCA1* or *BRCA2*, but familial cases usually have *BRCA2* rather than *BRCA1* mutations.¹⁰⁷-¹⁰⁹ Obesity increases the risk of MBC. Testicular disorders, including cryptorchidism, mumps, orchitis, and orchiectomy, are related to risk.¹¹⁰ The relationship between these factors and the risk of disease is not clearly defined.

Recent data on the most frequent molecular subtypes of male breast cancer appear to be different than those for female breast cancers. Luminal A and luminal B are most common; and basal-like, unclassifiable triple-negative, and *HER2*-driven male breast cancers are rare.¹¹¹,¹¹² Male breast tumors often resemble carcinoma of the breast in women (see p. 833). The majority of MBCs express estrogen and progesterone receptors. The malignant male breast lesion is usually a unilateral solid mass located near the nipple. Because the nipple is commonly involved, crusting and nipple discharge are typical clinical manifestations. Other findings include skin retraction, ulceration of the skin over the tumor, and axillary node involvement. Patterns of metastasis are similar to those in females.

The diagnosis of cancer is confirmed by biopsy. Because of delays in seeking
treatment, male breast cancer tends to be advanced at the time of diagnosis and therefore is likely to have a poor prognosis. Treatment protocols are similar to those for female breast cancer, but endocrine therapy is used more often for males because a higher percentage of male tumors are hormone-dependent. The mainstay of treatment is modified mastectomy with axillary node dissection to assess stage and prognosis. Because 90% of tumors are hormonal receptor positive, tamoxifen is standard adjuvant therapy. Orchiectomy is performed to treat metastatic disease. For metastatic disease, hormonal therapy is the main treatment but chemotherapy also can provide palliation.107
Sexually Transmitted Diseases

Sexually transmitted diseases (STDs) are a variety of clinical syndromes and infections caused by pathogens that can be acquired and transmitted through sexual activity. Sexually contracted infections affect approximately 20 million Americans per year, half among young people ages 15 to 24, and account for about one third of the reproductive mortality in the United States (Table 34-1). STDs can lead to severe reproductive health problems, for example infertility and ectopic pregnancy. Untreated or undertreated chlamydial infections are the primary cause of preventable infertility and ectopic pregnancy. In addition to ectopic pregnancy and infertility, other complications of STDs include pelvic inflammatory disease (PID), chronic pelvic pain, neonatal morbidity and mortality, genital cancer, and epidemiologic synergy with HIV transmission (Table 34-2). Long-term sequelae of untreated or undertreated STDs may be disastrous and can affect a person's physical, emotional, and financial well-being. Treatment guidelines for STDs can be found on the CDC website (http://www.cdc.gov/std/tg2015/2015-poster-press.pdf).

Anyone can become infected with an STD, but young people and gay and bisexual men are at greatest risk.\textsuperscript{114} Young people between the ages of 15 to 24 years continue to have the highest reported rates of chlamydia and gonorrhea compared with other groups. Both young men and women are heavily affected by STDs, but young women have the most serious long-term health consequences. Undiagnosed STDs cause 24,000 women to become infertile each year.\textsuperscript{114} Men who have sex with men (MSM) account for about 75\% of all primary and secondary syphilis cases. Primary and secondary syphilis are the most infectious stages of the disease and, if not treated adequately, can lead to visual impairment and stroke.\textsuperscript{114} Syphilis infection raises the risk of acquiring and transmitting HIV infection. Half of MSM with syphilis also are infected with HIV.\textsuperscript{114}

Individual risk behaviors, such as higher numbers of lifetime sex partners and environmental, social, and cultural factors, contribute to health disparities of MSM, for example, difficulty accessing health care. Homophobia and stigma also can make it difficult for gay and bisexual men to find culturally-sensitive and appropriate care and treatment.\textsuperscript{114} STD screening is critical. It is recommended that women who are sexually active and younger than 25 years of age or have multiple sex partners annual chlamydia and gonorrhea be tested. A woman should request syphilis, HIV, chlamydia, and hepatitis B testing early in her pregnancy. These tests also should be requested if a woman has a new or multiple sex partners.\textsuperscript{114} Recommended tests include syphilis, chlamydia, gonorrhea, and HIV once a year.
for gay, bisexual, or other men who have sex with men. More frequent testing is recommended for men at high risk.

Did You Understand?

Alterations of Sexual Maturation

1. Sexual maturation, or puberty, should begin in boys between the ages of 9 and 14 years.

2. Delayed puberty is the onset of sexual maturation after these ages; precocious puberty is the onset before these ages. Treatment depends on the cause.

Disorders of the Male Reproductive System

1. Disorders of the urethra include urethritis (infection of the urethra) and urethral strictures (narrowing or obstruction of the urethral lumen caused by scarring).

2. Most cases of urethritis result from sexually transmitted pathogens. Urologic instrumentation, foreign body insertion, trauma, or an anatomic abnormality can cause urethral inflammation with or without infection.

3. Urethritis causes urinary symptoms, including a burning sensation during urination (dysuria), frequency, urgency, urethral tingling or itching, and clear or purulent discharge.

4. The scarring that causes urethral stricture can be attributed to trauma or severe untreated urethritis.

5. Manifestations of urethral stricture include those of bladder outlet obstruction: urinary frequency and hesitancy, diminished force and caliber of the urinary stream, dribbling after voiding, and nocturia.

6. Phimosis and paraphimosis are penile disorders involving the foreskin (prepuce). In phimosis, the foreskin cannot be retracted over the glans. In paraphimosis, the foreskin is retracted and cannot be reduced (returned to its normal anatomic position over the glans). Phimosis is caused by poor hygiene and chronic infection and can lead to paraphimosis. Paraphimosis can constrict the penile blood vessels, preventing circulation to the glans.

7. Peyronie disease consists of fibrosis affecting the corpora cavernosa, which causes penile curvature during erection. Fibrosis prevents engorgement on the
affected side, causing a lateral curvature that can prevent intercourse.

8. Priapism is a prolonged, painful erection that is not stimulated by sexual arousal. The corpora cavernosa (but not the corpus spongiosum) fill with blood that will not drain from the area, probably because of venous obstruction. Priapism is associated with spinal cord trauma, sickle cell disease, leukemia, and pelvic tumors. It can also be idiopathic.

9. Balanitis is an inflammation of the glans penis. It is associated with phimosis, inadequate cleansing under the foreskin, skin disorders, and pathogens (e.g., *Candida albicans*).

10. Cancer of the penis is rare. Penile carcinoma in situ tends to involve the glans; invasive carcinoma of the penis involves the shaft as well.

11. A varicocele is an abnormal dilation of the veins within the spermatic cord caused either by congenital absence of valves in the internal spermatic vein or by acquired valvular incompetence.

12. A hydrocele is a collection of fluid between the testicular and scrotal layers of the tunica vaginalis. Hydroceles can be idiopathic or caused by trauma or infection of the testes.

13. A spermatocele is a cyst located between the testis and epididymis that is filled with fluid and sperm.

14. Cryptorchidism is a congenital condition in which one or both testes fail to descend into the scrotum. Uncorrected cryptorchidism is associated with infertility and significantly increased risk of testicular cancer.

15. Testicular torsion is the rotation of a testis, which twists blood vessels in the spermatic cord. This interrupts the blood supply to the testis, resulting in edema and, if not corrected within 6 hours, necrosis and atrophy of testicular tissues.

16. Orchitis is an acute infection of the testes. Complications of orchitis include hydrocele and abscess formation.

17. Testicular cancer is the most common malignancy in males 15 to 35 years of age. Although its cause is unknown, high androgen levels, genetic predisposition, and history of cryptorchidism, trauma, or infection may contribute to
18. Spermatogenesis (sperm production by the testes) can be impaired by disruptions of the hypothalamic-pituitary-testicular axis that reduce testosterone secretion and by testicular trauma, infection, or atrophy from any cause. Sperm production is also impaired by neoplastic disease, cryptorchidism, or any factor that causes testicular temperature to rise (e.g., circulatory impairment, wearing tight clothing).

19. Epididymitis, an inflammation of the epididymis, is usually caused by a sexually transmitted pathogen that ascends through the vasa deferentia from an already infected urethra or bladder.

20. Benign prostatic hyperplasia (BPH), also called benign prostatic hypertrophy, is the enlargement of the prostate gland. This condition becomes symptomatic as the enlarging prostate compresses the urethra, causing symptoms of bladder outlet obstruction and urine retention.

21. Prostatitis is inflammation of the prostate. Prostatitis syndromes have been classified by the National Institutes of Health as (1) acute bacterial prostatitis (ABP), (2) chronic bacterial prostatitis (CBP), (3) chronic pelvic pain syndrome (CPPS), and (4) asymptomatic inflammatory prostatitis.

22. Prostate cancer is the most common cancer in American males, and the incidence varies greatly worldwide. Possible causes include genetic predisposition, environmental and dietary factors, inflammation, and alterations in levels of hormones (testosterone, dihydrotestosterone, and estradiol) and growth factors. Incidence is greatest among northwestern European and North American men (particularly blacks) older than 65 years.

23. Most cancers of the prostate are adenocarcinomas that develop at the periphery of the gland.

24. Sexual dysfunction in males can be caused by any physical or psychologic factor that impairs erection, emission, or ejaculation.

**Disorders of the Male Breast**

1. Gynecomastia is the overdevelopment (hyperplasia) of breast tissue in a male. It is first seen as a firm, palpable mass at least 2 cm in diameter and is located in the
1. subareolar area.

2. Gynecomastia affects 32% to 40% of the male population. The incidence is greatest among adolescents and men older than 50 years of age.

3. Gynecomastia is caused by hormonal or breast tissue alterations that cause estrogen to dominate. These alterations can result from systemic disorders, drugs, neoplasms, or idiopathic causes.

4. Breast cancer is relatively uncommon in males, but it has a poor prognosis because men tend to delay seeking treatment until the disease is advanced. The incidence is greatest in men in their sixties.

5. Most breast cancers in men are estrogen receptor positive.

**Sexually Transmitted Infections**

1. Sexually transmitted diseases are infections contracted by intimate as well as sexual contact and include systemic infections, such as tuberculosis and hepatitis, which can spread to a sexual partner.

2. The etiology of an STI may be bacterial, viral, protozoan, parasitic, or fungal.

3. Although the majority of STIs can be treated, viral-induced STIs are considered incurable.

GERIATRIC CONSIDERATIONS: Aging & the Gastrointestinal System, 903
The digestive system includes the gastrointestinal tract and accessory organs of digestion: the salivary glands, liver, gallbladder, and exocrine pancreas (Figure 35-1). The digestive system breaks down ingested food, prepares it for uptake by the body's cells, absorbs fluid, and eliminates wastes. Food breakdown begins in the mouth with chewing and continues in the stomach, where food is churned and mixed with acid, mucus, enzymes, and other secretions. From the stomach, the fluid and partially digested food pass into the small intestine, where biochemical agents and enzymes secreted by the intestinal cells, liver, gallbladder, and exocrine pancreas break it down into absorbable components of proteins, carbohydrates, and fats. These nutrients pass through the walls of the small intestine into blood vessels and lymphatics that carry them to the liver for storage or further processing.
Ingested substances and secretions that are not absorbed in the small intestine pass into the large intestine, where fluid continues to be absorbed. Fluid wastes travel to the kidneys and are eliminated in the urine. Solid wastes pass into the rectum and are eliminated from the body through the anus. Except for chewing, swallowing, and defecation of solid wastes, the movements of the digestive system (peristalsis) are all controlled by hormones and the autonomic nervous system. The autonomic innervation, both sympathetic and parasympathetic, is controlled by centers in the brain and by local stimuli that are mediated at plexuses (networks of nerve fibers) within the gastrointestinal walls. The gastrointestinal tract and gut microbiome provide important immune and protective functions. Aging can alter the structure and function of the gastrointestinal tract (see *Geriatric Considerations: Aging & the Gastrointestinal System*).
The **gastrointestinal tract** (alimentary canal) consists of the mouth, esophagus, stomach, small intestine, large intestine, rectum, and anus (see Figure 35-1). It carries out the following digestive processes:

1. Ingestion of food
2. Propulsion of food and wastes from the mouth to the anus
3. Secretion of mucus, water, and enzymes
4. Mechanical digestion of food particles
5. Chemical digestion of food particles
6. Absorption of digested food
7. Elimination of waste products by defecation
8. Immune and microbial protection against infection

Histologically, the gastrointestinal tract consists of four layers. From the inside out they are the mucosa, submucosa, muscularis, and serosa or adventitia. These concentric layers vary in thickness, and each layer has sublayers (Figure 35-2). A network of intrinsic nerves that controls mobility, secretion, sensation, and blood flow is located solely within the gastrointestinal tract and controlled by local and autonomic nervous system stimuli through the **enteric (intramural) plexus** located in different layers of the gastrointestinal walls (see Figure 35-2).
Mouth and Esophagus

The mouth is a reservoir for the chewing and mixing of food with saliva. There are 32 permanent teeth in the adult mouth, and they are important for speech and mastication. As food particles become smaller and move around in the mouth, the taste buds and olfactory nerves are continuously stimulated, adding to the satisfaction of eating. The tongue's surface contains thousands of chemoreceptors, or taste buds, which can distinguish salty, sour, bitter, sweet, and savory (umami) tastes. Tastes and food odors help to initiate salivation and the secretion of gastric juice in the stomach.

Salivation

The three pairs of salivary glands—the submandibular, sublingual, and parotid glands (Figure 35-3)—secrete about 1 L of saliva per day. Saliva consists mostly of
water with mucus, sodium, bicarbonate, chloride, potassium, and salivary α-amylase (ptyalin), an enzyme that initiates carbohydrate digestion in the mouth and stomach.

Both sympathetic and parasympathetic divisions of the autonomic nervous system control salivation. Cholinergic parasympathetic fibers stimulate the salivary glands, and atropine (an anticholinergic agent) inhibits salivation and makes the mouth dry. β-Adrenergic stimulation from sympathetic fibers also increases salivary secretion. The salivary gland secretion is not regulated by hormones.

The composition of saliva depends on the rate of secretion (Figure 35-4). Aldosterone can increase epithelial exchange of sodium for potassium, increasing sodium conservation and potassium excretion. The bicarbonate concentration of saliva sustains a pH of about 7.4, which neutralizes bacterial acids and prevents tooth decay. Saliva also contains mucin, immunoglobulin A (IgA), and other antimicrobial substances, which help prevent infection. Mucin provides lubrication. Exogenous fluoride (e.g., fluoride in drinking water) is also secreted in the saliva,
providing additional protection against tooth decay.

**FIGURE 35-4** Salivary Electrolyte Concentrations and Flow Rate. Changes in concentrations of sodium (Na$^+$), potassium (K$^+$), chloride (Cl$^-$), and bicarbonate (HCO$_3^-$) increase flow rate of saliva. Green line, sodium; orange line, bicarbonate; red line, chloride; blue line, potassium. At low rates of salivary flow (i.e., between meals), sodium, chloride, and bicarbonate are reabsorbed in the collecting ducts of the salivary glands, and the saliva contains fewer of these electrolytes (i.e., is more hypotonic). At higher flow rates (i.e., stimulated by food), reabsorption decreases and saliva is hypertonic. By this mechanism, sodium, chloride, and bicarbonate are recycled until they are released to help with digestion and absorption.

**Swallowing**

The esophagus is a hollow, muscular tube approximately 25 cm long that conducts substances from the oropharynx to the stomach (see Figure 35-1). Swallowed food is moved to the stomach by peristalsis, the coordinated sequential contraction and relaxation of outer longitudinal and inner circular layers of muscles. The pharynx and upper third of the esophagus contain striated muscle (voluntary) that is directly innervated by skeletal motor neurons that control swallowing. The lower two thirds contain smooth muscle (involuntary) that is innervated by preganglionic cholinergic fibers from the vagus nerve. The fibers are activated in a downward sequence and coordinated by the swallowing center in the medulla. Peristalsis is stimulated when afferent fibers distributed along the length of the esophagus sense changes in wall tension caused by stretching as food passes. The greater the tension,
the greater the intensity of esophageal contraction. Occasionally, intense contractions cause pain similar to “heartburn” or angina.

Each end of the esophagus is opened and closed by a sphincter. The upper esophageal sphincter keeps air from entering the esophagus during respiration. The lower esophageal sphincter (cardiac sphincter) prevents regurgitation from the stomach and caustic injury to the esophagus.

Swallowing is coordinated primarily by the swallowing center in the medulla. During the oropharyngeal (voluntary) phase, the following steps occur:

1. Food is segmented into a bolus by the tongue and forced posteriorly toward the pharynx.

2. The superior constrictor muscle of the pharynx contracts so the food cannot move into the nasopharynx.

3. Respiration is inhibited, and the epiglottis slides down to prevent the food from entering the larynx and trachea.

   This entire sequence takes place in less than 1 second.

   The esophageal phase proceeds as follows:

1. The bolus of food enters the esophagus.

2. Waves of relaxation travel the esophagus, preparing for the movement of the bolus.

3. Peristalsis, the sequential waves of muscular contractions that travel down the esophagus, transports the food to the lower esophageal sphincter, which is relaxed at that point.

4. The bolus enters the stomach, and the sphincter muscles return to their resting tone.

   This phase takes 5 to 10 seconds, with the bolus moving 2 to 6 cm/sec.

   Peristalsis that immediately follows the oropharyngeal phase of swallowing is called primary peristalsis. If a bolus of food becomes stuck in the esophageal lumen, secondary peristalsis—a wave of contraction and relaxation independent of voluntary swallowing—occurs. This is in response to stretch receptors stimulated by increased wall tension, which activate impulses from the swallowing center of the brain.
The lower esophageal sphincter is normally constricted and serves as a barrier between the stomach and esophagus. The muscle tone of the lower sphincter changes with neural and hormonal stimulation and relaxes with swallowing. Cholinergic vagal input and the digestive hormone gastrin increase sphincter tone. Nonadrenergic, noncholinergic vagal impulses relax the lower esophageal sphincter, as do the hormones progesterone, secretin, and glucagon.

**Quick Check 35-1**

1. What are the functions of saliva?
2. What are the phases of swallowing and how are they controlled?

**Stomach**

The stomach is a hollow, muscular organ just below the diaphragm that stores food during eating, secretes digestive juices, mixes food with these juices, and propels partially digested food, called chyme, into the duodenum of the small intestine. The anatomy of the stomach is presented in Figure 35-5. Its major anatomic boundaries are the lower esophageal sphincter, where food passes through the cardiac orifice at the gastroduodenal junction into the stomach, and the pyloric sphincter, which relaxes as food is propelled through the pylorus (gastroduodenal junction) into the duodenum. Functional areas are the fundus (upper portion), body (middle portion), and antrum (lower portion).
The stomach has three layers of smooth muscle: an outer, longitudinal layer; a middle, circular layer; and an inner, oblique layer (the most prominent) (see Figure 35-5). These layers become progressively thicker in the body and antrum where food is mixed and pushed into the duodenum. The glandular epithelium is discussed under Gastric Secretion (see p. 888).

The stomach's blood supply comes from a branch of the celiac artery (Figure 35-6) and is so abundant that nearly all arterial vessels must be occluded before ischemic changes occur in the stomach wall. A series of small veins drain blood from the stomach towards the hepatic portal vein.
Sympathetic and parasympathetic divisions of the autonomic nervous system innervate the stomach. Some of the autonomic fibers are extrinsic—that is, they originate outside the stomach and are controlled by nerve centers in the brain. The vagus nerve provides parasympathetic innervation and branches of the celiac plexus innervate the stomach sympathetically. The myenteric (Auerbach) and submucosal (Meissner) plexuses are intrinsic and part of the enteric (intramural) nervous system. They originate within the stomach and respond to local stimuli.

**Gastric Motility**

In its resting state, the stomach is small and contains about 50 ml of fluid. There is no wall tension, and the muscle layers in the fundus contract very little. Swallowing causes the fundus to relax (receptive relaxation) to receive a bolus of food from the esophagus (see Swallowing, p. 886). Relaxation is coordinated by efferent, nonadrenergic, noncholinergic vagal fibers and is facilitated by gastrin and cholecystokinin—two polypeptide hormones secreted by the gastrointestinal mucosa. (The actions of digestive hormones are summarized in Table 35-1.) Food is stored in vertical or oblique layers as it arrives in the fundus, whereas fluids flow relatively quickly down to the antrum.

*NOTE: The digestive hormones are not secreted into the gastrointestinal lumen but instead into the bloodstream, where they travel to target tissues. There are more than 30 peptide hormone genes expressed in the gastrointestinal tract and more than 100 hormonally active peptides.

Gastric (stomach) motility increases with the initiation of peristaltic waves, which sweep over the body of the stomach toward the antrum. The rate of peristaltic contractions is approximately three per minute and is influenced by neural and hormonal activity. Gastrin, **motilin** (an intestinal hormone), and the vagus nerve increase the rate of contraction by lowering the threshold potential of muscle fibers. (The neural and biochemical mechanisms of muscle contraction are described in Chapter 38.) Sympathetic activity and **secretin** (another intestinal hormone) are inhibitory and raise the threshold potential. The rate of peristalsis is mediated by pacemaker cells that initiate a wave of depolarization (basic electrical rhythm), which moves from the upper part of the stomach to the pylorus.

Gastric mixing and emptying of gastric contents (chyme) from the stomach take
several hours. Mixing occurs as food is propelled toward the antrum. As food approaches the pylorus, the velocity of the peristaltic wave increases. This forces the contents back toward the body of the stomach. This retropulsion effectively mixes food with digestive juices, and the oscillating motion breaks down large food particles. With each peristaltic wave, a small portion of the gastric contents (chyme) passes through the pylorus and into the duodenum. The pyloric sphincter is about 1.5 cm long and is always open about 2.0 mm. It opens wider during antral contraction. Normally there is no regurgitation from the duodenum into the antrum.

The rate of gastric emptying (movement of gastric contents into the duodenum) depends on the volume, osmotic pressure, and chemical composition of the gastric contents. Larger volumes of food increase gastric pressure, peristalsis, and rate of emptying. Solids, fats, and nonisotonic solutions (i.e., hypertonic or hypotonic gastric tube feedings) delay gastric emptying. (Osmotic pressure and tonicity are described in Chapters 1 and 5.) Products of fat digestion, which are formed in the duodenum by the action of bile from the liver and enzymes from the pancreas, stimulate the secretion of cholecystokinin. This hormone inhibits food intake, reduces gastric motility, and decreases gastric emptying so that fats are not emptied into the duodenum at a rate that exceeds the rate of bile and enzyme secretion. Osmoreceptors in the wall of the duodenum are sensitive to the osmotic pressure of duodenal contents. The arrival of hypertonic or hypotonic gastric contents activates the osmoreceptors, which delay gastric emptying to facilitate formation of an isosmotic duodenal environment. The rate at which acid enters the duodenum also influences gastric emptying. Secretions from the pancreas, liver, and duodenal mucosa neutralize gastric hydrochloric acid in the duodenum. The rate of emptying is adjusted to the duodenum's ability to neutralize the incoming acidity.  

**Gastric Secretion**

The secretion of gastric juice is influenced by numerous stimuli that together facilitate the process of digestion. The phases of gastric secretion are the cephalic phase (stimulated by the thought, smell, and taste of food), the gastric phase (stimulated by distention of the stomach), and the intestinal phase (stimulated by histamine and digested protein). All phases promote the secretion of acid by the stomach.

Gastric secretion is stimulated by the process of eating (gastric distention), by the actions of the hormone gastrin and paracrine pathways (e.g., histamine, ghrelin, somatostatin), and by the effects of the neurotransmitter acetylcholine and other chemicals (e.g., ethanol, coffee, protein). The stomach secretes large volumes of gastric juices or gastric secretions, including mucus, acid, enzymes, hormones,
intrinsic factor, and gastroferrin. **Intrinsic factor** is necessary for the intestinal absorption of vitamin B₁₂, and gastroferrin facilitates small intestinal absorption of iron. The hormones are secreted into the blood and travel to target tissues. The other gastric secretions are released directly into the stomach lumen.³

In the fundus and **body of the stomach**, the **gastric glands** of the mucosa are the primary secretory units (Figure 35-7). The composition of gastric juice depends on volume and flow rate (Figure 35-8). Potassium level remains relatively constant, but its concentration is greater in gastric juice than in plasma. The rate of secretion varies with the time of day. Generally, the rate and volume of secretion are lowest in the morning and highest in the afternoon and evening. Loss of gastric juices through vomiting, drainage, or suction may decrease body stores of sodium and potassium and result in fluid, electrolyte (e.g., hyponatremia, hypokalemia, dehydration), and acid-base imbalances (e.g., metabolic alkalosis) (see Chapters 5 and 36).⁴
Gastric pits are depressions in the epithelial lining of the stomach. At the bottom of each pit are one or more tubular gastric glands. Chief cells produce pepsinogen, which is converted to pepsin (a proteolytic enzyme); parietal cells secrete hydrochloric acid and intrinsic factor; G cells produce gastrin; endocrine cells (enterochromaffin-like cells and D cells) secrete histamine and somatostatin. (From Patton KT, et al: Essentials of anatomy & physiology, St Louis, 2012, Mosby.)
Gastric secretion is inhibited by somatostatin, by unpleasant odors and tastes, and by rage, fear, or pain. A discharge of sympathetic impulses inhibits parasympathetic impulses. Increased secretions are associated with aggression or hostility and may contribute to some forms of gastric pathology.

**Gastric acid.**

The major functions of gastric hydrochloric acid are to dissolve food fibers, act as a bactericide against swallowed microorganisms, and convert pepsinogen to pepsin. The production of acid by the **parietal cells** requires the transport of hydrogen and chloride from the parietal cells to the stomach lumen. Acid is formed in the parietal cells, primarily through the hydrolysis of water (Figure 35-9). At a high rate of gastric secretion, bicarbonate moves into the plasma, producing an “alkaline tide” in the venous blood, which also may result in a more alkaline urine.¹
Acid secretion is stimulated by the vagus nerve, which releases acetylcholine and stimulates the secretion of gastrin; then gastrin stimulates the release of histamine from enterochromaffin cells (mast cells; see Chapter 6) in the gastric mucosa. Histamine stimulates acid secretion by activating histamine receptors (H2 receptors) on acid-secreting parietal cells. Caffeine stimulates acid secretion, as does calcium. Acid secretion is inhibited by somatostatin, secretin, and other intestinal hormones.3

**Pepsin.**

Acetylcholine, gastrin, and secretin stimulate the chief cells to release pepsinogen during eating. Pepsinogen is quickly converted to pepsin in the acidic gastric environment (optimum pH for pepsin activation = 2.0). Pepsin is a proteolytic enzyme—that is, it breaks down protein and forms polypeptides in the stomach. Once chyme has entered the duodenum, the alkaline environment of the duodenum inactivates pepsin.

**Mucus.**

The gastric mucosa is protected from the digestive actions of acid and pepsin by intercellular tight junctions, a coating of mucus called the mucosal barrier, and gastric mucosal blood flow. Prostaglandins protect the mucosal barrier by stimulating the secretion of mucus and bicarbonate and by inhibiting the secretion of acid. A break in the protective barrier may occur from ischemia or by exposure to *Helicobacter pylori*, aspirin, nonsteroidal anti-inflammatory drugs (inhibit prostaglandin synthesis), ethanol, or regurgitated bile. Breaks cause inflammation and ulceration.

Few substances are absorbed in the stomach. The stomach mucosa is
impermeable to water, but the stomach can absorb alcohol and aspirin.

Quick Check 35-2

1. Why are there three layers of stomach muscle and how do they function?
2. What hormones stimulate gastric motility?
3. What are the phases of gastric secretion?

Small Intestine

The **small intestine** is coiled within the peritoneal cavity and is about 5 to 6 meters long. Functionally, it is divided into three segments: the **duodenum**, **jejunum**, and **ileum** (Figure 35-10). The duodenum begins at the pylorus and ends where it joins the jejunum at a suspensory ligament called the *Treitz ligament*. The end of the jejunum and beginning of the ileum are not distinguished by an anatomic marker. These structures are not grossly different, but the jejunum has a slightly larger lumen than the ileum. The **ileocecal valve**, or **sphincter**, controls the flow of digested material from the ileum into the large intestine and prevents reflux into the small intestine.
The duodenum lies behind the peritoneum, or retroperitoneally, and is attached to the posterior abdominal wall. The ileum and jejunum are suspended in loose folds from the posterior abdominal wall by a peritoneal membrane called the mesentery. The mesentery facilitates intestinal motility and supports blood vessels, nerves, and lymphatics.

The peritoneum is the serous membrane surrounding the organs of the abdomen and pelvic cavity. It is analogous to the pericardium around the heart and the pleura around the lungs. The visceral peritoneum lies on the surface of the organs, and the parietal peritoneum lines the wall of the body cavity. The space between these two layers is called the peritoneal cavity and normally contains just enough fluid to lubricate the two layers and prevent friction during organ movement.

The arterial supply to the duodenum arises primarily from the gastroduodenal artery, a branch of the celiac artery. The jejunum and ileum are supplied by branches of the superior mesenteric artery. The superior mesenteric vein drains blood from the entire small intestine and empties into the hepatic portal circulation. The regional lymph nodes and lymphatics drain into the thoracic duct.

Enteric nerves from both divisions of the autonomic nervous system innervate the small intestine. Secretion, motility, pain sensation, and intestinal reflexes (e.g., relaxation of the lower esophageal sphincter) are mediated parasympathetically by
the vagus nerve. Sympathetic activity inhibits motility and produces vasoconstriction. Intrinsic reflexive activity is mediated by the myenteric plexus (Auerbach plexus) and the submucosal plexus (Meissner plexus) of the enteric nervous system.

The smooth muscles of the small intestine are arranged in two layers: a longitudinal outer layer and a thicker inner circular layer (see Figures 35-2 and 35-10). Circular folds of the small intestine slow the passage of food, thereby providing more time for digestion and absorption. The folds are most numerous and prominent in the jejunum and proximal ileum (see Figure 35-10).

Absorption occurs through villi (sing., villus), which cover the circular folds and are the functional units of the intestine. A villus is composed of absorptive columnar cells (enterocytes) and mucus-secreting goblet cells of the mucosal epithelium. Each villus (see Figure 35-10) secretes some of the enzymes necessary for digestion and absorbs nutrients. Near the surface, columnar cells closely adhere to each other at sites called tight junctions. Water and electrolytes are absorbed through these intercellular spaces. The surface of each columnar epithelial cell on the villus contains tiny projections called microvilli (sing., microvillus) (see Figure 35-10). Together the microvilli create a mucosal surface known as the brush border. Coating the brush border is an “unstirred” layer of water that is important for the absorption of water-soluble substances including emulsified micelles of fat. The lamina propria (a connective tissue layer of the mucous membrane) lies beneath the epithelial cells of the villi and contains lymphocytes and plasma cells, which produce immunoglobulins (see The Gastrointestinal Tract and Immunity).

Central arterioles ascend within each villus and branch into a capillary array that extends around the base of the columnar cells and cascades down to the venules that lead to the hepatic portal circulation (see Figure 35-10). A central lacteal, or lymphatic capillary, also is contained within each villus and is important for the absorption and transport of fat molecules. Contents of the lacteals flow to regional nodes and channels that eventually drain into the thoracic duct.

Between the bases of the villi are the crypts of Lieberkühn, which extend to the submucosal layer. Undifferentiated cells arise from stem cells at the base of the crypt and move toward the tip of the villus, maturing to become columnar epithelial secretory cells (water, electrolytes, and enzymes) and goblet cells (mucus). After completing their migration to the tip of the villus, they function for a few days and then are shed into the intestinal lumen and digested. Discarded epithelial cells are an important source of endogenous protein. The entire epithelial population is replaced about every 4 to 7 days. Many factors can influence this process of cellular proliferation. Starvation, vitamin B_{12} deficiency, and cytotoxic drugs or irradiation
suppress cell division and shorten the villi. Decreased absorption across the epithelial membrane can cause diarrhea and malnutrition. Nutrient intake and intestinal resection stimulate cell production.

**Intestinal Digestion and Absorption**

The process of digestion is initiated in the stomach by the actions of gastric hydrochloric acid and pepsin. The chyme that passes into the duodenum is a liquid with small particles of undigested food. Digestion continues in the proximal portion of the small intestine by the action of pancreatic enzymes, intestinal enzymes, and bile salts. In the proximal small intestine, carbohydrates are broken down to monosaccharides and disaccharides; proteins are degraded further to amino acids and peptides; and fats are emulsified and reduced to fatty acids (Box 35-1) and monoglycerides (Figure 35-11). These nutrients, along with water, vitamins, and electrolytes, are absorbed across the intestinal mucosa by active transport, diffusion, or facilitated diffusion. Products of carbohydrate and protein breakdown move into villus capillaries and then to the liver through the hepatic portal vein. Digested fats move into the lacteals and eventually reach the liver through the systemic circulation. Intestinal motility exposes nutrients to a large mucosal surface area by mixing chyme and moving it through the lumen. Different segments of the gastrointestinal tract absorb different nutrients. Digestion and absorption of all major nutrients and many drugs occur in the small intestine. Sites of absorption are shown in Figure 35-12. Box 35-2 outlines the major nutrients involved in this process.

---

**Box 35-1**

**Dietary Fat**

**Saturated Fatty Acids (e.g., Palmitic Acid [C_{16}H_{32}O_{2}])**

Each carbon atom in the chain is linked by single bonds to adjacent carbon and hydrogen atoms:

1. Solid at room temperature; include animal fat and tropical oils (coconut and palm oils).

2. Increase low-density lipoprotein (LDL) cholesterol (“bad”
cholesterol) blood levels.

3. Increase the risk of coronary artery disease.

**Unsaturated Fatty Acids**

Soft or liquid at room temperature; omega-6 fatty acids are found in plants and vegetables (olive, canola, and peanut oils); omega-3 fatty acids are found in fish and shellfish.

**Monounsaturated Fatty Acids (e.g., Oleic Acid [C\textsubscript{18}H\textsubscript{34}O\textsubscript{2}])**

Contain one double bond in the carbon chain:

1. Found in both plants and animals.

2. May be beneficial in reducing blood cholesterol level, glucose level, and systolic blood pressure.

3. Do not lower high-density lipoprotein (HDL) cholesterol (“good” cholesterol) level.

4. Low HDL levels have been associated with coronary heart disease.

**Polyunsaturated Fatty Acids (e.g., Linoleic Acid [C\textsubscript{18}H\textsubscript{32}O\textsubscript{2}])**

Contain two or more double bonds in the carbon chain:

1. Found in plants and fish oils.

2. Omega-6 fatty acids lower total and LDL cholesterol blood levels.
3. High levels of polyunsaturated fatty acids may lower LDL levels; omega-3 fatty acids lower blood triglyceride levels and reduce platelet aggregation and therefore blood coagulation.

4. Necessary for growth and development and may prevent coronary artery disease, hypertension, and inflammatory and immune disorders.

Box 35-2

Major Nutrients Absorbed in the Small Intestine

Water and Electrolytes

• Approximately 85% to 90% of the water that enters the gastrointestinal tract is absorbed in the small intestine.

• Sodium passes through tight junctions and is actively transported across cell membranes; it is exchanged for bicarbonate to maintain electroneutrality in the ileum; sodium absorption is enhanced by co-transport with glucose.

• Potassium moves passively across tight junctions with changes in the electrochemical gradient.

Carbohydrates

• Only monosaccharides are absorbed by intestinal mucosa; therefore complex carbohydrates must be hydrolyzed to simplest form.

• Salivary and pancreatic amylases break down starches to oligosaccharides (sucrose, maltose, lactose) in stomach and duodenum; brush-border enzymes hydrolyze them in intestine so they can pass through the unstirred water layer by diffusion.

• Fructose diffuses into the bloodstream; glucose and galactose diffuse or are actively transported.

• Cellulose remains undigested and stimulates large intestine motility.

Proteins

• From 90% to 95% of protein is absorbed; major hydrolysis is accomplished in the small intestine by the pancreatic enzymes trypsin, chymotrypsin, and carboxypeptidase.

• Brush-border enzymes break down proteins into smaller peptides that can cross cell membranes. In the cytosol, they are metabolized into amino acids,
specifically neutral amino acids, basic amino acids, and proline and hydroxyproline.

**Fats**

Digestion and absorption occur in four phases:

1. **Emulsification and lipolysis**—agents cover small fat particles and prevent them from re-forming into fat droplets; then lipolysis divides them into diglycerides, monoglycerides, free fatty acids, and glycerol.

2. **Micelle formation**—products are made water soluble.

3. **Fat absorption**—fat products move from micelle to absorbing surface of intestinal epithelium and diffuse through resynthesis.

4. **Triglycerides and phospholipids then**—become chylomicrons that eventually enter the systemic circulation

**Minerals**

- **Calcium**—absorbed by passive diffusion and transported actively across cell membranes bound to a carrier protein; absorption primarily in ileum.

- **Magnesium**—50% absorbed by active transport or passive diffusion in jejunum and ileum.

- **Phosphate**—absorbed by passive diffusion and active transport in small intestine.

- **Iron**—absorbed by epithelial cells of duodenum and jejunum; vitamin C facilitates.

**Vitamins**

- Absorbed mainly by sodium-dependent active transport, with vitamin \( B_{12} \) bound to intrinsic factor and absorbed in terminal ileum.

**Intestinal Motility**

The movements of the small intestine facilitate digestion and absorption. Chyme leaving the stomach and entering the duodenum stimulates intestinal movements that help blend secretions from the liver, gallbladder, pancreas, and intestinal glands. A
churning motion brings the luminal contents into contact with the absorbing cells of the villi. Propulsive movements then advance the chyme toward the large intestine. Intestinal motility is affected by the following two movements:

1. **Haustral segmentation.** Localized rhythmic contractions of circular smooth muscles divide and mix the chyme, enabling the chyme to have contact with digestive enzymes and the absorbent mucosal surface, and then propel it toward the large intestine.

2. **Peristalsis.** Waves of contraction along short segments of longitudinal smooth muscle allow time for digestion and absorption. The intestinal villi move with contractions of the muscularis mucosae, a thin layer of muscle separating the mucosa and submucosa, with absorption promoted by the swaying of the villi in the luminal contents.

Neural reflexes along the length of the small intestine facilitate motility, digestion, and absorption. The **ileogastric reflex** inhibits gastric motility when the ileum becomes distended. This prevents the continued movement of chyme into an already distended intestine. The **intestinointestinal reflex** inhibits intestinal motility when one part of the intestine is overdistended. Both of these reflexes require extrinsic innervation. The **gastroileal reflex**, which is activated by an increase in gastric motility and secretion, stimulates an increase in ileal motility and relaxation of the ileocecal valve (sphincter). This empties the ileum and prepares it to receive more chyme. The gastroileal reflex is probably regulated by the hormones gastrin and cholecystokinin.

During prolonged fasting or between meals, particularly overnight, slow waves sweep along the entire length of the intestinal tract from the stomach to the terminal ileum. This interdigestive myoelectric complex appears to propel residual gastric and intestinal contents into the colon.

The **ileocecal valve (sphincter)** marks the junction between the terminal ileum and the large intestine. This valve is intrinsically regulated and is normally closed. The arrival of peristaltic waves from the last few centimeters of the ileum causes the ileocecal valve to open, allowing a small amount of chyme to pass. Distention of the upper large intestine causes the sphincter to constrict, preventing further distention or retrograde flow of intestinal contents.

---

**Quick Check 35-3**

1. What cells arise from the crypts of Lieberkühn?
2. How are fats absorbed from the small intestine?

3. Which reflexes inhibit intestinal motility? Which promote it?

Large Intestine

The large intestine is approximately 1.5 meters long and consists of the cecum, appendix, colon (ascending, transverse, descending, and sigmoid), rectum, and anal canal (Figure 35-13). The cecum is a pouch that receives chyme from the ileum. Attached to it is the vermiform appendix, an appendage having little or no physiologic function. From the cecum, chyme enters the colon, which loops upward, traverses the abdominal cavity, and descends to the anal canal. The four parts of the colon are the ascending colon, transverse colon, descending colon, and sigmoid colon. Two sphincters control the flow of intestinal contents through the cecum and colon: the ileocecal valve, which admits chyme from the ileum to the cecum; and the rectosigmoid (O'Beirne) sphincter, which controls the movement of wastes from the sigmoid colon into the rectum. A thick (2.5 to 3 cm) portion of smooth muscle surrounds the anal canal, forming the internal anal sphincter. Overlapping it distally is the striated skeletal muscle of the external anal sphincter (anus).
In the cecum and colon, the longitudinal muscle layer consists of three longitudinal bands called teniae coli (see Figure 35-13). They are shorter than the colon and give it a gathered appearance. The circular muscles of the colon separate the gathers into outpouchings called haustra (sing., haustrum). The haustra become more or less prominent with the contractions and relaxations of the circular muscles. The mucosal surface of the colon has rugae (folds), particularly between the haustra, and Lieberkühn crypts but no villi. Columnar epithelial cells and mucus-secreting goblet cells form the mucosa throughout the large intestine. The columnar epithelium absorbs fluid and electrolytes, and the mucus-secreting cells lubricate the mucosa.

The enteric nervous system regulates motor and secretory activity independently of the extrinsic nervous system. Extrinsic parasympathetic innervation occurs through the vagus and extends from the cecum up to the first part of the transverse colon. Vagal stimulation increases rhythmic contraction of the proximal colon. Extrinsic parasympathetic fibers reach the distal colon through the sacral parasympathetic splanchnic nerves. The internal anal sphincter is usually contracted, and its reflex response is to relax when the rectum is distended. The myenteric plexus provides the major innervation of the internal anal sphincter, but responds to sympathetic stimulation to maintain contraction and parasympathetic stimulation that facilitates relaxation when the rectum is full. Sympathetic innervation of this sphincter arises from the celiac and superior mesenteric ganglia and the sphincter...
nerve. The external anal sphincter is innervated by the pudendal nerve arising from sacral levels of the spinal cord. Sympathetic activity in the entire large intestine modulates intestinal reflexes, conveys somatic sensations of fullness and pain, participates in the defecation reflex, and constricts blood vessels. The blood supply of the large intestine and rectum is derived primarily from branches of the superior and inferior mesenteric arteries (see Figure 35-6) and venous blood drains through the inferior mesenteric vein.

The primary type of colonic movement is segmental. The circular muscles contract and relax at different sites, shuttling the intestinal contents back and forth between the haustra, most commonly during fasting. The movements massage the intestinal contents, called the fecal mass at that point, and facilitate the absorption of water. Propulsive movement occurs with the proximal-to-distal contraction of several haustral units. Peristaltic movements also occur and promote the emptying of the colon. The gastrocolic reflex initiates propulsion in the entire colon, usually during or immediately after eating, when chyme enters from the ileum. The gastrocolic reflex causes the fecal mass to pass rapidly into the sigmoid colon and rectum, stimulating defecation. Gastrin may participate in stimulating this reflex. Epinephrine inhibits contractile activity.

Approximately 500 to 700 ml of chyme flows from the ileum to the cecum per day. Most of the water is absorbed in the colon by diffusion and active transport. Aldosterone increases membrane permeability to sodium, thereby increasing both the diffusion of sodium into the cell and the active transport of sodium to the interstitial fluid. (See Chapters 5 and 18 for a discussion of aldosterone secretion.) The colon does not absorb monosaccharides and amino acids, but some short-chain free fatty acids, which are produced by fermentation, are absorbed.

Absorption and epithelial transport occur in the cecum, ascending colon, transverse colon, and descending colon. By the time the fecal mass enters the sigmoid colon, the mass consists entirely of wastes and is called the feces, composed of food residue, unabsorbed gastrointestinal secretions, shed epithelial cells, and bacteria.

The movement of feces into the sigmoid colon and rectum stimulates the defecation reflex (rectosphinctoric reflex). The rectal wall stretches, and the tonically constricted internal anal sphincter (smooth muscle with autonomic nervous system control) relaxes, creating the urge to defecate. The defecation reflex can be overridden voluntarily by contraction of the external anal sphincter and muscles of the pelvic floor. The rectal wall gradually relaxes, reducing tension, and the urge to defecate passes. Retrograde contraction of the rectum may displace the feces out of the rectal vault until a more convenient time for evacuation. Pain or fear of pain associated with defecation (e.g., rectal fissures or hemorrhoids) can inhibit
the defecation reflex.

Squatting and sitting facilitate defecation because these positions straighten the angle between the rectum and anal canal and increase the efficiency of straining (increasing intra-abdominal pressure). Intra-abdominal pressure is increased by initiating the **Valsalva maneuver**—that is, inhaling and forcing the diaphragm and chest muscles against the closed glottis to increase both intrathoracic and intra-abdominal pressure, which is transmitted to the rectum.

Quick Check 35-4

1. What is the major arterial blood supply to the large intestine?
2. What is the function of haustra?
3. What is the Valsalva maneuver?

The Gastrointestinal Tract and Immunity

The gastrointestinal tract plays a major role in immune defenses by killing many microorganisms. The mucosa of the intestine covers a large surface area and mucosal secretions produce antibodies, particularly IgA, and enzymes that provide defenses against microorganisms. Small intestinal **Paneth cells**, located near the base of the crypts of Leiberkühn, produce defensins and other antimicrobial peptides and lysozymes important to mucosal immunity. Small intestinal **Peyer patches** (lymph nodules containing collections of lymphocytes, plasma cells, and macrophages) are most numerous in the ileum and produce antimicrobial peptides and immunoglobulin A as a component of the gut-associated lymph tissue in the small intestine (see Figures 35-2 and 7-3). Peyer patches are important for antigen processing and immune defense (see Chapter 7).

Intestinal Microbiome

The type and number of bacterial flora vary greatly throughout the normal gastrointestinal (GI) tract and among individuals. There are an increasing number of bacteria from the proximal to the distal GI tract with the highest number in the colon. Genetics, diet, environmental pollution, personal hygiene, vaccination, and antibiotics and other drugs affect the normal composition of bacterial flora. The intestinal bacteria do not have major digestive or absorptive functions but do play a role in metabolism of bile salts, estrogens, androgens, lipids, carbohydrates,
various nitrogenous substances, and drugs. They produce antimicrobial peptides, hormones, neurotransmitters, anti-inflammatory metabolites, and vitamins; destroy toxins; prevent pathogen colonization; and alert the immune system to protect against infection. They are important to overall health and when altered (dysbiosis) or translocated cause disease.\textsuperscript{8}

The intestinal tract is sterile at birth but becomes colonized within a few hours. Within 3 to 4 weeks after birth, the normal flora are established. The number and diversity of bacteria decrease with aging, increasing the risk for infection. The normal flora do not have the virulence factors associated with pathogenic microorganisms, thus permitting immune tolerances.\textsuperscript{9}

Bacteria in the stomach are relatively sparse because of the secretion of acid that kills ingested pathogens or inhibits bacterial growth (with the exception of \textit{Helicobacter pylori}). Bile acid secretion, intestinal motility, and antibody production suppress bacterial growth in the duodenum. In the duodenum and jejunum, there is a low concentration of aerobes (10\textsuperscript{-1} to 10\textsuperscript{-4}/ml), primarily streptococci, lactobacilli, staphylococci, and other enteric bacteria. Anaerobes are found distal to the ileocecal valve but not proximal to the ileum. They constitute about 95\% of the fecal flora in the colon and contribute one third of the solid bulk of feces. \textit{Bacteroides} and \textit{Firmicutes} are the most common intestinal bacteria.

\section*{Splanchnic Blood Flow}

The \textbf{splanchnic blood flow} provides blood to the esophagus, stomach, small and large intestines, liver, gallbladder, pancreas, and spleen (see Figure 35-6). Blood flow is regulated by cardiac output and blood volume, the autonomic nervous system, hormones, and local autoregulatory blood flow mechanisms. The splanchnic circulation serves as an important reservoir of blood volume to maintain circulation to the heart and lungs when needed. The superior and inferior mesenteric arteries provide the blood supply to the large intestine (see Figures 35-6 and 35-13).
Accessory Organs of Digestion

The liver, gallbladder, and exocrine pancreas all secrete substances necessary for the digestion of chyme. These secretions are delivered to the duodenum through the sphincter of Oddi at the major duodenal papilla (of Vater) (Figure 35-14). The liver produces bile, which contains salts necessary for fat digestion and absorption. Between meals, bile is stored in the gallbladder. The exocrine pancreas produces (1) enzymes needed for the complete digestion of carbohydrates, proteins, and fats; and (2) an alkaline fluid that neutralizes chyme, creating a duodenal pH that supports enzymatic action.

The liver also receives nutrients absorbed by the small intestine and metabolizes or synthesizes them into forms that can be absorbed by the body's cells. It then releases the nutrients into the bloodstream or stores them for later use.
Liver

The liver weighs 1200 to 1600 g. It is located under the right diaphragm and is divided into right and left lobes. The larger, right lobe is divided further into the caudate and quadrate lobes (Figure 35-15). The falciform ligament separates the right and left lobes and attaches the liver to the anterior abdominal wall. The round ligament (ligamentum teres) extends along the free edge of the falciform ligament, extending from the umbilicus to the inferior surface of the liver. The coronary ligament branches from the falciform ligament and extends over the superior surface of the right and left lobes, binding the liver to the inferior surface of the diaphragm. The liver is covered by the Glisson capsule, which contains blood vessels, lymphatics, and nerves. When the liver is diseased or swollen, distention of the capsule causes pain because it is innervated by sensory neurons.

The metabolic functions of the liver require a large amount of blood. The liver receives blood from both arterial and venous sources. The hepatic artery branches from the celiac artery and provides oxygenated blood at the rate of 400 to 500 ml/min (about 25% of the cardiac output). The hepatic portal vein receives deoxygenated blood from the inferior and superior mesenteric veins, the splenic vein, and the gastric and esophageal veins, and delivers about 1000 to 1500 ml/min to the liver. The hepatic portal vein, which carries 70% of the blood supply to the liver, is rich in nutrients that have been absorbed from the intestinal tract (Figure 35-16).
Within the liver lobes are multiple, smaller anatomic units called liver lobules (Figure 35-17). They are formed of cords or plates of hepatocytes, which are the functional cells of the liver. These cells can regenerate; therefore damaged or resected liver tissue can regrow. Small capillaries, or sinusoids, are located between the plates of hepatocytes. They receive a mixture of venous and arterial blood from branches of the hepatic artery and portal vein. Blood from the sinusoids drains to a central vein in the middle of each liver lobule. Venous blood from all the lobules then flows into the hepatic vein, which empties into the inferior vena cava. Small channels (bile canaliculi) conduct bile, which is produced by the hepatocytes, outward to bile ducts and eventually drain into the common bile duct (see Figure 35-17). This duct empties bile into the ampulla of Vater, and then into the duodenum.
through an opening called the **major duodenal papilla** (**sphincter of Oddi**).
A), are contractile in liver injury, regulate sinusoidal blood flow, may proliferate into myofibroblasts, participate in liver fibrosis, produce erythropoietin, can act as antigen-presenting cells, remove foreign substances from the blood, and trap bacteria. Natural killer cells (pit cells) also are found in the sinusoidal lumen; they produce interferon-γ and are important in tumor defense. Between the endothelial lining of the sinusoid and the hepatocyte is the Disse space, which drains interstitial fluid into the hepatic lymph system.

**Quick Check 35-5**

1. Where does blood in the portal vein originate?
2. What is the function of hepatocytes?
3. What is the function of Kupffer cells?

**Secretion of Bile**

The liver assists intestinal digestion by secreting 700 to 1200 ml of bile per day. Bile is an alkaline, bitter-tasting, yellowish green fluid that contains bile salts (conjugated bile acids), cholesterol, bilirubin (a pigment), electrolytes, and water. It is formed by hepatocytes and secreted into the canaliculi. Bile salts, which are conjugated bile acids, are required for the intestinal emulsification and absorption of fats. Having facilitated fat emulsification and absorption, most bile salts are actively absorbed in the terminal ileum and returned to the liver through the portal circulation for resecretion. The pathway for recycling of bile salts is termed the enterohepatic circulation (Figure 35-18).
Bile has two fractional components: the acid-dependent fraction and the acid-independent fraction. Hepatocytes secrete the **bile acid–dependent fraction**, which
consists of bile acids, cholesterol, lecithin (a phospholipid), and bilirubin (a bile pigment). The **bile acid–independent fraction**, which is secreted by the hepatocytes and epithelial cells of the bile canaliculi, is a bicarbonate-rich aqueous fluid that gives bile its alkaline pH.

Bile salts are conjugated in the liver from primary and secondary bile acids. The **primary bile acids** are cholic acid and chenodeoxycholic (chenic) acid. These acids are synthesized from cholesterol by the hepatocytes. The **secondary bile acids** are deoxycholic and lithocholic acid. These acids are formed in the small intestine by intestinal bacteria, after which they are absorbed and flow to the liver (see Figure 35-18). Both forms of bile acids are conjugated with amino acids (glycine or taurine) in the liver to form bile salts. Conjugation makes the bile acids more water soluble, thus restricting their diffusion from the duodenum and ileum. The primary and secondary bile acids together form the **bile acid pool**.

Some bile salts are deconjugated by intestinal bacteria to secondary bile acids. These acids diffuse passively into the portal blood from both small and large intestines. An increase in the plasma concentration of bile acids accelerates the uptake and resecretion of bile acids and salts by the hepatocytes. The cycle of hepatic secretion, intestinal absorption, and hepatic resecretion of bile acids completes the enterohepatic circulation.

Bile secretion is called **choleresis**. A **choleretic agent** stimulates the liver to secrete bile. One strong stimulus is a high concentration of bile salts. Other choleretics include cholecystokinin, vagal stimulation, and secretin, which increases the rate of bile flow by promoting the secretion of bicarbonate from canaliculi and other intrahepatic bile ducts.

**Metabolism of Bilirubin**

**Bilirubin** is a byproduct of the destruction of aged red blood cells. It gives bile a greenish black color and produces the yellow tinge of jaundice. Aged red blood cells are absorbed and destroyed by macrophages (Kupffer cells) of the mononuclear phagocyte system (also called the **reticuloendothelial system**), primarily in the spleen and liver. Within these cells, hemoglobin is separated into its component parts: heme and globin (Figure 35-19). The globin component is further degraded into its constituent amino acids, which are recycled to form new protein. The heme moiety is converted to biliverdin by the enzymatic (heme oxygenase) cleavage of iron. The iron attaches to transferrin in the plasma and can be stored in the liver or used by the bone marrow to make new red blood cells. The biliverdin is enzymatically converted to bilirubin in the Kupffer cell and then is released into the plasma where it binds to albumin and is known as **unconjugated bilirubin**, or free
bilirubin, which is lipid soluble. Bilirubin also may have a role as an antioxidant and provide cytoprotection.\textsuperscript{13}
In the liver, unconjugated bilirubin moves from plasma in the sinusoids into the hepatocyte. Within hepatocytes, unconjugated bilirubin joins with glucuronic acid to form **conjugated bilirubin**, which is water soluble and is secreted in the bile. When conjugated bilirubin reaches the distal ileum and colon, it is deconjugated by bacteria and converted to **urobilinogen**. Urobilinogen is then reabsorbed in the intestines and excreted in the urine as urobilin. A small amount is eliminated in feces, as stercobilin, which contributes to the stool’s brown pigmentation.

**Vascular and Hematologic Functions**

Because of its extensive vascular network, the liver can store a large volume of blood. The amount stored at any one time depends on pressure relationships in the arteries and veins. The liver also can release blood to maintain systemic circulatory volume in the event of hemorrhage.

The liver also has hemostatic functions. It synthesizes most clotting factors (see Chapter 20). Vitamin K, a fat-soluble vitamin, is essential for the synthesis of the clotting factors. Because bile salts are needed for reabsorption of fats, vitamin K absorption depends on adequate bile production in the liver.

**Metabolism of Nutrients**

**Fats.**

Ingested fat absorbed by lacteals in the intestinal villi enters the liver through the lymphatics, primarily as triglycerides. In the liver the triglycerides can be hydrolyzed to glycerol and free fatty acids and used to produce metabolic energy (ATP), or they can be released into the bloodstream bound to proteins (lipoproteins). The lipoproteins are carried by the blood to adipose cells for storage. The liver also synthesizes phospholipids and cholesterol, which are needed for the hepatic production of bile salts, steroid hormones, components of plasma membranes, and other special molecules.

**Proteins.**

Protein synthesis requires the presence of all the essential amino acids (obtained only from food), as well as nonessential amino acids. Proteins perform many important functions in the body; these are summarized in **Table 35-2**.

</table>

Within hepatocytes, amino acids are converted to carbohydrates (keto acids) by the removal of ammonia (NH₃), a process known as deamination. The ammonia is converted to urea by the liver and passes into the blood to be excreted by the kidneys. Depending on the nutritional status of the body, the keto acids either are converted to fatty acids for fat synthesis and storage or are oxidized by the Krebs tricarboxylic acid cycle (see Chapter 1) to provide energy for the liver cells.

The plasma proteins, including albumins and globulins (with the exception of gamma globulin, which is formed in lymph nodes and lymphoid tissue), are synthesized by the liver. They play an important role in preserving blood volume and pressure by maintaining plasma oncotic pressure. The liver also synthesizes several nonessential amino acids and serum enzymes, including aspartate aminotransferase (AST; previously SGOT), alanine aminotransferase (ALT; previously SGPT), lactate dehydrogenase (LDH), and alkaline phosphatase.

Carbohydrates.

The liver contributes to the stability of blood glucose levels by releasing glucose during hypoglycemia (low blood glucose level) and absorbing glucose during hyperglycemia (high blood glucose level) and storing it as glycogen (glyconeogenesis) or converting it to fat. When all glycogen stores have been used, the liver can convert amino acids and glycerol to glucose (gluconeogenesis).

Metabolic Detoxification

The liver alters exogenous and endogenous chemicals (e.g., drugs), foreign molecules, and hormones to make them less toxic or less biologically active. This process, called metabolic detoxification or biotransformation, diminishes intestinal or renal tubular reabsorption of potentially toxic substances and facilitates their intestinal and renal excretion. In this way alcohol, barbiturates, amphetamines, steroids, and hormones (including estrogens, aldosterone, antidiuretic hormone,
and testosterone) are metabolized or detoxified, preventing excessive accumulation and adverse effects. Although metabolic detoxification is usually protective, the end products of metabolic detoxification sometimes become toxins (see Health Alert: Paracetamol [Acetaminophen] and Acute Liver Failure) or active metabolites. Toxins of alcohol metabolism, for example, are acetaldehyde and hydrogen, which can damage the liver's ability to function (see Chapter 4 and Figure 4-21).

**Health Alert**

**Paracetamol (Acetaminophen) and Acute Liver Failure**

Paracetamol (acetaminophen) toxicity from chronic use or overdose is the leading cause of acute liver failure in the developed world (see Figure 4-18). Concomitant alcohol use or abuse, medications, genetics, and nutritional status can influence the susceptibility and severity of hepatotoxicity. Hepatotoxicity should be suspected when doses exceed 4 grams per day. Liver injury occurs in 17% of adults with unintentional acetaminophen overdose. The onset of toxicity is sudden and lasts for up to 24 hours. Symptoms include signs of gastrointestinal upset, nausea, vomiting, anorexia, diaphoresis, and pallor. Elevated levels of serum aminotransferase appear after 48 hours accompanied by hypoprothrombinemia, metabolic acidosis, and renal failure. Early treatment (within 8 hours) with N-acetylcysteine (NAC) provides a 66% chance of recovery. The acetaminophen-aminotransferase multiplication product (APAP × AT) and the Psi Parameter (acetaminophen level at 4 hours postingestion and the time-to-initiation of NAC) are predictors of acetaminophen toxicity in NAC-treated individuals. Liver transplant is lifesaving and there is about 70% survival at 1 year after liver transplantation.

**Storage of Minerals and Vitamins**

The liver stores certain vitamins and minerals, including iron and copper, in times of excessive intake and releases them in times of need. The liver can store vitamins B<sub>12</sub> and D for several months and vitamin A for several years. The liver also stores vitamins E and K. Iron is stored in the liver as ferritin, an iron-protein complex, and is released as needed for red blood cell production. Common tests of liver function are listed in Table 35-3.

### Gallbladder

The **gallbladder** is a saclike organ on the inferior surface of the liver (Figure 35-20). Its primary function is to store and concentrate bile between meals. During the interdigestive period, bile flows from the liver through the right or left hepatic duct into the common hepatic duct and meets resistance at the closed sphincter of Oddi (duodenal papilla), which controls flow into the duodenum and prevents backflow of duodenal contents into the pancreatobiliary system. Bile then flows through the **cystic duct** into the gallbladder, where it is concentrated and stored. The mucosa of the gallbladder wall readily absorbs water and electrolytes, leaving a high concentration of bile salts, bile pigments, and cholesterol. The gallbladder holds about 90 ml of bile.
Within 30 minutes after eating, the gallbladder begins to contract, forcing stored bile through the cystic duct and into the common bile duct. The sphincter of Oddi relaxes, and bile flows into the duodenum through the major duodenal papilla. During the cephalic and gastric phases of digestion, gallbladder contraction is mediated by cholinergic branches of the vagus nerve. Hormonal regulation of gallbladder contraction is derived primarily from the release of cholecystokinin secreted by the duodenal and jejunal mucosa in the presence of fat. Vasoactive intestinal peptide, pancreatic polypeptide, and sympathetic nerve stimulation relax
the gallbladder.

**Exocrine Pancreas**

The **pancreas** is approximately 20 cm long, with its head tucked into the curve of the duodenum and its tail touching the spleen. The body of the pancreas lies deep in the abdomen, behind the stomach (see Figure 35-20). The pancreas is unique in that it has both endocrine and exocrine functions. The endocrine pancreas secretes hormones: insulin, glucagon, somatostatin, and pancreatic polypeptide (see Chapter 18).

The **exocrine pancreas** is composed of acinar cells that secrete enzymes and networks of ducts that secrete alkaline fluids. Both have important digestive functions. The acinar cells are organized into spherical lobules around small secretory ducts (see Figure 35-20). Secretions drain into a system of ducts that leads to the **pancreatic duct (Wirsung duct)**, which empties into the common bile duct at the **ampulla of Vater**, and then into the duodenum. In some individuals, an accessory duct (the duct of Santorini) branches off the pancreatic duct and drains directly into the duodenum at the minor duodenal papilla.

Arterial blood is supplied to the pancreas by branches of the celiac and superior mesenteric arteries. Venous blood leaves the head of the pancreas through tributaries to the portal vein, with the body and tail being drained through the splenic vein. All hormonal pancreatic secretions also pass through the hepatic portal vein into the liver.

Pancreatic innervation arises from parasympathetic neurons of the vagus nerve. These fibers activate postganglionic fibers, which stimulate enzymatic and hormonal secretion. Sympathetic postganglionic fibers from the celiac and superior mesenteric plexuses innervate the blood vessels, cause vasoconstriction, and inhibit pancreatic secretion.

The aqueous secretions of the exocrine pancreas are isotonic and contain potassium, sodium, bicarbonate, and chloride. The highly alkaline pancreatic juice neutralizes the acidic chyme that enters the duodenum from the stomach and provides the alkaline medium needed for the actions of digestive enzymes and intestinal absorption of fat.

In the pancreas, transport of water and electrolytes through the ductal epithelium involves both active and passive mechanisms. The ductal cells actively transport hydrogen into the blood and bicarbonate into the duct lumen. Potassium and chloride are secreted by diffusion according to changes in electrochemical potential gradients. As the secretion flows down the duct, water is osmotically transported into the juice until it becomes isosmotic. At low flow rates bicarbonate is exchanged
passively for chloride, but at higher flow rates there is less time for this exchange and bicarbonate concentration increases. Because eating stimulates the flow of pancreatic juice, the juice is most alkaline when it needs to be: during digestion.

The pancreatic enzymes can hydrolyze proteins (proteases), carbohydrates (amylases), and fats (lipases) (see Figure 35-11). The proteolytic (protein-digesting) enzymes include trypsin, chymotrypsin, carboxypeptidase, and elastase. These enzymes are secreted in their inactive forms—that is, as trypsinogen, chymotrypsinogen, procarboxypeptidase, and proelastase, respectively—to protect the pancreas from the digestive effects of its own enzymes. For further protection, the pancreas produces trypsin inhibitor, which prevents the activation of proteolytic enzymes while they are in the pancreas. Once in the duodenum, the inactive forms (proenzymes) are activated by enterokinase, an enzyme secreted by the duodenal mucosa. Trypsinogen is the first proenzyme to be activated. Its conversion to trypsin stimulates the conversion of chymotrypsinogen to chymotrypsin and procarboxypeptidase to carboxypeptidase. Each of these enzymes cleaves specific peptide bonds to reduce polypeptides to smaller peptides.

Secretion of the aqueous and enzymatic components of pancreatic juice is controlled by hormonal and vagal stimuli. Secretin stimulates the acinar and duct cells to secrete the bicarbonate-rich fluid that neutralizes chyme and prepares it for enzymatic digestion. As chyme enters the duodenum, its acidity (pH of 4.5 or less) stimulates the S cells (secretin-producing cells) of the duodenum to release secretin, which is absorbed by the intestine and delivered to the pancreas in the bloodstream. In the pancreas, secretin causes ductal and acinar cells to release alkaline fluid. Secretin also inhibits the actions of gastrin, thereby decreasing gastric hydrochloric acid secretion and motility. The overall effect is to neutralize the contents of the duodenum.

Enzymatic secretion follows, stimulated by cholecystokinin, which activates acetylcholine (Ach) from the vagus nerve and release of Ach from pancreatic stellate cells. Cholecystokinin is released in the duodenum in response to the essential amino acids and fatty acids already present in chyme. Once in the small intestine, activated pancreatic enzymes inhibit the release of more cholecystokinin and Ach. This feedback mechanism inhibits the secretion of more pancreatic enzymes. Pancreatic polypeptide is released after eating and inhibits postprandial pancreatic exocrine secretion. (See Table 35-1 for a summary of hormonal stimulation of pancreatic secretions.) Selected tests of pancreatic function are listed in Table 35-4.
1. Trace the route of bile salts and acids from formation to recycling.

2. What are the sources of the two types of bilirubin?

3. What is the function of the gallbladder?

4. How do pancreatic beta cells differ from acinar cells?

### TABLE 35-4

## Geriatric Considerations

### Aging & the Gastrointestinal System
Age-related changes in gastrointestinal function vary among individuals and within organ systems. Changes can include the following:

#### Oral Cavity and Esophagus
1. Tooth enamel and dentin deteriorate, so cavities are more likely.
2. Teeth are lost as a result of periodontal disease and brittle roots that break easily.
3. Taste buds decline in number.
4. Sense of smell diminishes.
5. Salivary secretion decreases.
6. Dysphagia is much more common.
7. Eating is less pleasurable, appetite is reduced, and food is not sufficiently chewed or lubricated; therefore swallowing is difficult.

#### Stomach
1. Gastric motility, blood flow, and volume and acid content of gastric juice may be reduced, particularly with gastric atrophy, and gastric emptying may be delayed.
2. Protective mucosal barrier decreases.

#### Intestines
1. There is a change in the composition of the intestinal microbiota and resultant increased susceptibility to disease.
2. Size of Peyer patches and degree of mucosal immunity decline with increased risk for infection and inflammation.
3. The brain-gut axis (bidirectional neuroendocrine communication) may be disrupted and enteric neurons may degenerate with changes in gastrointestinal
motility, secretion, and absorption as well as the elder person's appetite, and overall nutritional status.

4. Intestinal villi may become shorter and more convoluted, with diminished reparative capacity.

5. Intestinal absorption, motility, and blood flow may decrease, prolonging transit time and altering nutrient absorption.

6. Rectal muscle mass decreases and the anal sphincter weakens.

7. Constipation, fecal impaction, and fecal incontinence may develop and is related to immobility, low-fiber diet, and changes in enteric nervous system structure and functions.

**Liver**

1. There is decreased hepatic regeneration; size and weight of liver decrease.

2. Ability to detoxify drugs decreases.

**Pancreas and Gallbladder**

1. Fibrosis, fatty acid deposits, and pancreatic atrophy occur.

2. Secretion of digestive enzymes, particularly proteolytic enzymes, decreases.

3. No changes in gallbladder and bile ducts occur, but there is an increased prevalence of gallstones and cholecystitis.

Did You Understand?
The Gastrointestinal Tract

1. The major functions of the gastrointestinal tract are the mechanical and chemical breakdown of food and the absorption of digested nutrients.

2. The gastrointestinal tract is a hollow tube that extends from the mouth to the anus.

3. The walls of the gastrointestinal tract have several layers: mucosa, muscularis mucosae, submucosa, tunica muscularis (circular muscle and longitudinal muscle), and serosa.

4. The peritoneum is a double layer of membranous tissue. The visceral layer covers the abdominal organs, and the parietal layer extends along the abdominal wall. The peritoneal cavity is the space between the two layers.

5. Except for swallowing and defecation, which are controlled voluntarily, the functions of the gastrointestinal tract are controlled by extrinsic and intrinsic autonomic nerves and intestinal hormones.

6. Digestion begins in the mouth, with chewing and salivation. The digestive component of saliva is α-amylase, which initiates carbohydrate digestion.

7. The esophagus is a muscular tube that transports food from the mouth to the stomach. The tunica muscularis in the upper part of the esophagus is striated muscle, and that in the lower part is smooth muscle.

8. Swallowing is controlled by the swallowing center in the reticular formation of the brain. The two phases of swallowing are the oropharyngeal phase (voluntary swallowing) and the esophageal phase (involuntary swallowing).

9. Food is propelled through the esophagus by peristalsis: waves of sequential relaxations and contractions of the tunica muscularis.

10. The lower esophageal sphincter opens to admit swallowed food into the stomach and then closes to prevent regurgitation of food back into the esophagus.

11. The stomach is a baglike structure that secretes digestive juices, mixes and stores food, and propels partially digested food (chyme) through the pylorus into the
12. The vagus nerve stimulates gastric (stomach) secretion and motility.

13. The hormones gastrin and motilin stimulate gastric emptying; the hormones secretin and cholecystokinin delay gastric emptying.

14. Mucus is secreted throughout the stomach and protects the stomach wall from acid and digestive enzymes.

15. Gastric glands in the fundus and body of the stomach secrete intrinsic factor, which is needed for vitamin $\text{B}_{12}$ absorption; and hydrochloric acid, which dissolves food fibers, kills microorganisms, and activates the enzyme pepsin.

16. Chief cells in the stomach secrete pepsinogen, which is converted to pepsin in the acidic environment created by hydrochloric acid.

17. Acid secretion is stimulated by the vagus nerve, gastrin, and histamine and is inhibited by sympathetic stimulation and cholecystokinin.

18. The three phases of acid secretion by the stomach are the cephalic phase (anticipation and swallowing), the gastric phase (food in the stomach), and the intestinal phase (chyme in the intestine).

19. The small intestine is 5 meters long and has three segments: the duodenum, jejunum, and ileum.

20. The duodenum receives chyme from the stomach through the pyloric valve. The presence of chyme stimulates the liver and gallbladder to deliver bile and the pancreas to deliver digestive enzymes. Bile and enzymes flow through an opening guarded by the sphincter of Oddi.

21. Enzymes secreted by the small intestine (maltase, sucrase, lactase), pancreatic enzymes, and bile salts act in the small intestine to digest proteins, carbohydrates, and fats.

22. Digested substances are absorbed across the intestinal wall and then transported to the liver, where they are metabolized further.

23. The ileocecal valve connects the small and large intestines and prevents reflux into the small intestine.
24. Villi are small fingerlike projections that extend from the small intestinal mucosa and increase its absorptive surface area.

25. Carbohydrates, amino acids, and fats are absorbed primarily by the duodenum and jejunum; bile salts and vitamin $B_{12}$ are absorbed by the ileum. Vitamin $B_{12}$ absorption requires the presence of intrinsic factor.

26. Bile is produced by the liver and is necessary for fat digestion and absorption. Bile's alkalinity helps to neutralize chyme, thereby creating a pH that enables the pancreatic enzymes to digest proteins, carbohydrates, and fats.

27. Bile salts emulsify and hydrolyze fats and incorporate them into water-soluble micelles, which are then transported through the unstirred water layer to the brush border of the intestinal mucosa. The fat content of the micelles readily diffuses through the epithelium into lacteals (lymphatic ducts) in the villi. From there, fats flow into lymphatics and into the systemic circulation, which delivers them to the liver.

28. Minerals and water-soluble vitamins are absorbed by both active and passive transport throughout the small intestine.

29. Peristaltic movements created by longitudinal muscles propel the chyme along the intestinal tract, and contractions of the circular muscles (haustral segmentation) mix the chyme.

30. The ileogastric reflex inhibits gastric motility when the ileum is distended.

31. The intestinointestinal reflex inhibits intestinal motility when one intestinal segment is overdistended.

32. The gastroileal reflex increases intestinal motility when gastric motility increases.

33. The large intestine consists of the cecum, appendix, colon (ascending, transverse, descending, and sigmoid), rectum, and anal canal.

34. The teniae coli are three bands of longitudinal muscle that extend the length of the colon.

35. Haustra are pouches of colon formed with alternating contraction and relaxation
of the circular muscles.

36. The mucosa of the large intestine contains mucus-secreting cells and mucosal folds, but no villi.

37. The large intestine massages the fecal mass and absorbs water and electrolytes.

38. Distention of the ileum with chyme causes the gastrocolic reflex, or the mass propulsion of feces to the rectum.

39. Defecation is stimulated when the rectum is distended with feces. The tonically contracted internal anal sphincter relaxes, and if the voluntarily regulated external sphincter relaxes, defecation occurs.

40. The immune system of the GI tract consists of Paneth cells, which produce defensins and other antimicrobial peptides and lysozymes; and the lymph nodes of Peyer patches, which contain lymphocytes, plasma cells, and macrophages.

41. The largest number of intestinal bacteria (intestinal microbiome) is in the colon. The most numerous anaerobes are *Bacteroides* and *Firmicutes*. Intestinal bacteria are important for metabolism of bile salts, metabolism of selected drugs and hormones, and prevention of pathogen colonization.

42. The intestinal tract is sterile at birth and becomes totally colonized within 3 to 4 weeks.

43. The splanchnic blood flow provides blood to the esophagus, stomach, small and large intestines, gallbladder, pancreas, and spleen.

**Accessory Organs of Digestion**

1. The liver is the second largest organ in the body. It has digestive, metabolic, hematologic, vascular, and immunologic functions.

2. The liver is divided into the right and left lobes and smaller units called liver lobules. The liver is supported by the falciform, round, and coronary ligaments.

3. Liver lobules consist of plates of hepatocytes, which are the functional cells of the liver.
4. The hepatocytes synthesize 700 to 1200 ml of bile per day and secrete it into the bile canaliculi, which are small channels between the hepatocytes. The bile canaliculi drain bile into the common bile duct and then into the duodenum through an opening called the major duodenal papilla (sphincter of Oddi).

5. Sinusoids are capillaries located between the plates of hepatocytes. Blood from the portal vein and hepatic artery flows through the sinusoids to a central vein in each lobule and then to the hepatic vein and inferior vena cava.

6. Kupffer cells, which are part of the mononuclear phagocyte system, line the sinusoids and destroy microorganisms in sinusoidal blood; they are important in bilirubin production and lipid metabolism.

7. The primary bile acids are synthesized from cholesterol by the hepatocytes. The primary acids are then conjugated to form bile salts. The secondary bile acids are the product of bile salt deconjugation by bacteria in the intestinal lumen.

8. Most bile salts and acids are recycled. The absorption of bile salts and acids from the terminal ileum and their return to the liver are known as the enterohepatic circulation of bile.

9. Bilirubin is a pigment liberated by the lysis of aged red blood cells in the liver and spleen. Unconjugated bilirubin is fat soluble and can cross cell membranes. Unconjugated bilirubin is converted to water-soluble, conjugated bilirubin by hepatocytes and is secreted with bile.

10. The liver produces clotting factors and can store a large volume of blood.

11. The liver plays a major role in the metabolism of fats, proteins, and carbohydrates; and stores minerals, vitamin B$_{12}$, and fat-soluble vitamins.

12. The liver metabolically transforms or detoxifies hormones, toxic substances, and drugs to less active substances.

13. The gallbladder is a saclike organ located on the inferior surface of the liver. The gallbladder stores bile between meals and ejects it when chyme enters the duodenum.

14. Stimulated by cholecystokinin, the gallbladder contracts and forces bile through the cystic duct and into the common bile duct. The sphincter of Oddi relaxes,
enabling bile to flow through the major duodenal papilla into the duodenum.

15. The pancreas is a gland located behind the stomach. The endocrine pancreas produces hormones (glucagon, insulin) that facilitate the formation and cellular uptake of glucose. The exocrine pancreas secretes an alkaline solution and the enzymes (trypsin, chymotrypsin, carboxypeptidase, α-amylase, lipase) that digest proteins, carbohydrates, and fats.

16. Secretin stimulates pancreatic secretion of alkaline fluid, and cholecystokinin and acetylcholine stimulate secretion of enzymes. Pancreatic secretions originate in acini and ducts of the pancreas and empty into the duodenum through the common bile duct or an accessory duct that opens directly into the duodenum.

The gastrointestinal (GI) tract is a continuous, hollow organ that extends from the mouth to the anus. It includes the esophagus, stomach, small intestine, large intestine, and rectum. The accessory organs of digestion include the salivary glands, liver, gallbladder, and pancreas.

Disorders of the gastrointestinal tract disrupt one or more of its functions. Structural and neural abnormalities can slow, obstruct, or accelerate the movement of intestinal contents at any level of the gastrointestinal tract. Inflammatory and ulcerative conditions of the gastrointestinal wall disrupt secretion, motility, and absorption. Inflammation or obstruction of the liver, pancreas, or gallbladder can alter metabolism and result in local and systemic symptoms. Many clinical manifestations of gastrointestinal tract disorders are nonspecific and can be caused by a variety of impairments.
Disorders of the Gastrointestinal Tract

Clinical Manifestations of Gastrointestinal Dysfunction

Anorexia

Anorexia is lack of a desire to eat despite physiologic stimuli that would normally produce hunger. This nonspecific symptom is often associated with nausea, abdominal pain, diarrhea, and psychologic stress. Side effects of drugs and disorders of other organ systems, including cancer, heart disease, and renal disease, are often accompanied by anorexia.

Vomiting

Vomiting (emesis) is the forceful emptying of stomach and intestinal contents (chyme) through the mouth. The vomiting center lies in the medulla oblongata. Stimuli initiating the vomiting reflex include severe pain; distention of the stomach or duodenum; the presence of ipecac or copper salts in the duodenum; stimulation of the vestibular system through the eighth cranial nerve (motion sickness); side effects of many drugs; torsion or trauma affecting the ovaries, testes, uterus, bladder, or kidney; motion; and activation of the chemoreceptor trigger zone (CTZ) (area postrema) in the medulla (e.g., morphine). Nausea and retching (dry heaves) are distinct events that usually precede vomiting. Nausea is a subjective experience associated with various conditions, including abnormal pain and labyrinthine stimulation (i.e., spinning movement). Specific neural pathways have not been identified, but hypersalivation and tachycardia are common associated symptoms. Retching is the muscular event of vomiting without the expulsion of vomitus.

Vomiting begins with deep inspiration. The glottis closes, the intrathoracic pressure falls, and the esophagus becomes distended. Simultaneously, the abdominal muscles contract, creating a pressure gradient from abdomen to thorax. The lower esophageal sphincter (LES) and body of the stomach relax, but the duodenum and antrum of the stomach spasm. The reverse peristalsis and pressure gradient force chyme from the stomach and duodenum up into the esophagus. Because the upper esophageal sphincter is closed, chyme does not enter the mouth. As the abdominal muscles relax, the contents of the esophagus drop back into the stomach. This process may be repeated several times before vomiting occurs. A diffuse sympathetic discharge causes the tachycardia, tachypnea, and diaphoresis that accompany retching and vomiting. The parasympathetic system mediates copious salivation, increased gastric motility, and relaxation of the upper and lower
esophageal sphincters.

With vomiting, the duodenum and antrum of the stomach produce reverse peristalsis, while the body of the stomach and the esophagus relax. When the stomach is full of gastric contents, the diaphragm is forced high into the thoracic cavity by strong contractions of the abdominal muscles. The higher intrathoracic pressure forces the upper esophageal sphincter to open, and chyme is expelled from the mouth. Then the stomach relaxes and the upper part of the esophagus contracts, forcing the remaining chyme back into the stomach. The lower esophageal sphincter then closes. The cycle is repeated if there is a volume of chyme remaining in the stomach.

Spontaneous vomiting not preceded by nausea or retching is called projectile vomiting. It is caused by direct stimulation of the vomiting center by neurologic lesions (e.g., increased intracranial pressure, tumors, or aneurysms) involving the brainstem or can be a symptom of gastrointestinal obstruction (pyloric stenosis). The metabolic consequences of vomiting are fluid, electrolyte, and acid-base disturbances including hyponatremia, hypokalemia, hypochloremia, and metabolic alkalosis (see Chapter 5).

Constipation

**Constipation** is difficult or infrequent defecation. It is a common problem, particularly among the elderly, and usually means a decrease in the number of bowel movements per week, hard stools, and difficult evacuation. The definition must be individually determined since normal bowel habits range from one to three evacuations per day to one per week. Constipation is not significant until it causes health risks or impairs quality of life.

Pathophysiology

Constipation can occur as a primary or secondary condition. Primary constipation is generally classified into three categories. *Normal transit (functional) constipation* involves a normal rate of stool passage but there is difficulty with stool evacuation. *Functional constipation* is associated with a sedentary lifestyle, low-residue diet (the habitual consumption of highly refined foods), or low fluid intake. *Slow-transit constipation* involves impaired colonic motor activity with infrequent bowel movements, straining to defecate, mild abdominal distention, and palpable stool in the sigmoid colon. *Pelvic floor or outlet dysfunction* refers to an inability or difficulty expelling stool because of dysfunction of the pelvic floor muscles or anal sphincter. Examples include pelvic floor dyssynergia, rectal fissures, strictures, or hemorrhoids.
Secondary constipation can be caused by diet, medications, or neurogenic disorders (e.g., stroke, Parkinson disease, spinal cord lesions, multiple sclerosis, Hirschsprung disease) in which neural pathways or neurotransmitters are altered and colon transit time delayed. Opiates (particularly codeine), antacids containing calcium carbonate or aluminum hydroxide, anticholinergics, iron, and bismuth tend to inhibit bowel motility. Endocrine or metabolic disorders associated with constipation include hypothyroidism, diabetes mellitus, hypokalemia, and hypercalcemia. Pelvic hiatal hernia (herniation of the bowel through the floor of the pelvis), diverticuli, irritable bowel syndrome (constipation predominant), and pregnancy are associated with constipation. Aging may result in decreased mobility, changes in neuromuscular function, use of medications, and comorbid medical conditions causing constipation.\(^2\) Constipation as a notable change in bowel habits can be an indication of colorectal cancer.

**Clinical manifestations**

Indicators of constipation include two of the following for at least 3 months: (1) straining with defecation at least 25% of the time; (2) lumpy or hard stools at least 25% of the time; (3) sensation of incomplete emptying at least 25% of the time; (4) manual maneuvers to facilitate stool evacuation for at least 25% of defecations; and (5) fewer than three bowel movements per week.\(^3\) Changes in bowel evacuation patterns, such as less frequent defecation, smaller stool volume, hard stools, difficulty passing stools (straining), or a feeling of bowel fullness and discomfort, require investigation. Fecal impaction (hard, dry stool retained in the rectum) is associated with rectal bleeding, abdominal or cramping pain, nausea and vomiting, weight loss, and episodes of diarrhea. Straining to evacuate stool may cause engorgement of the hemorrhoidal veins and hemorrhoidal disease or thrombosis with rectal pain, bleeding, and itching. Passage of hard stools can cause painful anal fissures.

**Evaluation and treatment**

The history, current use of medications, physical examination, and stool diaries provide precise clues regarding the nature of constipation. The individual's description of frequency, stool consistency, associated pain, and presence of blood or whether evacuation was stimulated by enemas or cathartics (laxatives) is important. Palpation may disclose colonic distention, masses, and tenderness. Digital examination of the rectum and anorectal manometry are performed to assess sphincter tone and detect anal lesions. Colonic transit time and imaging techniques can assist in identifying the cause of constipation. Colonoscopy is used to visualize the lumen directly.
The treatment for constipation is to manage the underlying cause or disease for each individual. Management of constipation usually consists of bowel retraining, in which the individual establishes a satisfactory bowel evacuation routine without becoming preoccupied with bowel movements. The individual also may need to engage in moderate exercise, drink more fluids, and increase fiber intake. Fiber supplements, stool softeners, and laxative agents are useful for some individuals. Enemas can be used to establish bowel routine, but they should not be used habitually. Biofeedback may be beneficial in some instances for forming new bowel evacuation habits. When there is failure to respond to dietary or medical therapies, surgery (colectomy) is considered as a last resort.4

Diarrhea

Diarrhea is the presence of loose, watery stools. Acute diarrhea is more than three loose stools developing within 24 hours and lasting less than 14 days. Persistent diarrhea lasts longer than 14 to 30 days and chronic diarrhea lasts longer than 4 weeks.5,6 Diarrhea can have high rates of morbidity and mortality in children younger than 5 years of age, particularly in developing countries (see Chapter 37) and in the elderly. Many factors determine stool volume, including water content of the colon, diet, the presence of nonabsorbed food, nonabsorbable material, and intestinal secretions. Stool volume in the normal adult averages less than 200 g/day. Stool volume in children depends on age and size. An infant may pass up to 100 g/day. The adult intestine processes approximately 9 L of luminal contents per day: 2 L are ingested and the remaining 7 L consist of intestinal secretions. Of this volume, 99% of the fluid is absorbed: 90% (7 to 8 L) in the small intestine and 9% (1 to 2 L) in the colon. Normally, approximately 150 ml of water is excreted daily in the stool.

Pathophysiology

Diarrhea in which the volume of feces is increased is called large-volume diarrhea. It generally is caused by excessive amounts of water or secretions or both in the intestines. Small-volume diarrhea, in which the volume of feces is not increased, usually results from excessive intestinal motility.

The three major mechanisms of diarrhea are osmotic, secretory, and motile:

1. Osmotic diarrhea. A nonabsorbable substance in the intestine draws excess water into the intestine and increases stool weight and volume, producing large-volume diarrhea. Causes include lactase and pancreatic enzyme deficiency; excessive ingestion of synthetic, nonabsorbable sugars; full-strength tube-feeding formulas; or dumping syndrome associated with gastric resection (see p. 918).
2. **Secretory diarrhea.** Excessive mucosal secretion of fluid and electrolytes produces large-volume diarrhea. Infectious causes include viruses (e.g., rotavirus), bacterial enterotoxins (e.g., *Escherichia coli* and *Vibrio cholerae*), exotoxins from overgrowth of *Clostridium difficile* following antibiotic therapy (see Health Alert: *Clostridium difficile* and Fecal Microbiome Transplant), or small bowel bacterial overgrowth. Small-volume diarrhea is usually caused by an inflammatory disorder of the intestine, such as ulcerative colitis, Crohn disease, or microscopic colitis, but also can result from colon cancer or fecal impaction.

---

**Health Alert**

*Clostridium difficile* and Fecal Microbiome Transplant

Virulent *Clostridium difficile* (*C. diff*) is a gram-positive toxin producing bacteria that cause pseudomembranous colitis and *C. difficile*-associated diarrhea, particularly in hospitalized individuals treated with antibiotics. These infections are more frequent, severe, and resistant to treatment; tend to recur; and increase morbidity and mortality as well as treatment costs. Infection with *C. diff* (CDI) occurs when antibiotic therapy alters normal gut flora (dysbiosis), allowing *C. diff* to proliferate. The spore form is resistant to treatment and also can remain on dry surfaces for weeks and infect healthy individuals. New strains are more common and more virulent, and demonstrate increased resistance to treatment.

Metronidazole is the first-line treatment for *C. diff*. However, it may be ineffective; then vancomycin is used, which suppresses growth of all gram-positive aerobic and anaerobic organisms, including commensal gut bacteria that are important for mucosal immunity, digestion, and control of pathogens promoting recurrence. Fidaxomicin treatment has fewer recurrences but is very costly. With resistance, spore forms remain in the gut and transition to the vegetative toxin form, causing recurrent infection and disease. Nonantibiotic treatment is being evaluated in an effort to break the cycle of recurrent infection and restore gut microbiota, protect the gut mucosa, and control *C. diff* spores. Nonantibiotic treatment includes fecal microbiota transplantation, which has been successful in about 90% of cases. The assumption is that microbiota transplant can restore the diversity and proportion of phyla that promote colonic health. The treatment is safe, efficacious, and inexpensive. Fecal microbiota transplantation is under the surveillance of the Food and Drug Administration; the FDA has approved fecal microbiota therapy in individuals not responding to standard treatment (response rates of 83% to 94% for recurrent CDI). Informed consent is required; however, fecal microbiota
transplantation is not recommended for use in pregnant women. Fecal microbiome transplantation for recurrent CDI in inflammatory bowel disease has been associated with colitis exacerbation in the majority of individuals who have received this treatment. Clinical investigations are continuing, and fecal microbiome transplant is being evaluated for diseases other than recurrent CDI.

3. **Motility diarrhea** is caused by resection of the small intestine (short bowel syndrome), surgical bypass of an area of the intestine or fistula formation between loops of intestine, irritable bowel syndrome—diarrhea predominant, diabetic neuropathy, hyperthyroidism, and laxative abuse. Excessive motility decreases transit time and opportunity for fluid absorption, resulting in diarrhea.

**Clinical manifestations**

Diarrhea can be acute or chronic depending on its cause. Systemic effects of prolonged diarrhea are dehydration, electrolyte imbalance (hyponatremia, hypokalemia), and weight loss. Manifestations of acute bacterial or viral infection include fever, with or without vomiting or cramping pain. Most infectious diarrhea usually lasts less than 2 weeks. The exceptions are *Clostridium difficile*, *Aeromonas*, or *Yersinia enterocolitica*. Fever, cramping pain, and bloody stools accompany chronic diarrhea caused by inflammatory bowel disease or dysentery. **Steatorrhea** (fat in the stools), bloating, and diarrhea are common signs of malabsorption syndromes. Anal and perineal skin irritation can occur.

**Evaluation and treatment**

A thorough history is taken to document the onset, frequency, volume of stools, duration of diarrhea, and presence of blood in the stools. Malabsorption syndromes usually manifest steatorrhea. Exposure to contaminated food or water is indicated if the individual has traveled in foreign countries or areas where drinking water might be contaminated. Iatrogenic diarrhea is suggested if the individual has undergone abdominal radiation therapy, intestinal resection, or treatment with selected drugs (e.g., antibiotics, diuretics, antihypertensives, laxatives, anticoagulants or chemotherapy). Physical examination helps identify underlying systemic disease. Stool studies, abdominal imaging, endoscopy, and intestinal biopsies provide more specific data, particularly for persistent diarrhea.
Treatment for diarrhea includes restoration of fluid and electrolyte balance, administration of antimitotility (e.g., loperamide) and/or water absorbent (e.g., attapulgite and polycarbophil) medications, and treatment of causal factors. Nutritional deficiencies need to be corrected in cases of chronic diarrhea or malabsorption.\textsuperscript{9}

**Abdominal Pain**

Abdominal pain is the presenting symptom of a number of gastrointestinal diseases and can be acute or chronic.\textsuperscript{10} The causal mechanisms of abdominal pain are *mechanical, inflammatory, or ischemic*. Generally, the abdominal organs are not sensitive to mechanical stimuli, such as cutting, tearing, or crushing. These organs are, however, sensitive to stretching and distention, which activate nerve endings in both hollow and solid structures. Pain accompanies rapid distention rather than gradual distention. Traction on the peritoneum caused by adhesions, distention of the common bile duct, or forceful peristalsis resulting from intestinal obstruction causes pain because of increased tension. Capsules that surround solid organs, such as the liver and gallbladder, contain pain fibers that are stimulated by stretching if these organs swell. Abdominal pain may be generalized to the abdomen or localized to a particular abdominal quadrant. The nature of the pain is often described as sharp, dull, or colicky.

Abdominal pain is usually associated with tissue injury and inflammation. Biochemical mediators of the inflammatory response, such as histamine, bradykinin, and serotonin, stimulate organic nerve endings and produce abdominal pain. The edema and vascular congestion that accompany chemical, bacterial, or viral inflammation also cause painful stretching. Hindrance of blood flow from the distention of bowel obstruction or mesenteric vessel thrombosis produces the pain of ischemia, and increased concentrations of tissue metabolites stimulate pain receptors.

Abdominal pain can be parietal (somatic), visceral, or referred. **Parietal pain**, from the parietal peritoneum, is more localized and intense than visceral pain, which arises from the organs themselves. Parietal pain lateralizes because, at any particular point, the parietal peritoneum is innervated from only one side of the nervous system.

**Visceral pain** arises from a stimulus (distention, inflammation, ischemia) acting on an abdominal organ. Inflammatory mediators associated with chronic low-grade inflammation can cause pain hypersensitivity.\textsuperscript{11} The pain is usually poorly localized, diffuse, or vague with a radiating pattern because nerve endings in abdominal organs are sparse and multisegmented. Pain arising from the stomach, for example,
is experienced as a sensation of fullness, cramping, or gnawing in the midepigastric area. **Referred pain** is visceral pain felt at some distance from a diseased or affected organ. It is usually well localized and is felt in the skin dermatomes or deeper tissues that share a central afferent pathway with the affected organ. For example, acute cholecystitis may have pain referred to the right shoulder or scapula.

**Gastrointestinal Bleeding**

**Upper gastrointestinal bleeding** is bleeding in the esophagus, stomach, or duodenum, and is characterized by frank, bright red bleeding or dark, grainy digested blood (“coffee grounds”) that has been affected by stomach acids (Table 36-1). Upper gastrointestinal (GI) bleeding is commonly caused by bleeding varices (varicose veins) in the esophagus, peptic ulcers, arteriovenous malformations, or a Mallory-Weiss tear at the esophageal-gastric junction caused by severe retching.\(^\text{12}\)**

**Lower gastrointestinal bleeding**, or bleeding from the jejunum, ileum, colon, or rectum, can be caused by polyps, diverticulitis, inflammatory disease, cancer, or hemorrhoids. **Occult bleeding** is usually caused by slow, chronic blood loss that is not obvious and results in iron deficiency anemia as iron stores in the bone marrow are slowly depleted.\(^\text{13}\) Acute, severe GI bleeding is life-threatening depending on the volume and rate of blood loss, associated disease and age of the affected individual, and effectiveness of treatment.

<tr>
<td>Occult Bleeding</td>
<td>Trace amounts of blood in normal-appearing stools or gastric secretions; detectable only with positive fecal occult blood test (guaiac test)</td>
</tr>
</tbody>
</table>

Physiologic response to GI bleeding depends on the amount and rate of the loss (Figure 36-1). Changes in blood pressure and heart rate are the best indicators of massive blood loss in the GI tract. During the early stages of blood volume depletion, the peripheral arteries and arterioles constrict to shunt blood to vital organs, including the brain. Signs of large-volume blood loss are postural hypotension (a drop in blood pressure that occurs with a change from the recumbent position to a sitting or upright position), lightheadedness, and loss of vision. Tachycardia develops as a compensatory response to maintain cardiac output and tissue perfusion. If blood loss continues, hypovolemic shock develops (see Chapter
24). Diminished blood flow to the kidneys causes decreased urine output and may lead to oliguria (low urine output), tubular necrosis, and renal failure. Ultimately, insufficient cerebral and coronary blood flow causes irreversible anoxia and death.
The presentations of GI bleeding are summarized in Table 36-1. The accumulation of blood in the gastrointestinal tract is irritating and increases peristalsis, causing vomiting or diarrhea, or both. If bleeding is from the lower GI tract, the diarrhea is frankly bloody. Bleeding from the upper GI tract also can be rapid enough to produce hematochezia (bright red stools), but generally some
digestion of the blood components will have occurred, producing **melena**—black or tarry stools that are sticky and have a characteristic foul odor. The digestion of blood proteins originating from massive upper GI bleeding is reflected by an increase in blood urea nitrogen (BUN) levels (see Figure 36-1).

The hematocrit and hemoglobin values are not the best indicators of acute gastrointestinal bleeding because plasma volume and red cell volume are lost proportionately. As the plasma volume is replaced, the hematocrit and hemoglobin values begin to reflect the extent of blood loss. The interpretation of these values is modified to account for exogenous replacement of fluids and the hydration status of the tissues.

**Quick Check 36-1**

1. How is visceral pain “referred”?  
2. How does osmotic diarrhea differ from secretory diarrhea?  
3. What are the best clinical indicators of acute GI bleeding blood loss?

**Disorders of Motility**

**Dysphagia**

**Pathophysiology**

**Dysphagia** is difficulty swallowing. It can result from **mechanical obstruction** of the esophagus or a functional disorder that impairs esophageal motility. Intrinsic obstructions originate in the wall of the esophageal lumen (esophageal dysphagia) and include tumors, strictures, and diverticular herniations (outpouchings). Extrinsic mechanical obstructions originate outside the esophageal lumen and narrow the esophagus by pressing inward on the esophageal wall. The most common cause of extrinsic mechanical obstruction is tumor.

**Functional dysphagia** is caused by neural or muscular disorders that interfere with voluntary swallowing or peristalsis. Disorders that affect the striated muscles of the hypopharyngeal area and upper esophagus interfere with the oropharyngeal (voluntary) phase of swallowing (oropharyngeal dysphagia). Typical causes are dermatomyositis (a muscle disease) and neurologic impairments caused by cerebrovascular accidents, Parkinson disease, multiple sclerosis, muscular dystrophy, or achalasia.
Achalasia is a rare form of dysphagia related to loss of inhibitory neurons in the myenteric plexus with smooth muscle atrophy in the middle and lower portions of the esophagus. The myenteric neurons are attacked by a cell-mediated and antibody-mediated immune response against an unknown antigen. This leads to altered esophageal peristalsis and failure of the lower esophageal sphincter (LES) to relax, causing functional obstruction of the lower esophagus with varying severity. Food accumulates above the obstruction, distends the esophagus, and causes dysphagia (Figure 36-2). Cough and aspiration can occur. As hydrostatic pressure increases, food is slowly forced past the obstruction into the stomach. Chronic esophageal distention requires dilation or surgical myotomy of the lower esophageal sphincter (LES).

Clinical manifestations

Distention and spasm of the esophageal muscles during eating or drinking may cause a mild or severe stabbing pain at the level of obstruction. Discomfort occurring 2 to 4 seconds after swallowing is associated with upper esophageal obstruction. Discomfort occurring 10 to 15 seconds after swallowing is more common in obstructions of the lower esophagus. If obstruction results from a growing tumor, dysphagia begins with difficulty swallowing solids and advances to difficulty swallowing semisolids and liquids. If motor function is impaired, both solids and liquids are difficult to swallow. Regurgitation of undigested food, unpleasant taste sensation, vomiting, aspiration, and weight loss are common.
manifestations of all types of dysphagia. Aspiration of esophageal contents can lead to cough and pneumonia.

**Evaluation and treatment**

Knowledge of the person's history and clinical manifestations contributes significantly to a diagnosis of dysphagia. Imaging is used to visualize the contours of the esophagus and identify structural defects. High-resolution manometry and intraluminal impedance monitoring document the duration and amplitude of abnormal pressure changes associated with obstruction or loss of neural regulation. Esophageal endoscopy is performed to examine the esophageal mucosa and obtain biopsy specimens.

The individual is taught to manage symptoms by eating small meals slowly, taking fluid with meals, and sleeping with the head elevated to prevent regurgitation and aspiration. Food and medications may need to be formulated so they can be swallowed. Anticholinergic drugs (e.g., botulinum toxin) may relieve symptoms of dysphagia. Mechanical dilation of the esophageal sphincter and surgical separation of the lower esophageal muscles with a longitudinal incision (myotomy) are the most effective treatments for achalasia.\(^\text{16}\)

**Gastroesophageal Reflux Disease (GERD)**

**Gastroesophageal reflux disease (GERD)** is the reflux of acid and pepsin or bile salts from the stomach into the esophagus that causes esophagitis. The prevalence of GERD is estimated at 18% to 27% in North America.\(^\text{17}\) Risk factors for GERD include older age, obesity, hiatal hernia, and drugs or chemicals that relax the LES (anticholinergics, nitrates, calcium channel blockers, nicotine).\(^\text{18}\) GERD may be a trigger for asthma or chronic cough. Gastroesophageal reflux that does not cause symptoms is known as physiologic reflux. In nonerosive reflux disease (NERD), individuals have symptoms of reflux disease but no visible esophageal mucosal injury (functional heartburn).\(^\text{19}\)

**Pathophysiology**

Abnormalities in lower esophageal sphincter function, esophageal motility, and gastric motility or emptying can cause GERD. The resting tone of the LES tends to be lower than normal from either transient relaxation or weakness of the sphincter. Vomiting, coughing, lifting, bending, obesity, or pregnancy increases abdominal pressure, contributing to the development of reflux esophagitis. Hiatal hernia can weaken the LES. Delayed gastric emptying can contribute to reflux esophagitis by (1) lengthening the period during which reflux is possible and (2) increasing gastric
acid content. Disorders that delay emptying include gastroparesis, gastric or duodenal ulcers, which can cause pyloric edema and strictures that narrow the pylorus.

The severity of the esophagitis depends on the composition of the gastric contents and the esophageal mucosa exposure time. An acid pocket is an area of postprandial unbuffered gastric acid immediately distal to the gastroesophageal junction. It is enlarged in hiatal hernia and can contribute to GERD. If the gastric content is highly acidic or contains bile salts and pancreatic or intestinal enzymes, reflux esophagitis can be severe. In individuals with weak esophageal peristalsis, refluxed chyme remains in the esophagus longer than usual. This increases the amount of time the esophageal mucosa is exposed to acids, enzymes, and bile. The refluxate causes mucosal injury and inflammation with hyperemia, increased capillary permeability, edema, tissue fragility, and erosion. Fibrosis and thickening may develop. Precancerous lesions (Barrett esophagus, see p. 938) can be a long-term consequence. Precancerous lesions can progress to adenocarcinoma.20

Clinical manifestations
The clinical manifestations of erosive reflux esophagitis are heartburn (pyrosis), acid regurgitation, dysphagia, chronic cough, asthma attacks (see Chapter 27), laryngitis, and upper abdominal pain within 1 hour of eating. The symptoms worsen if the individual lies down or if intra-abdominal pressure increases (e.g., as a result of coughing, vomiting, or straining at stool). Edema, strictures, esophageal spasm, or decreased esophageal motility may result in dysphagia with weight loss. Alcohol or acid-containing foods, such as citrus fruits, can cause discomfort during swallowing.

Evaluation and treatment
Diagnosis of GERD is based on history and clinical manifestations. Esophageal endoscopy shows hyperemia, edema, erosion, and strictures. Dysplastic changes (Barrett esophagus) can be identified by tissue biopsy. Impedance/pH monitoring measures the movement of stomach contents upward into the esophagus and the acidity of the refluxate. Because heartburn also may be experienced as chest pain, cardiac ischemia must be ruled out.

Proton pump inhibitors are the agents of choice for controlling symptoms and healing esophagitis. Other therapies include H2-receptor antagonists or prokinetics and antacids. Weight reduction, smoking cessation, elevation of the head of the bed 6 inches, and avoiding tight clothing also help to alleviate symptoms. Laparoscopic fundoplication is the most common surgical intervention when medical treatment fails.21
**Eosinophilic esophagitis** is an idiopathic inflammatory disease of the esophagus characterized by infiltration of eosinophils associated with atopic disease, including asthma and food allergies. It occurs in adults and children. Dysphagia, food impaction, vomiting, and weight loss are common symptoms. Endoscopy with biopsy identifies the eosinophilic infiltration and differentiation from GERD. Treatment is symptomatic including elimination diets and steroids.

**Hiatal Hernia**

**Pathophysiology**

**Hiatal hernia** is a type of diaphragmatic hernia with protrusion (herniation) of the upper part of the stomach through the diaphragm and into the thorax (Figure 36-3). In **sliding hiatal hernia** (Type 1 and the most common), the proximal portion of the stomach moves into the thoracic cavity through the esophageal hiatus, an opening in the diaphragm for the esophagus and vagus nerves. A congenitally short esophagus, fibrosis or excessive vagal nerve stimulation, or weakening of the diaphragmatic muscles at the gastroesophageal junction contributes to the hernia. GERD is associated with this type of herniation. Coughing, bending, tight clothing, ascites, obesity, and pregnancy accentuate the hernia.
**Paraesophageal hiatal hernia (Type 2)** is the herniation of the greater curvature of the stomach through a secondary opening in the diaphragm alongside the esophagus. The position of a portion of the stomach above the diaphragm causes congestion of mucosal blood flow, leading to gastritis and ulcer formation. Strangulation of the hernia is a major complication. It can present with vomiting and epigastric and retrosternal epigastric pain and is a surgical emergency.\(^{23}\)

**Mixed hiatal hernia (Type 3)** is less common and is a combination of sliding and paraesophageal hiatal hernias. It tends to occur in conjunction with several other diseases, including reflux esophagitis, peptic ulcer, cholecystitis (gallbladder inflammation), cholelithiasis (gallstones), chronic pancreatitis, and diverticulosis.

### Clinical manifestations
Hiatal hernias are often asymptomatic. Generally, a wide variety of symptoms develop later in life and are associated with other gastrointestinal disorders, including GERD. Symptoms include heartburn, regurgitation, dysphagia, and epigastric pain. Ischemia from hernia strangulation causes acute, severe chest or epigastric pain, nausea, vomiting, and GI bleeding.

### Evaluation and treatment
Diagnostic procedures include radiology with barium swallow, endoscopy, and high-resolution manometry. A chest x-ray film often will show the protrusion of the stomach into the thorax, indicating paraesophageal hiatal hernia.

Treatment for sliding hiatal hernia is usually conservative. The individual can diminish reflux by eating small, frequent meals and avoiding the recumbent position after eating. Abdominal supports and tight clothing should be avoided, and weight control is recommended for obese individuals. Antacids alleviate reflux esophagitis. Individuals who are uncomfortable at night benefit from sleeping with the head of the bed elevated 6 inches. Surgery (fundoplication) is performed if medical management fails to control symptoms.

**Gastroparesis** is delayed gastric emptying in the absence of mechanical gastric outlet obstruction. It is most commonly associated with diabetes mellitus, surgical vagotomy, or fundoplication. It can be idiopathic. The pathophysiology is not well understood but involves abnormalities of the autonomic nervous system, smooth muscle cells, enteric neurons, and gastrointestinal hormones. Diabetic gastroparesis represents a form of neuropathy involving the vagus nerve. Symptoms include nausea, vomiting, abdominal pain, and postprandial fullness or bloating. Treatment options include dietary management; prokinetic drugs; and, in some cases, gastric electrical stimulation; or surgical venting gastrostomy.\(^{24}\)
**Pyloric Obstruction**

**Pathophysiology**

Pyloric obstruction (gastric outlet obstruction) is the narrowing or blocking of the opening between the stomach and the duodenum. This condition can be congenital (e.g., infantile hypertrophic pyloric stenosis; see Chapter 37) or acquired. Acquired obstruction is caused by peptic ulcer disease or carcinoma near the pylorus. Duodenal ulcers are more likely than gastric ulcers to obstruct the pylorus. Ulceration causes obstruction resulting from inflammation, edema, spasm, fibrosis, or scarring. Tumors cause obstruction by growing into the pylorus.

**Clinical manifestations**

Early in the course of pyloric obstruction, the individual experiences vague epigastric fullness, which becomes more distressing after eating and at the end of the day. Nausea and epigastric pain may occur as the muscles of the stomach contract in attempts to force chyme past the obstruction. These symptoms disappear when the chyme finally moves into the duodenum. As obstruction progresses, anorexia develops, sometimes accompanied by weight loss. Severe obstruction causes gastric distention and atony (lack of muscle tone and gastric motility). Gastric distention stimulates gastric secretion, which increases the feeling of fullness. Rolling or jarring of the abdomen produces a sloshing sound called the *succussion splash*. At this stage, vomiting is a cardinal sign of obstruction. It is usually copious and occurs several hours after eating. The vomitus contains undigested food but no bile. Prolonged vomiting leads to dehydration, which is accompanied by a hypokalemic and hypochloremic metabolic alkalosis caused by loss of gastric potassium and acid, respectively. Because food does not enter the intestine, stools are infrequent and small. Prolonged pyloric obstruction causes severe malnutrition, dehydration, and extreme debilitation.

**Evaluation and treatment**

Diagnosis is based on clinical manifestations, a history of ulcer disease, and examination of residual gastric contents. Endoscopy is performed if gastric carcinoma is the suggested cause of pyloric obstruction.

Obstructions resulting from ulceration often resolve with conservative management. A large-bore nasogastric tube is used to aspirate stomach contents and relieve distention. Then nasogastric suction is maintained for 2 to 3 days to decompress the stomach and restore normal motility. Gastric secretions that contribute to inflammation and edema can be suppressed with proton pump
inhibitors or histamine₂ (H2) receptor antagonists. Fluids and electrolytes (saline and potassium) are given intravenously to promote rehydration and correct hypokalemia and alkalosis (see Chapter 5). Severely malnourished individuals may require parenteral hyperalimentation (intravenous nutrition). Surgery or the placement of pyloric stents may be required to treat gastric carcinoma or persistent obstruction caused by fibrosis and scarring.²⁵

**Intestinal Obstruction and Paralytic Ileus**

**Intestinal obstruction** can be caused by any condition that prevents the normal flow of chyme through the intestinal lumen (Table 36-2).²⁶ Obstructions can occur in either the small or the large intestine (Table 36-3). The small intestine is more commonly obstructed because of its narrower lumen. Classifications of intestinal obstruction are summarized in Table 36-4. Intestinal obstruction is classified by cause as simple or functional. *Simple obstruction* is mechanical blockage of the lumen by a lesion and it is the most common type of intestinal obstruction. *Paralytic ileus*, or *functional obstruction*, is a failure of intestinal motility often occurring after intestinal or abdominal surgery, acute pancreatitis, or hypokalemia. Acute obstructions usually have mechanical causes, such as adhesions or hernias (Figure 36-4). Chronic or partial obstructions are more often associated with tumors or inflammatory disorders, particularly of the large intestine.

Pathophysiology

The major pathophysiologic alterations are presented in Figure 36-5. Postoperative paralytic ileus results from inhibitory neural reflexes associated with inflammatory mediators, and the influence of exogenous (i.e., meperidine or morphine) and endogenous opioids (endorphins) that affect the entire GI tract. **Small bowel obstruction (SBO)** is caused by postoperative adhesions, tumors, Crohn disease, and hernias. SBO leads to distention caused by impaired absorption and increased secretion with accumulation of fluid and gas inside the lumen proximal to the obstruction. Distention decreases the intestine's ability to absorb water and electrolytes and increases the net secretion of these substances into the lumen. Copious vomiting or sequestration of fluids in the intestinal lumen prevents their reabsorption and produces severe fluid and electrolyte disturbances. Extracellular fluid volume and plasma volume decrease, causing dehydration, increased
hematocrit level, hypotension, and tachycardia. Severe dehydration leads to hypovolemic shock. Metabolic alkalosis initially develops as a result of excessive loss of hydrogen ions that would normally be reabsorbed from the gastric juice and vomiting. With prolonged obstruction or obstruction lower in the intestine, metabolic acidosis is more likely to occur because bicarbonate from pancreatic secretions and bile cannot be reabsorbed. Hypokalemia from vomiting and decreased potassium absorption can be extreme, promoting acidosis and atony of the intestinal wall. Metabolic acidosis also may be accentuated by ketosis, the result of declining carbohydrate stores caused by starvation. Lack of circulation permits the buildup of significant amounts of lactic acid, which worsen the metabolic acidosis. If pressure from the distention is severe enough, it occludes the arterial circulation and causes ischemia, necrosis, perforation, and peritonitis. Fever and leukocytosis are often associated with overgrowth of bacteria, ischemia, and bowel necrosis. Bacterial proliferation and translocation across the mucosa to the systemic circulation cause peritonitis or sepsis. The release of inflammatory mediators into the circulation causes remote organ failure.
Large bowel obstruction is less common and often related to cancer. Diverticulitis, inflammatory bowel disease, and other causes of obstruction are less common. Acute colonic pseudo-obstruction (Ogilvie syndrome) is a rare massive dilation of the large bowel that is related to excessive sympathetic motor input or decreased parasympathetic motor input with absence of mechanical obstruction. It occurs primarily in people who are critically ill and immobilized older adults.

Clinical manifestations

Signs and symptoms of small intestine obstruction include colicky pains caused by intestinal distention followed by nausea and vomiting. Pain intensifies for seconds
or minutes as a peristaltic wave of muscle contraction meets the obstruction. Pain may be continuous with severe distention and then diminish in intensity. If ischemia occurs, the pain loses its colicky character and becomes more constant and severe. Sweating and tachycardia occur as a sympathetic nervous system response to hypotension. Fever, severe leukocytosis, abdominal distention, and rebound tenderness develop as ischemia progresses to necrosis, perforation, and peritonitis.

Obstruction at the pylorus causes early, profuse vomiting. Obstruction in the proximal small intestine causes mild distention and vomiting of bile-stained fluid. Lower obstruction in the small intestine causes more pronounced distention because a greater length of intestine is proximal to the obstruction. In this case, vomiting may not occur early but may occur later and contain fecal material. Partial obstruction can cause diarrhea or constipation, but complete obstruction usually causes constipation only. Complete obstruction increases the number of bowel sounds, which may be tinkly and accompanied by peristaltic rushes and crampy abdominal pain. Signs of hypovolemia and metabolic acidosis may be observed as early as 24 hours after the occurrence of complete obstruction. Distention may be severe enough to push against the diaphragm and decrease lung volume. This can lead to atelectasis and pneumonia, particularly in debilitated individuals.

**Large intestine obstruction** usually presents with hypogastric pain and abdominal distention. Pain can vary from vague to excruciating, depending on the degree of ischemia and the development of peritonitis. Vomiting occurs late in the obstructive process. Small and large intestinal perforation presents the same with acute, persistent abdominal pain, nausea, vomiting, and fever. Acute colonic pseudo-obstruction is characterized by abdominal distention, abdominal pain, and nausea and vomiting. Bowel sounds are usually present.

**Evaluation and treatment**

Evaluation is based on clinical manifestations and imaging studies. Successful management requires early identification of the site and type of obstruction. Replacement of fluid and electrolytes and decompression of the lumen with gastric or intestinal suction are essential forms of therapy. Laparoscopic procedures can release adhesions. Immediate surgical intervention is required for strangulation, complete obstruction, or perforation. Colonic stents may be placed for malignant obstruction. Neostigmine, a parasympathomimetic, is used for colonic pseudo-obstruction and colonoscopic decompression may be required.

**Quick Check 36-2**
1. Why is heartburn associated with gastroesophageal reflux?

2. How does peritonitis develop with bowel obstruction?

3. What causes postoperative paralytic ileus?

**Gastritis**

Gastritis is an inflammatory disorder of the gastric mucosa; it has an incidence of less than 1% in the United States.\(^{30}\) It can be acute or chronic and affect the superficial mucosa of the fundus or antrum, or both.

**Acute gastritis** is caused by injury of the protective mucosal barrier caused by drugs, chemicals, or *Helicobacter pylori* infection. Nonsteroidal anti-inflammatory drugs (NSAIDs; e.g., ibuprofen, naproxen, indomethacin, and aspirin) inhibit the action of cyclooxygenase-1 (COX-1) and cause gastritis because they inhibit prostaglandin synthesis, which normally stimulates the secretion of mucus. Alcohol, histamine, digitalis, and metabolic disorders, such as uremia, are contributing factors. *H. pylori*–associated acute gastritis causes inflammation, increased gastric secretion in antral gastritis, decreased gastric section in fundal gastritis, pain, nausea, and vomiting. The clinical manifestations of acute gastritis can include vague abdominal discomfort, epigastric tenderness, and bleeding. Healing usually occurs spontaneously within a few days. Discontinuing injurious drugs, using antacids, or decreasing acid secretion with H2-receptor antagonists facilitates healing.

**Chronic gastritis** tends to occur in older adults and causes chronic inflammation, mucosal atrophy, and epithelial metaplasia. Chronic gastritis is classified as type A, immune (fundal), or type B, nonimmune (antral), depending on the pathogenesis and location of the lesions. When both types of chronic gastritis occur, it is known as type AB, or pangastritis, and the antrum is more severely involved. Type C gastritis is associated with reflux of bile and pancreatic secretions into the stomach, causing chemical injury.

**Chronic immune (fundal) gastritis** is the most rare form of gastritis and is associated with loss of T-cell tolerance and development of autoantibodies to gastric H\(^+\)-K\(^+\) ATPase. The gastric mucosa degenerates extensively in the body and fundus of the stomach, leading to gastric atrophy. Loss of parietal cells diminishes acid and intrinsic factor secretion. Pernicious anemia can develop from decreased vitamin B\(_{12}\) absorption (see Chapter 21). The feedback mechanism that normally inhibits gastrin secretion is impaired, causing elevated plasma levels of gastrin. Chronic fundal gastritis occurs in association with other autoimmune diseases (e.g.,
rheumatoid arthritis, autoimmune thyroid disease, or type 1 diabetes mellitus) and is a risk factor for gastric carcinoma, particularly in individuals who develop pernicious anemia.

Chronic nonimmune (antral gastritis) generally involves the antrum only and is more common than fundal gastritis. It is caused by H. pylori bacteria and it also is associated with use of alcohol, tobacco, and nonsteroidal anti-inflammatory drugs.31 There are high levels of hydrochloric acid secretion with an increased risk of duodenal ulcers. H. pylori also can progress to autoimmune atrophic gastritis and involves the fundus, thus becoming pangastritis. There is greater risk for the development of gastric cancer in these cases.32

Signs and symptoms of chronic gastritis often include vague symptoms: anorexia, fullness, nausea, vomiting, and epigastric pain. Gastric bleeding may be the only clinical manifestation of gastritis. Gastroscopic examination and biopsy may show a long-standing inflammatory process and gastric atrophy in an individual with no history of abdominal distress. Failure to stimulate acid secretion confirms achlorhydria (diminished secretion of hydrochloric acid). The gastric secretions also can be evaluated for the presence of intrinsic factor. Symptoms can usually be managed by eating smaller meals in conjunction with a soft, bland diet and by avoiding alcohol and aspirin. H. pylori infection is treated with antibiotics, and vitamin B₁₂ is administered to correct pernicious anemia.

**Peptic Ulcer Disease**

A peptic ulcer is a break or ulceration in the protective mucosal lining of the lower esophagus, stomach, or duodenum. Ulcers develop when mucosal protective factors are overcome by erosive factors commonly caused by NSAIDs and H. pylori infection. Risk factors for peptic ulcer disease are summarized in Risk Factors: Peptic Ulcer. Psychologic stress may be a risk factor for peptic ulcer disease but the exact mechanism of causation is not known.33 The prevalence of peptic ulcer in 2011 in the United States was 15.5 million people.34

**Risk Factors**

**Peptic Ulcer**

- Infection of the gastric and duodenal mucosa with *Helicobacter pylori*
- Chronic use of nonsteroidal anti-inflammatory drugs (NSAIDs)
• Alcohol
• Smoking
• Advanced age
• Chronic diseases, such as emphysema, rheumatoid arthritis, cirrhosis, obesity, and diabetes
• Type O blood
• Psychologic stress

Peptic ulcers can be single or multiple, acute or chronic, and superficial or deep. Superficial ulcerations are called *erosions* because they erode the mucosa but do not penetrate the muscularis mucosae (Figure 36-6). True ulcers extend through the muscularis mucosae and damage blood vessels, causing hemorrhage, or perforate the gastrointestinal wall.

**Zollinger-Ellison syndrome** is a rare syndrome that also is associated with peptic ulcers caused by a gastrin-secreting neuroendocrine tumor or multiple tumors (gastrinoma) of the pancreas or duodenum. Increased secretion of gastrin causes excess secretion of gastric acid, resulting in gastric and duodenal ulcers, gastroesophageal reflux with abdominal pain, and diarrhea.35

**Duodenal Ulcers**

*Duodenal ulcers* occur with greater frequency than other types of peptic ulcers and
Idiopathic duodenal ulcers are rare and can be associated with altered mucosal defenses, rapid gastric emptying, elevated serum gastrin levels, or acid production stimulated by smoking.\textsuperscript{37}

**Pathophysiology**

Causative factors, singly or in combination, cause acid and pepsin concentrations in the duodenum to penetrate the mucosal barrier and cause ulceration (Figure 36-7). The host response to *H. pylori* infection is activation of T and B lymphocytes with infiltration of neutrophils. Release of inflammatory cytokines damages the gastric epithelium. An *H. pylori* virulence factor (cytotoxin associated gene A [Cag A]) produces a vacuolating toxin (VacA) causing apoptosis of gastric epithelial cells and promoting inflammation. *H. pylori* mucosal infection underlies gastric and duodenal ulcer and gastric cancer.\textsuperscript{38}
Clinical manifestations

The characteristic manifestation of a duodenal ulcer is chronic intermittent pain in the epigastric area. The pain begins 2 or 3 hours after eating, when the stomach is empty. It is not unusual for pain to occur in the middle of the night and disappear by morning. Pain is relieved rapidly by ingestion of food or antacids, creating a typical pain-food-relief pattern. Some individuals with duodenal ulcer may have no symptoms; the first manifestation may be hemorrhage or perforation, particularly with a history of NSAID or anticoagulant use.

Complications of duodenal ulcer include bleeding, perforation, and obstruction of the duodenum or outlet of the stomach. Bleeding is the most common cause of mortality, particularly among the elderly. Perforation occurs with destruction of all
layers of the duodenal wall and causes sudden, severe epigastric pain.\textsuperscript{39} Obstruction may be the result of edema from inflammation or scarring from chronic injury. It is not clear why individuals infected with \textit{H. pylori} duodenal ulcers are negatively associated with gastric cancer.\textsuperscript{40}

Duodenal ulcers often heal spontaneously but recur within months without treatment. Exacerbations tend to develop in the spring and fall. Relief of pain accompanies healing. Constant, unremitting pain may be caused by complications, such as intestinal obstruction or perforation. Bleeding from duodenal ulcers causes hematemesis or melena.\textsuperscript{41}

**Evaluation and treatment**

Several diagnostic approaches are used to differentiate duodenal ulcers from gastric ulcers or gastric carcinoma. Endoscopic evaluation allows visualization of lesions and biopsy. Radioimmune assays of gastrin levels are evaluated to identify ulcers associated with gastric carcinomas. \textit{H. pylori} is detected using the urea breath test, \textit{H. pylori}–specific serum IgG and IgA antibodies, and measurement of \textit{H. pylori} stool antigen levels. Findings from gastric biopsy detect \textit{H. pylori} infection and confirm eradication after treatment.\textsuperscript{42}

Management of duodenal ulcers is aimed at relieving the causes and effects of hyperacidity and preventing complications. Antacids neutralize gastric contents and relieve pain. Acid secretion can be suppressed with drugs that block H2 receptors and inhibit the secretion of acid. Proton pump inhibitors inhibit acid production. \textit{H. pylori} is treated with a combination of antibiotics and proton pump inhibitors, but antibiotic resistance is an increasing problem.\textsuperscript{43} Surgical resection may be required for bleeding or perforating ulcers, obstruction, or peritonitis.

**Gastric Ulcers**

\textbf{Gastric ulcers} are ulcers of the stomach and occur about equally in males and females, usually between the ages of 55 and 65 years. They are about one fourth as common as duodenal ulcers (Table 36-5).

### Pathophysiology

Generally, gastric ulcers develop in the antral region, adjacent to the acid-secreting mucosa of the body. The primary defect is an abnormality that increases the mucosal barrier's permeability to hydrogen ions. Gastric secretion may be normal or less than normal, and there may be a decreased mass of parietal cells. Chronic gastritis is often associated with development of gastric ulcers and may precipitate ulcer formation by limiting the mucosa's ability to secrete a protective layer of mucus (Figure 36-8). Other factors include the following:

1. Decreased mucosal synthesis of prostaglandins
2. Duodenal reflux of bile and pancreatic enzymes damage the mucosal membrane
3. Use of NSAIDs (decreases prostaglandin synthesis)
4. *H. pylori* infection
A break in the mucosal barrier permits hydrogen ions to diffuse into the mucosa, where they disrupt permeability and cellular structure. A vicious cycle can be established as the damaged mucosa liberates histamine, which stimulates the increase of acid and pepsinogen production, blood flow, and capillary permeability. The disrupted mucosa becomes edematous and loses plasma proteins. Destruction of small vessels causes bleeding.

**Clinical manifestations**

The clinical manifestations of gastric ulcers are similar to those of duodenal ulcers (see Table 36-5). The pattern of pain is common but the pain of gastric ulcers also occurs immediately after eating. Gastric ulcers also tend to be chronic rather than alternating between periods of remission and exacerbation and cause more anorexia, vomiting, and weight loss than duodenal ulcers. The evaluation and
treatment of gastric ulcers are similar to the evaluation and treatment of duodenal ulcers.

**Stress-Related Mucosal Disease**

A stress-related mucosal disease (stress ulcer) is an acute form of peptic ulcer that tends to accompany the physiologic stress of severe illness or major trauma. Usually multiple sites of ulceration are distributed within the stomach or duodenum. Stress ulcers may be classified as ischemic ulcers or Cushing ulcers.

Ischemic ulcers develop within hours of an event such as hemorrhage, multisystem trauma, severe burns, heart failure, or sepsis. Shock, anoxia, inflammation, and sympathetic responses cause ischemia of the stomach and duodenal mucosa, disrupting the mucosal barrier. Stress ulcers that develop as a result of burn injury are often called Curling ulcers. Cushing ulcer is a stress ulcer associated with severe brain trauma or brain surgery. Decreased mucosal blood flow and hypersecretion of acid caused by overstimulation of the vagal nuclei damage the mucosal barrier, causing erosions and ulceration.

The primary clinical manifestation of stress-related mucosal disease is bleeding, which is uncommon, but occurs more readily with the presence of coagulopathy and more than 48 hours of mechanical ventilation. Prophylactic treatment regimens are used to prevent this disease. Stress ulcers seldom become chronic.

**Surgical Treatment of Ulcer**

Advances in the medical treatment of peptic ulcer disease with acid suppression and eradication of *H. pylori* have reduced the number of cases requiring surgery. The most common indications for ulcer surgery are recurrent or uncontrolled bleeding and perforation of the stomach or duodenum. The primary objectives of surgical treatment are to reduce stimuli for acid secretion, decrease the number of acid-secreting cells in the stomach, and correct complications of ulcer disease.

Acute complications of gastrectomy or anastomosis are relatively uncommon except in debilitated persons. Chronic complications, however, are likely to develop if a large portion of the stomach has been removed. These complications and their pathophysiologic mechanisms are described in the next section.

**Quick Check 36-3**

1. What is the most common cause of chronic gastritis?

2. Compare the three types of peptic ulcers.
3. What causes a stress ulcer?

**Postgastrectomy Syndromes**

Postgastrectomy syndromes are a group of signs and symptoms that occur after gastric resection for the treatment of peptic ulcer, gastric carcinoma, or bariatric surgery for extreme obesity. They are caused by anatomic and functional changes in the stomach and upper small intestine\(^4^5\) and include the following:

1. **Dumping syndrome.** Rapid emptying of hypertonic chyme from the surgically residual stomach (the stomach component remaining after surgical resection following gastric or bariatric surgery) into the small intestine 10 to 20 minutes after eating; promoted by loss of gastric capacity, loss of emptying control when pylorus is removed, and loss of feedback control by duodenum when it is removed; responds to dietary management. Symptoms include cramping pain, nausea, vomiting, osmotic diarrhea, weakness, pallor, and hypotension.

2. **Alkaline reflux gastritis.** Stomach inflammation caused by reflux of bile and alkaline pancreatic secretions containing proteolytic enzymes that disrupt the mucosal barrier in the remnant stomach. Symptoms include nausea, bilious vomiting, and sustained epigastric pain that worsens after eating and is not relieved by antacids; responds somewhat to avoidance of aspirin and alcohol,\(^4^6\) but surgical correction may be required.

3. **Afferent loop obstruction.** Intermittent severe pain and epigastric fullness after eating as a result of volvulus, hernia, adhesion, or stenosis of the duodenal stump on the proximal side of the gastrojejunostomy; vomiting relieves symptoms; management includes low-fat diet, but decompression or surgery revision is required for complete obstruction.\(^4^7\)

4. **Diarrhea.** Either frequent, persistent elimination of loose stools or intermittent, precipitous, and unpredictable elimination of a large volume of stool; related to rapid gastric emptying and osmotic attraction of water into the gut, especially after large intake of high-carbohydrate liquids; small, dry meals and anticholinergic drugs are effective control measures (see p. 907).

5. **Weight loss.** Commonly caused by inadequate caloric intake because individual cannot tolerate carbohydrates or a normal-size meal; stomach is also less able to mix, churn, and break down food. In the case of bariatric surgery for extreme obesity, weight loss is the intended outcome but nutrient deficiencies, including
vitamins and minerals, must be supplemented.  

6. **Anemia.** Iron malabsorption may result from decreased acid secretion or lack of duodenum after Billroth II procedure (gastrojejunostomy); deficiencies of iron and vitamin $B_{12}$ or folate may result.

7. **Bone and mineral disorders.** Related to altered calcium absorption and metabolism with increased risk for fractures and deformity and malabsorption of vitamins and nutrients, such as vitamin D.

**Malabsorption Syndromes**

Malabsorption syndromes interfere with nutrient absorption in the small intestine. Historically they have been classified as maldigestion or malabsorption. **Maldigestion** is failure of the chemical processes of digestion that take place in the intestinal lumen or at the brush border of the intestinal mucosa. **Malabsorption** is failure of the intestinal mucosa to absorb (transport) the digested nutrients. Often these two syndromes are interrelated, or occur together, making classification difficult. Generally, however, maldigestion is caused by deficiencies of the enzymes needed for digestion or inadequate secretion of bile salts and inadequate reabsorption of bile in the ileum. Malabsorption is the result of mucosal disruption caused by gastric or intestinal resection, vascular disorders, or intestinal disease.

**Pancreatic Exocrine Insufficiency**

The pancreatic enzymes (lipase, amylase, trypsin, chymotrypsin) are required for the digestion of proteins, carbohydrates, and fats. **Pancreatic insufficiency** is the deficient production of these enzymes, particularly lipase, by the pancreas. Causes include chronic pancreatitis, pancreatic carcinoma, pancreatic resection, and cystic fibrosis. Significant damage to or loss of pancreatic tissue must occur before enzyme levels decrease sufficiently to cause maldigestion. Although pancreatic insufficiency causes poor digestion of all nutrients, fat maldigestion is the chief problem. Absence of pancreatic bicarbonate in the duodenum and jejunum causes an acidic pH that worsens maldigestion by precipitating bile salts and preventing activation of the pancreatic enzymes that are present. A large amount of fat in the stool (steatorrhea) is the most common sign of pancreatic insufficiency. There is also a deficit of fat-soluble vitamins (A, D, E, and K) and weight loss.

**Lactase Deficiency (Lactose Intolerance)**

Deficiency of disaccharidase at the brush border of the small intestine is caused by a
genetic defect in which a single enzyme, usually lactase, is lacking. **Lactase deficiency** inhibits the breakdown of lactose (milk sugar) into monosaccharides and therefore prevents lactose digestion and absorption across the intestinal wall. Lactase deficiency is most common in blacks, Latinos, and Native Americans and usually does not develop until adulthood. Secondary (acquired) lactase deficiency can be caused by several diseases of the intestine, including gluten-sensitive enteropathy, enteritis, and bacterial overgrowth.

The undigested lactose remains in the intestine, where bacterial fermentation causes formation of gases. Undigested lactose also increases the osmotic gradient in the intestine, causing irritation and osmotic diarrhea. Clinical manifestations of lactose consumption with lactase deficiency are bloating, crampy pain, diarrhea, and flatulence. The disorder is diagnosed by a lactose-tolerance test. Avoiding milk products (more than 1 cup of milk) and adhering to a lactose-free diet relieve symptoms.50

### Bile Salt Deficiency

Conjugated bile acids (bile salts) are necessary for the digestion and absorption of fats. Bile salts are conjugated in the bile that is secreted from the liver. When bile enters the duodenum, the bile salts aggregate with fatty acids and monoglycerides to form micelles. Micelle formation makes fat molecules more soluble and allows them to pass through the unstirred layer at the brush border of the small intestinal villi (see Chapter 35). A minimum concentration of bile salts, termed the **critical micelle concentration**, is required to allow formation of micelles. Therefore, conditions that decrease the production or secretion of bile result in decreased micelle formation and fat malabsorption. These conditions include advanced liver disease, which decreases the production of bile salts; obstruction of the common bile duct, which decreases flow of bile into the duodenum (cholestasis); intestinal stasis (lack of motility), which permits overgrowth of intestinal bacteria that deconjugate bile salts; and diseases of the ileum, which prevent the reabsorption and recycling of bile salts (enterohepatic circulation).51

Clinical manifestations of bile salt deficiency are related to poor intestinal absorption of fat and fat-soluble vitamins (A, D, E, and K). Increased fat in the stools (steatorrhea) leads to diarrhea and decreased levels of plasma proteins. The losses of fat-soluble vitamins and their effects include the following:

1. **Vitamin A deficiency** results in night blindness.

2. **Vitamin D deficiency** results in decreased calcium absorption with bone demineralization (osteoporosis), bone pain, and fractures.
3. Vitamin K deficiency prolongs prothrombin time, leading to spontaneous development of purpura (bruising) and petechiae.

4. Vitamin E deficiency has uncertain effects but may cause testicular atrophy and neurologic defects in children.

The most effective treatment for fat-soluble vitamin deficiency is to increase consumption of medium-chain triglycerides in the diet, for example, by using coconut oil for cooking. Vitamins A, D, and K are given parenterally. Oral bile salts are an effective therapy.

**Inflammatory Bowel Disease**

Ulcerative colitis (UC) and Crohn disease (CD) are chronic relapsing inflammatory bowel diseases (IBDs). The prevalence of IBD is about 1.6 million people in the United States with about 70,000 new cases per year. The disease is more prevalent among white populations and Ashkenazi Jews. Risk factors and theories of causation include susceptibility genes, environmental factors, alterations in epithelial cell barrier functions, and an altered immune response to intestinal microflora (Table 36-6). Environmental factors or infections are thought to alter the barrier function of the mucosal epithelium, leading to loss of immune tolerance to normal intestinal antigens. There is possible loss of discrimination of potentially harmful pathogens from commensal microorganisms in the intestinal mucosa. The loss of tolerance activates dendritic cells, triggering their transport to mesenteric lymph nodes, where they promote differentiation of naïve T cells to Th1, Th2, and Th17 cells, or T-regulatory cells. Production of proinflammatory cytokines and chemokines, including tumor necrosis factor, interleukins, toxic oxygen free radicals, and interferon-gamma (IFN-γ), damages the intestinal epithelium. The risk of colon cancer increases significantly after 30 to 35 years of inflammatory bowel disease, particularly in untreated disease. Future research is directed at an integration of these factors to refine our understanding of disease cause and trajectory, particularly interactions between genetics, the microflora, mucosa, and immune responses.

### Ulcerative Colitis

**Ulcerative colitis (UC)** is a chronic inflammatory disease that causes ulceration of the colonic mucosa, most commonly in the rectum and sigmoid colon. The lesions appear in susceptible individuals between 20 and 40 years of age. UC is less common in people who smoke.60

### Pathophysiology

The primary lesion of UC begins with inflammation at the base of the crypt of Lieberkühn in the large intestine. The disease begins in the rectum (proctitis) and may extend proximally to the entire colon (pancolitis). The mucosa is hyperemic and may appear dark red and velvety, and is involved in a continuous fashion. Small erosions form and coalesce into ulcers. Abscess formation, necrosis, and ragged ulceration of the mucosa ensue. Edema and thickening of the muscularis mucosae may narrow the lumen of the involved colon. Mucosal destruction and inflammation causes bleeding, cramping pain, and an urge to defecate. Frequent diarrhea, with passage of small amounts of blood and purulent mucus, is common. Loss of the absorptive mucosal surface and rapid colonic transit time cause large volumes of watery diarrhea.
**Clinical manifestations**

The course of UC consists of intermittent periods of remission and exacerbation. Mild UC involves less mucosa, so that the frequency of bowel movements, bleeding, and pain is minimal. Severe forms may involve the entire colon and are characterized by abdominal pain, fever, elevated pulse rate, frequent diarrhea (10 to 20 stools/day), urgency, obviously bloody stools, and continuous, crampy pain. Dehydration, weight loss, anemia, and fever result from fluid loss, bleeding, and inflammation. Complications include anal fissures, hemorrhoids, and perirectal abscess. Severe hemorrhage is rare. Edema, strictures, or fibrosis can obstruct the colon. Perforation is an unusual but possible complication. Extraintestinal manifestations include cutaneous lesions (erythema nodosum), polyarthritis, episcleritis, uveitis, disorders of the liver, and alterations in coagulation.⁶¹

**Evaluation and treatment**

Diagnosis of UC is based on the medical history, clinical manifestations, and laboratory, serologic, radiologic, endoscopic, and biopsy findings. Infectious causes are ruled out by stool culture. The symptoms of UC may be similar to those of Crohn disease, making differential diagnosis challenging.⁶² Treatment is individualized and depends on the severity of symptoms and the extent of mucosal involvement. A goal is to promote mucosal healing and avoid surgery. Mild to moderate disease is treated with 5-aminosalicylate therapy followed by steroids. Thioprine and immunomodulatory agents (cyclosporine and tumor necrosis factor [TNF] blocking agents [i.e., tacrolimus]) or vedolizumab are used for serious disease.⁶³ New immunotherapies are emerging.⁶⁴ Severe, unremitting disease can require hospital admission for administration of intravenous fluids and steroids. Extreme malnutrition may require total parenteral nutrition (TPN). Surgical resection of the colon may be performed if other forms of therapy are unsuccessful or if there are acute serious complications (sepsis, hemorrhage, perforation, or obstruction). Surgical approaches for severe UC include total proctocolectomy, with end ileostomy or ileorectal anastomosis, or ileal pouch anal anastomosis (IPAA).⁶⁵ *Pouchitis* is a complication of restorative proctocolectomy with ileal pouch–anal anastomosis performed as surgical treatment for both UC and Crohn disease. Antibiotic treatment is usually successful.⁶⁶

**Crohn Disease**

Crohn disease (CD) (granulomatous colitis, ileocolitis, or regional enteritis) is an idiopathic inflammatory disorder that affects any part of the gastrointestinal tract from the mouth to the anus. In a small percentage of cases, CD is difficult to
differentiate from ulcerative colitis (see Table 36-6). The distal small intestine and proximal large colon are most commonly involved.\textsuperscript{54}

**Pathophysiology**
Inflammation begins in the intestinal submucosa and spreads with discontinuous transmural involvement (“skip lesions”). The ascending colon and the transverse colon are the most common sites of the disease, but both the large and small intestines may be involved, particularly the ileum. One side of the intestinal wall may be affected and not the other. The ulcerations of CD can produce fissures that extend inflammation into lymphoid tissue. The typical lesion is a granuloma (granulomata are described in Chapter 6) with a cobblestone appearance from projections of inflamed tissue surrounded by ulceration. Fistulae may form in the perianal area between loops of intestine or extend into the bladder, rectum, or vagina. Strictures may develop, promoting obstruction. Smoking increases the risk of developing severe disease, and may cause a poorer response to treatment.\textsuperscript{67}

**Clinical manifestations**
Individuals with CD may have no specific symptoms for several years. Symptoms vary according to the location of the disease but are similar to those for UC. Diarrhea is one of the most common symptoms and, occasionally, rectal bleeding if the colon is involved. Weight loss and abdominal pain accompany CD. If the ileum is involved, the individual may be anemic as a result of malabsorption of vitamin B\textsubscript{12}. There also may be deficiencies in folic acid and vitamin D absorption. In addition, proteins may be lost, leading to hypoalbuminemia. Extraintestinal complications are similar to those occurring in ulcerative colitis.

**Evaluation and treatment**
The diagnosis and treatment of CD are similar to the diagnosis and treatment of ulcerative colitis; however, imaging of the small intestine is used in the diagnosis of CD, including either a small bowel series or a capsule endoscopy (camera pill). There are no specific biomarkers or definitive treatments. Smoking cessation is a component of therapy. Immunosuppressants (i.e., anti-TNF) are effective for initial therapy or for resistance to other drugs.\textsuperscript{68} Surgery may be performed to manage complications such as fistula, abscess, or obstruction. Routine colonoscopy for cancer screening should be performed for long-standing colonic disease.

**Microscopic Colitis**
**Microscopic colitis** is a relatively common cause of diarrhea primarily in females
and older adults. Although the mucosa appears normal, there are two histologic forms: lymphocytic and collagenous. Lymphocytic colitis shows an increase in the number of intraepithelial lymphocytes. Collagenous colitis is characterized by a thickened subepithelial collagen layer, alteration of the vascular mucosal pattern, and mucosal nodularity. The cause is unknown. Risk factors include age ≥50 years, female gender, weight loss, absence of abdominal pain, and use of proton pump inhibitors or nonsteroidal anti-inflammatory drugs.69

The symptoms of frequent, chronic daily watery diarrhea are the same for both types and can be accompanied by abdominal pain and weight loss. Antidiarrheal agents and budesonide (an anti-inflammatory steroid) are the best documented treatments. The disease is negatively associated with colorectal cancer.70

**Irritable Bowel Syndrome**

Irritable bowel syndrome (IBS) currently is a symptom-based disease characterized by recurrent abdominal pain with altered bowel habits. There is increasing evidence of organic causes of disease. In North America the prevalence is about 12% and is probably underestimated.71 It is more common in women (1.5 to 3 times greater than men) with a higher prevalence during youth and middle age. Individuals with symptoms of IBS also are more likely to have anxiety, depression, and reduced quality of life.72

The pathophysiology of IBS is unknown and there are no specific biomarkers for the disease. There is increasing evidence to explain the varying symptom presentations, particularly in relation to altered gut microflora, gut immune responses, gut neuroendocrine cell function, the brain-gut axis, genetic susceptibility, and epigenetic factors.73,74 The presentations are summarized below:

1. **Visceral hypersensitivity or hyperalgesia**, particularly with distention of the rectum but also other areas of the gut, may originate in either the peripheral or the central nervous system. The mechanism may be related to dysregulation of the bidirectional “brain-gut axis” (alterations in gut or central nervous system processing of gut nociceptive information).75 Factors include genetic related changes in the function of serotonin-secreting cells of gut-brain pain modulation, alterations in gut microbiota metabolite production with activation of the gut immune system, increased visceral sensitivity and permeability, and altered motility.76

2. **Abnormal gastrointestinal permeability, motility, and secretion** are associated with IBS. Individuals with diarrhea-type IBS have more rapid colonic transit times and increased intestinal permeability. Those with bloating and constipation have delayed
transit times and decreased intestinal permeability. The mechanism may be related to dysregulation of the brain-gut axis, alterations in the function of gut neuroendocrine cells or dorsal root ganglion neurons, or changes in the activity of mast cells.\textsuperscript{77}

3. \textit{Postinflammatory (infectious or noninfectious) IBS} is diagnosed if two or more of the following occur: fever, vomiting, diarrhea, and a positive stool culture. Intestinal infection (bacterial enteritis) and low-grade inflammation have been associated with symptoms of IBS and appear to be related to alteration of gut microbiota, immune activation in gut tissues, and changes in intestinal permeability.\textsuperscript{78,79}

4. \textit{Alteration in gut microbiota (dysbiosis)} influences the sensory, motor, and immune systems of the gut and interacts with higher brain centers and may contribute to symptoms of IBS.\textsuperscript{80} Small intestine overgrowth of normal gut bacteria may be associated with IBS symptoms in some cases.\textsuperscript{81} Nonabsorbable antibiotics and prebiotics and probiotics may be helpful in some individuals.

5. \textit{Food allergy or food intolerance} is associated with IBS in some cases. Food antigens may activate the mucosal immune system, alter intestinal flora, or mediate hypersensitivity reactions and IBS symptoms. Food elimination approaches are helpful in some cases.\textsuperscript{82}

6. \textit{Psychosocial factors (epigenetic factors)}—including early life trauma or abuse or emotional stress interacting with neuroendocrine, neuroimmune, autonomic nervous system, and pain modulatory responses—contribute to the symptoms of IBS.\textsuperscript{74,83}

\textbf{Clinical manifestations}

IBS is characterized by lower abdominal pain or discomfort and bloating. Women report more abdominal pain and constipation and men report more diarrhea.\textsuperscript{84} IBS can be grouped as diarrhea-predominant, constipation-predominant, or alternating diarrhea/constipation. Symptoms including gas, bloating, and nausea are usually relieved with defecation and do not interfere with sleep.

\textbf{Evaluation and treatment}

The diagnosis of IBS is based on signs, symptoms, and personal history and includes the exclusion of structural or biochemical causes of disease. Diagnostic procedures to rule out other causes of symptoms may include endoscopic evaluations, computed tomography (CT) scans or abdominal ultrasound, blood
tests, and tests for lactose intolerance, celiac disease (see Chapter 37), or other disorders. The person may be evaluated for food allergies, parasites, or bacterial growth. The Rome III criteria for diagnosing IBS guide evaluation (Box 36-1).

Box 36-1

**Rome III—Diagnostic Criteria for Irritable Bowel Syndrome (IBS)**

Recurrent abdominal pain or discomfort* at least 3 days/month in the last 3 months associated with two or more of the following:

- Improvement with defecation
- Onset associated with a change in frequency of stool
- Onset associated with a change in form (appearance) of stool†
- Onset of symptoms more than 6 months before diagnosis

*“Discomfort” means an uncomfortable sensation not described as pain.
†Diagnostic criterion.

There is no cure for IBS and treatment is individualized. Treatment of symptoms may include laxatives and fiber, antidiarrheals, antispasmodics, prosecretory drugs, low-dose antidepressants, visceral analgesics, and serotonin agonists or antagonists. Alternative therapies include prebiotics and probiotics to manipulate the microflora, hypnosis, acupuncture, yoga, cognitive-behavioral therapy, and dietary interventions. Research continues to advance the management and understanding of the pathophysiology of this complex syndrome.\(^{85,86}\)

**Diverticular Disease of the Colon**

**Diverticula** are herniations or saclike outpouchings of the mucosa and submucosa through the muscle layers, usually in the wall of the sigmoid colon (Figure 36-9). They rarely occur in the small intestine.\(^{87}\) **Diverticulosis** is asymptomatic
Diverticular disease. **Diverticulitis** represents inflammation. The cause of diverticular disease is unknown. It is associated with increased intracolonic pressure, abnormal neuromuscular function, and alterations in intestinal motility. Approximately 300,000 hospital admissions per year are related to diverticular disease.\(^\text{88}\) Predisposing factors include older age, genetic predisposition, obesity, smoking, diet, lack of physical activity, and medication use, such as aspirin and nonsteroidal anti-inflammatory drugs.\(^\text{89}\) Lack of dietary fiber may or may not contribute to diverticular disease.\(^\text{90}\)

![Diverticular Disease](image)

**Figure 36-9** Diverticular Disease. In diverticular disease, the outpouches (arrows) of mucosa seen in the sigmoid colon appear as slitlike openings from the mucosal surface of the opened bowel. (From Stevens A et al: Core pathology, ed 3, London, 2009, Mosby)

**Pathophysiology**

Diverticula can occur anywhere in the gastrointestinal tract, particularly at weak points in the colon wall, usually where arteries penetrate the tunica muscularis. The most common sites are the left sigmoid colon (prevalent in Western countries) and the right colon (prevalent in Asian countries). A common associated finding is thickening of the circular muscles and shortening of the longitudinal (teniae coli) muscles surrounding the diverticula. Increased collagen and elastin deposition, not muscle hypertrophy, is associated with muscle thickening and this contributes to increased intraluminal pressure and herniation. According to the law of Laplace (see Chapter 23), wall pressure increases as the diameter of a cylindrical structure decreases. Therefore, pressure within the narrow lumen can increase enough to
rupture the diverticula, causing inflammation and diverticulitis. Bacteria and local ischemia also may be contributing factors. Complicated diverticulitis includes abscess, fistula, obstruction, bleeding, or perforation.

Clinical manifestations
Symptoms of uncomplicated diverticular disease may be vague or absent. Cramping pain of the lower abdomen can accompany constriction of the thickened colonic muscles. Diarrhea, constipation, distention, or flatulence may occur. If the diverticula become inflamed or abscesses form, the individual develops fever, leukocytosis (increased white blood cell count), and tenderness of the lower left quadrant.

Evaluation and treatment
Diverticula are often discovered during diagnostic procedures performed for other problems. Ultrasound, sigmoidoscopy, or colonoscopy permits direct observation of the lesions. Abdominal computed tomography is used for diagnosis of complicated cases.

An increase of dietary fiber intake often relieves symptoms and probiotics and mesalazine are being evaluated. Uncomplicated diverticulitis is usually treated with bowel rest and analgesia. Antibiotics are not required. Laparoscopic resection and other minimally invasive approaches are implemented for more severe complications.

Appendicitis
Appendicitis is an inflammation of the vermiform appendix, which is a projection from the apex of the cecum. It is the most common surgical emergency of the abdomen, usually occurs between 10 and 19 years of age (although it may develop at any age), and has an incidence in the United States of 7 to 10 per 10,000 persons.

Pathophysiology
The exact mechanism of the cause of appendicitis is controversial. Obstruction of the lumen with stool, tumors, or foreign bodies with consequent bacterial infection is the most common theory. The obstructed lumen does not allow drainage of the appendix, and as mucosal secretion continues, intraluminal pressure increases. The increased pressure decreases mucosal blood flow, and the appendix becomes hypoxic. The mucosa ulcerates, promoting bacterial or other microbial invasion with further inflammation and edema. Inflammation may involve the distal or entire appendix. Gangrene develops from thrombosis of the luminal blood vessels,
followed by perforation.\textsuperscript{94}

**Clinical manifestations**

Gastric or periumbilical pain is the typical symptom of an inflamed appendix. The pain may be vague at first and in the periumbilical area, increasing in intensity over 3 to 4 hours. It may subside and then migrate to the right lower quadrant, indicating extension of the inflammation to the surrounding tissues. Nausea, vomiting, and anorexia follow the onset of pain, and a low-grade fever is common. Diarrhea occurs in some individuals, particularly children; others have a sensation of constipation. Perforation, peritonitis, and abscess formation are the most serious complications of appendicitis.

**Evaluation and treatment**

In addition to clinical manifestations, there is pain with abdominal palpation and rebound tenderness, usually referred to the right lower quadrant. The white blood cell count is greater than 10,000 cells/mm\textsuperscript{3} with increased neutrophils and C-reactive protein. Abdominal ultrasound, CT scans, and MRI (particularly for pregnant women and children) assist with diagnostic accuracy and help rule out nonappendiceal disease.\textsuperscript{95} Antibiotics and appendectomy are the treatment for simple or perforated appendicitis. There is controversy regarding antibiotics first, then surgery.\textsuperscript{96} Laparoscopic surgery provides quick recovery for simple appendicitis. Recovery is more complicated in cases of perforation, abscess formation, peritonitis, or older age.

**Mesenteric Vascular Insufficiency**

Mesenteric vascular insufficiency is rare with an incidence of about 2 to 3 cases per 100,000 persons.\textsuperscript{97} Three branches of the abdominal aorta supply the stomach and intestines: the celiac artery and the superior and inferior mesenteric arteries (see Figure 35-6). The inferior mesenteric vein drains into the splenic vein and the splenic vein and superior mesenteric vein join the portal vein. Mesenteric venous thrombosis is the least common of the causes of mesenteric vascular insufficiency. Malignancies, right-sided heart failure, and deep vein thrombosis are risk factors. Mesenteric venous thrombosis presents with abdominal pain and is treated with anticoagulants.\textsuperscript{98}

Acute mesenteric arterial insufficiency results in a significant reduction in mucosal blood flow to the large and small intestines and can be acute or chronic.\textsuperscript{99} Preexisting morbidities include dissecting aortic aneurysms, arterial thrombi, or emboli. Embolic obstruction is associated with atrial fibrillation, mitral valve
disease, heart valve prostheses, and myocardial infarction. The superior mesenteric artery has a more direct line of flow from the aorta; therefore, emboli enter it more readily than the inferior branch, causing ischemia and necrosis of the small intestine. Ischemia and necrosis (intestinal infarction) alter membrane permeability. Initially, there is increased motility, nausea and vomiting, urgent bowel evacuation, and severe abdominal pain. Ischemia leads to decreased motility and distention. The damaged intestinal mucosa cannot produce enough mucus to protect itself from digestive enzymes. Mucosal alteration causes fluid to move from the blood vessels into the bowel wall and peritoneum. Fluid loss causes hypovolemia, and further decreases intestinal blood flow. As intestinal infarction progresses, shock, fever, bloody diarrhea, and leukocytosis develop. Bacteria invade the necrotic intestinal wall, causing gangrene and peritonitis.

Chronic mesenteric ischemia is rare but can develop with atherosclerotic stenosis or occlusion or secondary to congestive heart failure, acute myocardial infarction, hemorrhage, thrombus formation, or any condition that decreases arterial blood flow. Chronic occlusion is often accompanied by formation of collateral circulation. The collateral vessels may be able to nourish the resting intestine, but after eating, when the intestine requires more blood, the arterial supply may be insufficient. Ischemia develops, causing cramping abdominal pain (abdominal angina), a cardinal symptom. Some individuals suffer significant weight loss because they stop eating to control the pain. Progressive vascular obstruction eventually causes continuous abdominal pain and necrosis of the intestinal tissue.

Diagnosis of acute and chronic mesenteric ischemia is based on clinical manifestations, laboratory findings, and imaging studies. A bruit can often be heard over a partially occluded artery. Treatment includes aggressive rehydration and the use of antibiotics, anticoagulants, vasodilators, and inhibitors of reperfusion injury. Surgery, including endovascular techniques, is required to remove necrotic tissue, repair sclerosed vessels, and revascularize affected tissue. Acute occlusion is a surgical emergency and mortality is high (50% to 90%). Early diagnosis and aggressive treatment result in the best survival rates.

Disorders of Nutrition

Obesity

Obesity is an increase in body fat mass and a metabolic disorder that has become an epidemic worldwide with a prevalence of 35.7% in the United States in 2010, with no sex differences. The incidence is rapidly increasing among children and adolescents, and they tend to become obese adults. Obesity is associated with higher all-cause mortality.
**Obesity** is defined as a body mass index (body mass index [BMI] = kg/m²) that exceeds 30\(^{104}\) and generally develops when caloric intake exceeds caloric expenditure. Obesity is a major risk factor for morbidity, death, and high healthcare costs.\(^{105}\) Three leading causes of death associated with obesity are coronary artery disease, type 2 diabetes mellitus, and cancer (colorectal, breast in postmenopausal women, endometrial, prostate, renal, and esophageal). Obesity also is a risk factor for hypertension, stroke, hyperlipidemia, gallstones, nonalcoholic steatohepatitis, gastroesophageal reflux, osteoarthritis, infectious disease, and sleep apnea.\(^{106}\)

The causes and consequences of obesity are multiple and complex. Rapidly advancing research regarding risk factors, causal mechanisms, complications, and treatment is in progress. Obesity is known to occur in families and genotypes, and gene-environment interactions are important predisposing factors.\(^{107}\) Environmental factors include culture, socioeconomic status, food intake habits, level of physical activity. Metabolic abnormalities associated with obesity include Cushing syndrome, Cushing disease, polycystic ovarian syndrome, hypothyroidism, and hypothalamic injury.

**Pathophysiology**

The pathophysiology of obesity involves the interaction of peripheral and central pathways and numerous cytokines, hormones, and neurotransmitters. In the periphery, white adipocytes (fat cells) store triglyceride and increase in size and number. Adipocytes also secrete hormones and cytokines, known as adipocytokines.\(^{108}\) These adipocytokines and other hormones (Box 36-2) participate in regulation of food intake, lipid storage, insulin sensitivity, vascular homeostasis, blood pressure regulation, angiogenesis, coagulation, bone metabolism, inflammatory and immune responses, female reproduction, and regulation of energy metabolism. Visceral white fat accumulation causes dysfunction in the regulation and interaction of these cytokines and hormones and contributes to the complications and consequences of obesity (see **Health Alert**: Types of Adipose Tissue and Obesity).

**Health Alert**

**Types of Adipose Tissue and Obesity**

Adipose tissue is often classified according to color as white (WAT), beige (bAT), or brown (BAT). WAT is located in visceral (central) and subcutaneous (peripheral) stores. Visceral adipocytes store fat as triglycerides, which are released as energy...
in the form of fatty acids when needed. WAT has stromal structure that contains macrophages, fibroblasts, and endothelial cells. When energy balance is positive, excess fat is stored in mature white adipocytes, which undergo hypertrophy, and adipogenesis (new fat cells) is stimulated. Chronic positive energy balance can overwhelm adipogenesis, and fat storage then depends only on hypertrophy. Visceral WAT is more likely to store fat by adipose tissue hypertrophy (visceral obesity); produce more adiponectin, less leptin, and more inflammatory cytokines; and result in central obesity. Subcutaneous fat is more likely to store fat by adipogenesis (peripheral obesity) and has higher leptin production, lower adiponectin production, and lower production of inflammatory cytokines. Visceral WAT hypertrophy is associated with greater macrophage infiltration, increased vascularity, and inflammation. Numerous adipokines are released, promoting a proinflammatory state, insulin resistance, and altered lipid metabolism, which are characteristics of the metabolic syndrome associated with obesity. Insulin resistance results in type 2 diabetes mellitus, and excess lipolysis leads to increased release of free fatty acids in the circulation. The increase in free fatty acids contributes to cardiovascular disease and nonalcoholic steatohepatitis (NASH). Adipogenesis has a lower association with inflammation and resistance. Estrogen receptors (ERs) also influence fat storage. ERa is involved in fat mass reduction and ERb is involved in fat mass expansion. ERb is more dense in subcutaneous WAT and may explain the higher incidence of peripheral obesity among premenopausal women and the increase in central obesity with menopause. The complications of obesity are related to where fat is stored, not just the accumulation of fat stores.

Chronic exposure to cold stimulates WAT transition to bAT, which is thermogenic. With warm adaptation bAT reverts to WAT. Leptin and insulin together promote bAT, increasing energy expenditure and weight loss. bAT is diminished in obesity.

BAT is located in the supraclavicular area of the neck and interscapular areas, and is rich in mitochondria containing iron (giving it a brown color). BAT produces nonshivering thermogenesis when stimulated by exposure to cold, stimulation of the sympathetic nervous system, and activation of triiodothyronine (T₃). Mitochondrial activity is uncoupled from ATP synthesis and energy production is released as heat. Leptin and adiponectin are minimally produced by BAT so there is little effect on appetite and satiety. There also is an inverse relationship between amount of BAT and body mass index and age. Interindividual differences in BAT-mediated thermogenesis may explain some of the variability in obesity susceptibility and the increased prevalence of obesity with aging. Most research related to BAT has been conducted in mouse models and research in humans is just beginning. Investigators are interested in discovering if there is a
way to stimulate synthesis and activity of BAT as an approach to preventing or treating obesity and diabetes mellitus.

### Box 36-2

**Examples of Adipocytokines and Other Hormones Related to Complications of Obesity**

**Cytokines from Adipose Cells**

**Adipocytokines**

- **Leptin**: Suppresses appetite at hypothalamus; promotes insulin sensitivity
- **Adiponectin**: Insulin sensitizing for regulation of blood glucose level; promotes anti-inflammatory and anti-hypertensive vascular effects; reduces atherosclerosis and oncogenesis; increases metabolic rate
- **Resistin**: Promotes insulin resistance and increases blood glucose levels
- **Visfatin**: Mimics insulin and binds to insulin receptors

**Proinflammatory Cytokines**

- **Tumor necrosis factor-alpha (TNF-α)**: A proinflammatory hormone; suppresses appetite; induces insulin resistance
- **Interleukins-6, -8, and -10**: Proinflammatory mediators; suppress appetite; induce insulin resistance
- **Monocyte chemotactic protein-1 (MCP-1)**: Involved in macrophage recruitment
- **Plasminogen activator inhibitor-1 (PAI-1)**: Promotes clot formation by inhibiting plasminogen and urokinase (also released by endothelial cells)
- **Retinol binding protein-4 (RBP-4)**: Promotes insulin resistance
Other Hormones

Insulin: Secreted from pancreatic beta cells; suppresses appetite at hypothalamus; promotes glucose utilization in muscle and fat

Amylin: Secreted from pancreatic beta cells; suppresses appetite and postprandial glucagon secretion

Ghrelin: Secreted from stomach; stimulates appetite and controls gastric motility and acid secretion

Peptide YY: Secreted from intestine; reduces appetite and inhibits gastric motility

Incretin: Stimulates insulin release; inhibits glucagon release; slows gastric emptying to reduce postprandial hyperglycemia

Glucagon-like peptide-1 (GLP-1): Gastric inhibitory peptide (glucose-dependent insulinotropic peptide) (GIP)

Neuroendocrine regulation of appetite, eating behavior, energy metabolism, and body fat mass are controlled by a dynamic circuit of signaling mediators from the periphery acting centrally on the hypothalamus and brainstem to regulate hunger and satiety. Peripheral sources of mediators include insulin from the beta cells of the pancreas; ghrelin from the stomach; peptide YY from the intestines; glucagon-like peptide-1 from intestinal endocrine cells; and the adipokines leptin, adiponectin, and resistin. Obesity is associated with increased circulating plasma levels of leptin, insulin, resistin, and ghrelin. There are decreased levels of adiponectin and peptide YY (see Box 36-2).

Within the hypothalamus are the orexigenic neurons (increase food intake and decrease metabolism) and the anorexigenic neurons (decrease food intake and increase metabolism). They interact with peripheral mediators to control food intake and energy expenditure. The hypothalamus also communicates with higher brain centers related to reward, pleasure, and addictive behavior. These centers can override hypothalamic control of food intake and satiety, increasing consumption of highly palatable foods and resulting in increased fat stores. Interaction of altered levels of hormones and adipocytokines with hypothalamic neurons is an important determinant of excessive fat mass and the complications of obesity.

Leptin, a product of the obesity gene (Ob gene), acts on the hypothalamus to suppress appetite and functions to regulate body weight within a fairly narrow
range. Leptin levels increase as the number of adipocytes increases; however, for unknown reasons, high leptin levels are ineffective at decreasing appetite and energy expenditure, a condition known as leptin resistance.\textsuperscript{112} Leptin resistance fails to inhibit orexigenic hypothalamic satiety signaling and promotes overeating and excessive weight gain. Leptin resistance is also associated with insulin resistance (hyperinsulinemia/glucose intolerance) and the cardiovascular complications of obesity. Simultaneously there is an increase in ghrelin, which stimulates orexigenic neurons and increases appetite. Decreased levels of adiponectin and peptide YY decrease stimulation of anorexigenic neurons. Adiponectin also is insulin sensitizing, promotes glucose uptake, and has anti-inflammatory actions. A decrease in adiponectin is associated with insulin resistance, coronary artery disease, and hypertension, contributing to the complications of obesity.

Enlarged adipocytes increase lipolysis (with release of fatty acids) and secrete proinflammatory adipokines from T lymphocytes and activated macrophages. The result is a low-grade systemic inflammation. The inflammatory state and accelerated lipolysis contribute to the development of insulin resistance and metabolic syndrome (hypertriglyceridemia, reduced high-density lipoproteins, increased low-density lipoproteins, hypertension, and insulin resistance).\textsuperscript{113,114} Figure 36-10 summarizes the pathophysiology and major consequences of obesity.
Clinical manifestations

Obesity usually presents with two different forms of adipose tissue distribution, visceral and peripheral.\textsuperscript{115} Visceral obesity (also known as intra-abdominal, central, or masculine obesity) occurs when the distribution of body fat is localized around the abdomen and upper body, resulting in an apple shape.\textsuperscript{116} Visceral obesity has an
increased risk for systemic inflammation, metabolic syndrome, obstructive sleep apnea syndrome, cardiovascular complications, nonalcoholic steatohepatitis cancer, osteoarthritis, and type 2 diabetes mellitus.\textsuperscript{117,118} (Diabetes mellitus is discussed in Chapter 19.)

Peripheral obesity (also known as gluteal-femoral, feminine, or subcutaneous obesity) occurs when the distribution of body fat is extraperitoneal and distributed around the thighs and buttocks and through the muscle, resulting in a pear shape, and is more common in women. Peripheral and subcutaneous fat is less metabolically active, is less lipolytic, and releases fewer adipocytokines (particularly adiponectin) than visceral fat. Risk factors are still present for the complications of obesity but they are less severe than those for visceral obesity.

Normal weight obesity (NWO) describes individuals with normal body weight and BMI with percent of body fat greater than 30%. These individuals are at risk for metabolic dysregulation, increases in inflammatory cytokines, insulin resistance, increased risk for cardiovascular disease, and higher mortality.\textsuperscript{119} NWO is estimated to occur in 2% to 28% of women and 3% of men.\textsuperscript{120}

Metabolically healthy obesity (MHO) describes about 10% to 30% of individuals who are obese but have no metabolic-obesity–associated complications and decreased risk for morbidity and mortality. MHO is more prevalent among women and declines with age with adverse long-term outcomes.\textsuperscript{121} Research is in progress to better understand the genetics, body fat distribution patterns, metabolic pathways, lifestyle practices, and therapeutic options for these individuals.

**Evaluation and treatment**

There are several methods for measuring or estimating body fat mass, including computed tomography (CT) and magnetic resonance imaging (MRI) techniques; bioimpedance analysis; underwater weighing; and anthropometric measurements, such as skinfold thickness, circumferences, and various body diameters (i.e., waist-to-hip ratios and waist circumference; body mass index tables).\textsuperscript{122} The BMI and waist-to-hip ratios are most commonly used because they are the easiest to measure and are most cost-effective. Overweight is defined as a BMI greater than 25 kg/m\textsuperscript{2} and obesity is a BMI greater than 30 kg/m\textsuperscript{2}. BMI charts are available for children ages 2 to 20 years; these can be used for comparison during adulthood because obese children generally become obese adults.\textsuperscript{123} No specific diagnostic criteria for obesity have been established. The complications of obesity affect nearly every body system (see Figure 36-10).

Obesity is a chronic disease for which various approaches to treatment have been used; these include correction of metabolic abnormalities, individually tailored weight reduction diets and exercise programs, psychotherapy, behavioral
Weight loss (bariatric) surgery is the most effective treatment for decreasing obesity-related morbidity. Unraveling the causes of obesity will lead to more specific prevention and pharmacotherapeutic strategies.

**Malnutrition and Starvation**

**Malnutrition** is lack of nourishment from inadequate amounts of calories, protein, vitamins, or minerals and is caused by improper diet, alterations in digestion or absorption, chronic disease, or a combination of these factors. **Starvation** is a reduction in energy intake leading to weight loss. Short-term starvation and long-term starvation have different effects. Therapeutic short-term starvation is part of many weight-reduction programs because it causes an initial rapid weight loss that reinforces the individual's motivation to diet. Therapeutic long-term starvation is used in medically controlled environments to facilitate rapid weight loss in morbidly obese individuals. Pathologic long-term starvation can be caused by poverty (particularly in third-world countries); chronic diseases of the cardiovascular, pulmonary, hepatic, renal, and digestive systems; malabsorption syndromes; and cancer.

**Short-term starvation**, or extended fasting, consists of several days of total dietary abstinence or deprivation. Once all available energy has been absorbed from the intestine, glycogen in the liver is converted to glucose through **glycogenolysis**, the metabolism of glycogen into glucose. This process peaks within 4 to 8 hours, and gluconeogenesis begins. **Gluconeogenesis** is the formation of glucose from noncarbohydrate molecules: lactate, pyruvate, amino acids, and the glycerol portion of fats. Like glycogenolysis, gluconeogenesis takes place within the liver. Both of these processes deplete stored nutrients and thus cannot meet the body's energy needs indefinitely. Proteins continue to be catabolized to a minimal degree, providing carbon for the synthesis of glucose needed by brain and blood cells.

**Long-term starvation** begins after several days of dietary abstinence and eventually causes death. The major characteristics of long-term starvation are decreased energy expenditure, a decreased dependence on gluconeogenesis, and an increased use of ketone bodies (products of lipid and pyruvate metabolism) as a cellular energy source. Depressed insulin and glucagon levels promote lipolysis in adipose tissue. Lipolysis liberates fatty acids, which supply energy to cardiac and skeletal muscle cells, as well as ketone bodies, which sustain brain tissue. Fatty acid or ketone body oxidation meets most energy needs of the cells. (Some glucose is still needed as fuel for brain tissue.) Once the supply of adipose tissue is depleted, proteolysis begins. The breakdown of muscle protein is the last process to supply...
energy for life. Death results from severe alterations in electrolyte balance and loss of renal, pulmonary, and cardiac function.\textsuperscript{128}

Adequate ingestion of appropriate nutrients is the obvious treatment for starvation. In medically induced starvation, the body is maintained in a ketotic state until the desired amount of adipose tissue has been lysed. Starvation imposed by chronic disease, long-term illness, or malabsorption is treated with enteral or parenteral nutrition. Care must be taken to prevent \textit{refeeding syndrome} during the treatment of long-term starvation.\textsuperscript{129} With refeeding, insulin release, hypophosphatemia, hypomagnesemia, and hypokalemia can cause life-threatening complications.

\textbf{Cachexia} (also known as cytokine-induced malnutrition) is physical wasting with loss of weight and muscle atrophy, fatigue, and weakness. Inflammatory cytokines induce skeletal muscle wasting and a blunted response to ghrelin. Adiponectin suppresses appetite. Cancer, acquired immunodeficiency syndrome (AIDS), tuberculosis, and other major chronic progressive diseases contribute to cachexia (see \textit{Chapter 10}).\textsuperscript{130}

\section*{Quick Check 36-4}

1. Why are Crohn disease and ulcerative colitis called \textit{inflammatory bowel diseases}?
2. How is leptin resistance associated with obesity?
3. When does proteolysis begin in long-term starvation?
Disorders of the Accessory Organs of Digestion

The accessory organs of digestion (liver, gallbladder, pancreas) secrete substances necessary for digestion and, in the case of the liver, carry out metabolic functions needed to maintain life. Disorders of these organs include inflammatory disease, obstruction of ducts, and tumors. (Cancers of the digestive system are described at the end of this chapter.)

Common Complications of Liver Disorders

Of all the accessory organ disorders, acute or chronic liver disease leads to the most significant systemic, life-threatening complications. These complications are common to all liver disorders and include portal hypertension, ascites, hepatic encephalopathy, jaundice, and hepatorenal syndrome.

Portal Hypertension

Portal hypertension is abnormally high blood pressure in the portal venous system caused by resistance to blood flow. Pressure in this system is normally 3 mm Hg; portal hypertension is an increase to at least 10 mm Hg.

Pathophysiology

Portal hypertension is caused by disorders that obstruct or impede blood flow through any component of the portal venous system or vena cava. Intrahepatic causes result from vascular remodeling with shunts, thrombosis, inflammation, or fibrosis of the sinusoids, as occurs in cirrhosis of the liver, biliary cirrhosis, viral hepatitis, or schistosomiasis (a parasitic infection). Posthepatic causes occur from hepatic vein thrombosis or cardiac disorders that impair the pumping ability of the right side of the heart. This causes blood to collect and increases pressure in the veins of the portal system. The most common cause of portal hypertension is fibrosis and obstruction caused by cirrhosis of the liver (see p. 931). Long-term portal hypertension causes several pathophysiologic problems that are difficult to treat and can be fatal. These problems include varices, splenomegaly, ascites, hepatic encephalopathy, and hepatopulmonary syndrome. Varices are distended, tortuous collateral veins. Prolonged elevation of pressure in the portal vein cause collateral veins to open between the portal vein and systemic veins and their transformation into varices, particularly in the lower esophagus and stomach, but also over the abdominal wall (known as the caput medusae [Medusa
head]) and rectum (hemorrhoidal varices) (Figure 36-11). Rupture of varices can cause life-threatening hemorrhage.\textsuperscript{132}

**FIGURE 36-11 Varices Related to Portal Hypertension.** Portal vein, its major tributaries, and the most important shunts (collateral veins) between the portal and caval systems. The shunted blood returns to the systemic venous system, bypassing the liver. (From Monahan FD et al: Phipps’ medical-surgical nursing: concepts and clinical practice, ed 8, St Louis, 2007, Mosby)

**Splenomegaly** is enlargement of the spleen caused by increased pressure in the splenic vein, which branches from the portal vein. Thrombocytopenia is the most
common symptom of congestive splenomegaly. The enlarged spleen can be palpated. **Hepatopulmonary syndrome** (vasodilation, intrapulmonary shunting, and hypoxia) and **portopulmonary hypertension** (pulmonary vasoconstriction and vascular remodeling) are complications of liver disease and portal hypertension. The pathophysiology is complex and involves different effects of vasoactive substances. There may be no clinical manifestations, although dyspnea, cyanosis, and clubbing may occur.\(^{133}\)

**Clinical manifestations**

Vomiting of blood (hematemesis) from bleeding **esophageal varices** is the most common clinical manifestation of portal hypertension. Bleeding is usually from varices that have developed slowly over a period of years. Slow, chronic bleeding from varices causes anemia or melena. Rupture of esophageal varices causes hemorrhage and voluminous vomiting of dark-colored blood. The ruptured varices are usually painless. Rupture is caused by a combination of erosion by gastric acid and elevated venous pressure. Mortality from ruptured esophageal varices ranges from 30% to 60%. Recurrent bleeding of esophageal varices indicates a poor prognosis. Hemorrhoidal varices present as hematochezia and copious rectal bleeding. Most individuals die within 1 year.

**Evaluation and treatment**

Portal hypertension is often diagnosed at the time of variceal bleeding and confirmed by upper gastrointestinal endoscopy and evaluation of portal venous pressure. The individual usually has a history of jaundice, hepatitis, alcoholism, or cirrhosis. Pressure in the portal venous system can be reduced with nonselective beta-blocking drugs to assist in preventing variceal bleeding.\(^{134}\)

Emergency management of bleeding varices includes use of vasopressors and compression of the varices with an inflatable tube or balloon, sclerotherapy, variceal ligation, or portacaval shunt. Surgical construction of transjugular intrahepatic portosystemic shunts (TIPS procedure: anastomosis of the portal vein to the inferior vena cava) may decompress the varices. This treatment can precipitate encephalopathy. Liver transplant is the most successful option for liver failure.\(^{135}\)

**Ascites**

**Ascites** is the accumulation of fluid in the peritoneal cavity. Ascites traps body fluid in the peritoneal space from which it cannot escape. The effect is to reduce the amount of fluid available for normal physiologic functions. Cirrhosis is the most
common cause of ascites, but other causes include heart failure, constrictive pericarditis, abdominal malignancies, nephrotic syndrome, and malnutrition. Of individuals who develop ascites caused by cirrhosis, 25% die within 1 year. Continued heavy drinking of alcohol is associated with this mortality and is related to cirrhosis.

**Pathophysiology**

Several factors contribute to the development of ascites, including portal hypertension, decreased synthesis of albumin by the liver, splanchnic arterial vasodilation, and renal sodium and water retention. Portal hypertension and reduced serum albumin levels cause capillary hydrostatic pressure to exceed capillary osmotic pressure (see Chapter 5), pushing water into the peritoneal cavity. Portal hypertension also increases the production of hepatic lymph, which “weeps” into the peritoneal cavity. Splanchnic arterial vasodilation, associated with increased nitric oxide produced by the diseased liver, can decrease effective circulating blood volume, activating aldosterone and antidiuretic hormone, which promote renal sodium and water retention. The sodium and water retention expands plasma volume, thereby accelerating portal hypertension and ascites formation. Translocation of bacteria and release of endotoxin cause peritonitis with an inflammatory response that increases mesenteric capillary permeability and fluid movement into the peritoneal cavity, promoting ascites. Figure 36-12 summarizes the mechanisms by which cirrhosis of the liver cause ascites.
Clinical manifestations

The accumulation of ascitic fluid causes abdominal distention, increased abdominal girth and weight gain (Figure 36-13). Large volumes of fluid (10 to 20 L) displace the diaphragm and cause dyspnea by decreasing lung capacity. Respiratory rate increases, and the individual assumes a semi-Fowler position to relieve the dyspnea. Some peripheral edema is usually present. Approximately 10% of individuals with ascites develop bacterial peritonitis, which causes fever, chills, abdominal pain, decreased bowel sounds, and cloudy ascitic fluid.
Evaluation and treatment

Diagnosis is usually based on clinical manifestations and identification of liver disease. Dietary salt restriction and use of potassium-sparing diuretics can reduce ascites. Stronger diuretics, such as furosemide or ethacrynic acid, may be used and vasopressin receptor 2 antagonists are effective for dilutional hyponatremia. Albumin may be given. Paracentesis is used to aspirate ascitic fluid for bacterial culture, biochemical analysis, and microscopic examination. The goal of treatment is to relieve discomfort. If the restoration of liver function is possible, the ascites diminishes spontaneously. Levels of serum electrolytes are monitored carefully because the individual is at risk for hyponatremia and hypokalemia.

Palliative measures include paracentesis to remove 1 or 2 L of ascitic fluid and relieve respiratory distress. However, the removal of too much fluid relieves pressure on blood vessels and carries the risk of hypotension, shock, or death. Despite repeated paracentesis, ascitic fluid reaccumulates because of the persistent portal hypertension and reduced plasma albumin levels associated with irreversible disease. Peritonitis is treated with antibiotics. Other procedures include peritoneovenous shunt (peritoneal fluid into veins) and transjugular intrahepatic portosystemic shunt (TIPS) (bypass of blood flow from the portal venous branch to the hepatic venous branch). Individuals with ascites and portal hypertension have a poor prognosis and liver transplant is the best treatment option.
**Hepatic Encephalopathy**

**Hepatic encephalopathy** (portal-systemic encephalopathy) is a complex neurologic syndrome characterized by impaired behavioral, cognitive, and motor function. The syndrome may develop rapidly during acute fulminant hepatitis or slowly during the course of cirrhosis and the development of portal hypertension or after portosystemic bypass or shunting.

**Pathophysiology**

Hepatic encephalopathy results from a combination of biochemical alterations that affect neurotransmission and brain function. Liver dysfunction and the development of collateral vessels that shunt blood around the liver to the systemic circulation permit toxins absorbed from the gastrointestinal tract and normally removed by the liver, to accumulate and circulate freely to the brain. The accumulated toxins alter cerebral energy metabolism, interfere with neurotransmission, and cause edema. The most hazardous substances are end products of intestinal protein digestion, particularly ammonia, which cannot be converted to urea by the diseased liver. Other substances include inflammatory cytokines, short-chain fatty acids, serotonin, tryptophan, and manganese. These substances cause astrocyte swelling and alter the blood-brain barrier, promoting cerebral edema. Infection, hemorrhage, and electrolyte imbalance (including zinc deficiency), constipation and use of sedatives and analgesics can precipitate hepatic encephalopathy in the presence of liver disease.\(^\text{138}\)

**Clinical manifestations**

Subtle changes in personality, memory loss, irritability, disinhibition, lethargy, and sleep disturbances are common initial manifestations of hepatic encephalopathy. Symptoms then can progress to confusion, disorientation to time and space, flapping tremor of the hands (asterixis), slow speech, bradykinesia, stupor, convulsions, and coma. Coma is usually a sign of liver failure and ultimately results in death. Variceal bleeding and ascites may develop concurrently. Symptoms may be episodic, recurrent, or persistent.\(^\text{139}\) Hepatic encephalopathy is often associated with bleeding varices and ascites.

**Evaluation and treatment**

Diagnosis of hepatic encephalopathy is based on a history of liver disease, clinical manifestations, psychometric tests, and exclusion of other causes of brain dysfunction. Electroencephalography and blood chemistry tests provide supportive data. Tracking levels of serum ammonia assesses treatment effectiveness and liver
Correction of fluid and electrolyte imbalances and withdrawal of depressant drugs metabolized by the liver are the first steps in the treatment of hepatic encephalopathy. Dietary protein is maintained to prevent malnutrition but at levels that reduce blood ammonia levels. Lactulose prevents ammonia absorption in the colon. Neomycin eliminates ammonia-producing intestinal bacteria but can be nephrotoxic. Glutamase inhibitors reduce gut ammonia. Rifaximin decreases intestinal production of ammonia and is used for lactulose nonresponders. Extracorporeal liver support systems remove toxins from the blood and are an option for managing overt hepatic encephalopathy.

Jaundice

Jaundice, or icterus, is a yellow or greenish pigmentation of the skin caused by hyperbilirubinemia (plasma bilirubin concentrations greater than 2.5 to 3.0 mg/dl). Hyperbilirubinemia and jaundice can result from (1) extrahepatic (posthepatic) obstruction to bile flow, (2) intrahepatic obstruction, or (3) prehepatic excessive production of unconjugated bilirubin (i.e., excessive hemolysis of red blood cells) (Figure 36-14). Jaundice in newborns is caused by impaired bilirubin uptake and conjugation (see Chapter 37).
Pathophysiology

Obstructive jaundice can result from extrahepatic or intrahepatic obstruction. Extrahepatic obstructive jaundice develops if the common bile duct is occluded (e.g., by a gallstone, tumor, or inflammation). Bilirubin conjugated by the hepatocytes cannot flow through the obstructed common bile duct into the duodenum. Therefore, it accumulates in the liver and enters the bloodstream, causing hyperbilirubinemia and jaundice. Intrahepatic obstructive jaundice involves disturbances in hepatocyte function and obstruction of bile canaliculi. The uptake, conjugation, or excretion of bilirubin can be affected with elevated levels of both conjugated and unconjugated bilirubin. Obstruction of bile canaliculi diminishes flow of conjugated bilirubin into the common bile duct. In mild cases, some of the bile canaliculi open. Consequently, the amount of bilirubin in the intestinal tract may be only slightly decreased.

Excessive hemolysis (destruction) of red blood cells can cause hemolytic jaundice (prehepatic or nonobstructive jaundice). Increased unconjugated bilirubin is formed through metabolism of the heme component of destroyed red blood cells.
and exceeds the conjugation ability of the liver, causing blood levels of unconjugated bilirubin to rise. Decreased bilirubin uptake or conjugation also causes unconjugated hyperbilirubinemia, as occurs with reaction to some drugs (e.g., rifampin) and in genetic disorders such as Gilbert syndrome. Because unconjugated bilirubin is not water soluble, it is not excreted in the urine. The causes of jaundice are summarized in Table 36-7.

</tbody>
</table>

**Clinical manifestations**

Conjugated bilirubin is water soluble and appears in the urine. The urine may darken several days before the onset of jaundice. The complete obstruction of bile flow from the liver to the duodenum causes light-colored stools. With partial obstruction, the stools are normal in color and bilirubin is present in the urine.

Fever, chills, and pain often accompany jaundice resulting from viral or bacterial inflammation of the liver (e.g., viral hepatitis). Yellow discoloration may first occur in the sclera of the eye and then progress to the skin as bilirubin attaches to elastic fibers. Pruritus (itching) often accompanies jaundice because bilirubin accumulates in the skin.

**Evaluation and treatment**

Laboratory evaluation of serum establishes whether elevated plasma bilirubin is conjugated or unconjugated, or both. The history and physical examination identify underlying disorders, such as cirrhosis, exposure to hepatitis virus, and gallbladder or pancreatic disease. The treatment for jaundice consists of correcting the cause.

**Hepatorenal Syndrome**
Hepatorenal syndrome is functional renal failure that develops as a complication of advanced liver disease. The renal failure is not caused by primary renal disease or other extrinsic factors but rather by portal hypertension, cardiac impairment, and other circulatory alterations associated with advanced liver disease, such as cirrhosis or fulminant hepatitis with portal hypertension. Manifestations include oliguria, sodium and water retention (usually with ascites and peripheral edema), hypotension, and peripheral vasodilation. The kidney usually has a normal structure.

Pathophysiology

Type 1 hepatorenal syndrome accompanies a sudden decrease in blood volume secondary to massive gastrointestinal or variceal bleeding and hypotension caused by bleeding and peripheral vasodilation associated with failing liver function. Hypotension also can be caused by the excessive use of diuretics to treat ascites or decreased cardiac output. The decrease in blood volume and hypotension result in decreased renal perfusion, decreased glomerular filtration, and oliguria (see Chapter 30). Type 2 hepatorenal syndrome develops slowly and is related to ascites. Ineffective circulating blood volume causes decreased glomerular filtration and oliguria. Intrarenal vasoconstriction may result from the selective effects of vasoactive substances that accumulate in the blood because of liver failure or a compensatory response to portal hypertension and the pooling of blood in the splanchnic circulation.

Clinical manifestations

The onset of hepatorenal manifestations may be acute or gradual. Oliguria and complications of advanced liver disease, including jaundice, ascites, peripheral edema, hypotension and gastrointestinal bleeding, are usually present. Systolic blood pressure is usually below 100 mm Hg. Nonspecific symptoms of hepatorenal syndrome include anorexia, weakness, and fatigue.

Evaluation and treatment

Despite oliguria, serum potassium levels do not become dangerously elevated until the terminal stages of the hepatorenal syndrome. Blood urea level increases, followed by an increase in creatinine concentration. Urine osmolality increases, but urine sodium concentrations are below normal. Urine specific gravity is greater than 1.015.

The prognosis is usually poor and is related to a failing liver requiring liver transplant. Bridge treatments include albumin administration and terlipressin (a vasopressin analog).
Quick Check 36-5

1. How does portal hypertension cause varices and promote formation of ascites?

2. What are two factors that cause hepatic encephalopathy?

3. Why is the concentration of unconjugated bilirubin elevated in hemolytic jaundice?

4. Describe how failure of liver function causes renal failure (hepatorenal syndrome).

Disorders of the Liver

Acute Liver Failure

Acute liver failure (fulminant liver failure) is a rare clinical syndrome resulting in severe impairment or necrosis of liver cells without preexisting liver disease or cirrhosis. Paracetamol (acetaminophen) overdose is a leading cause of acute liver failure in the United States (see Health Alert: Paracetamol [Acetaminophen] and Acute Liver Failure in Chapter 35). Acute liver failure also can occur with concurrent liver disease (acute on chronic liver failure), including complication of viral hepatitis, particularly hepatitis B virus (HBV) infection; compounded by infection with the delta virus; as well as metabolic liver disorders. Edematous hepatocytes and patchy areas of necrosis and inflammatory cell infiltrates disrupt the parenchyma. The death of hepatocytes may be caused by viral or toxic injury or immunologic and inflammatory damage with necrosis or apoptosis.

Acute liver failure usually develops 6 to 8 weeks after the initial symptoms of viral hepatitis or a metabolic liver disorder, or within 5 days to 8 weeks of acetaminophen overdose. Anorexia, vomiting, abdominal pain, and progressive jaundice are initial signs followed by ascites and gastrointestinal bleeding. Hepatic encephalopathy is manifested as lethargy, and altered motor functions. Coma is related to cerebral edema, ischemia, and brainstem herniation. Liver function tests show elevations in the levels of both direct and indirect serum bilirubin, serum transaminases, and blood ammonia. Prothrombin time is prolonged. Renal failure and pulmonary distress can occur. Treatment of acute liver failure requires rapid evaluation and critical care. The hepatic necrosis is irreversible, and 60% to 90% of affected children die. Liver transplantation may be lifesaving. Artificial liver support devices are being evaluated. Survivors usually do not develop cirrhosis or chronic liver disease.
Cirrhosis

Cirrhosis is an irreversible inflammatory, fibrotic liver disease and has a prevalence in the United States of about 633,323 with a death rate of about 26%. Many disorders can cause cirrhosis and are listed in Box 36-3. The process of cellular injury depends on the cause of cirrhosis, and the pathologic mechanisms are not all clearly understood. Structural changes result from injury (e.g., viruses or toxicity from alcohol) and fibrosis, which is a consequence of infiltration of leukocytes, release of inflammatory mediators, and activation of hepatic stellate cells and myofibroblasts. Chaotic fibrosis alters or obstructs biliary channels and blood flow, producing jaundice and portal hypertension (see pp. 927 and 929). New vascular channels form shunts, and blood from the portal vein bypasses the liver, contributing to portal hypertension, metabolic alterations, and toxin accumulation. The process of regeneration is disrupted by hypoxia, necrosis, atrophy, and (ultimately) liver failure. The formation of fibrous bands and regenerating nodules distorts the architecture of the liver parenchyma and gives the liver a cobbly appearance. The liver may be larger or smaller than normal and is usually firm or hard when palpated.

Box 36-3

Causes of Cirrhosis

Hepatitis virus—B and C (common)

Excessive alcohol intake (common)

Idiopathic (common)

Nonalcoholic fatty liver disease (NAFLD), also known as nonalcoholic steatohepatitis (NASH)

Autoimmune disorders

Autoimmune hepatitis

Primary biliary cirrhosis
Primary sclerosing cholangitis

Hereditary metabolic disorder

α₁-Antitrypsin deficiency

Hemochromatosis

Wilson disease

Glycogen or lipid storage diseases

Prolonged exposure to drugs or toxins (e.g., carbon tetrachloride, cleaning and industrial solvents, copper salts)

Hepatic venous outflow obstruction

Budd-Chiari syndrome

Right-sided heart failure

Cirrhosis develops slowly over a period of years. Its severity and rate of progression depend on the cause. If toxins, such as alcohol metabolites, are involved, the rate of cell death and the severity of inflammation depend on the amount of toxin present. Removal of the toxin slows the progression of liver damage and enhances the process of regeneration.¹⁵²

**Alcoholic liver disease.**

Alcoholic liver disease is related to toxic effects of alcohol (see *Chapter 4*) and coexisting liver disease. The incidence of alcoholic cirrhosis is greatest in middle-age men; however, women develop more severe liver injury than men.¹⁵³ Mortality resulting from cirrhosis in the United States is highest among non-whites. Although alcoholic cirrhosis is the most prevalent of the various types of cirrhosis, the occurrence of cirrhosis among persons with alcoholism is relatively low
(approximately 25%). The spectrum of alcoholic liver disease includes alcoholic fatty liver, alcoholic steatohepatitis, and alcoholic cirrhosis.

**Pathophysiology**

**Alcoholic fatty liver (steatosis)** is the mildest form of alcoholic liver disease. It can be caused by relatively small amounts of alcohol, may be asymptomatic, and is reversible with cessation of drinking. Fat deposition (deposition of triglycerides) within the liver is caused primarily by increased lipogenesis, cholesterol synthesis, and decreased fatty acid oxidation by hepatocytes. Lipids mobilized from adipose tissue or dietary fat intake may contribute to fat accumulation.

**Alcoholic steatohepatitis (alcoholic hepatitis)** is a precursor of cirrhosis characterized by increased hepatic fat storage, inflammation, and degeneration and necrosis of hepatocytes with infiltration of neutrophils and lymphocytes. The injured hepatocytes contain Mallory bodies (hyaline endoplasmic reticulum), indicating the onset of fibrosis. The inflammation and necrosis caused by alcoholic steatohepatitis stimulate the irreversible fibrosis characteristic of the cirrhotic stage of disease.

**Alcoholic cirrhosis** is caused by the toxic effects of alcohol metabolism on the liver, immunologic alterations, inflammatory cytokines, oxidative stress from lipid peroxidation, and malnutrition. Alcohol is transformed to acetaldehyde, and excessive amounts significantly alter hepatocyte function and activate hepatic stellate cells, a primary cell involved in liver fibrosis. Mitochondrial function is impaired, decreasing oxidation of fatty acid. Enzyme and protein synthesis may be depressed or altered, and hormone and ammonia degradation is diminished. Acetaldehyde inhibits export of proteins from the liver, alters metabolism of vitamins and minerals, and induces malnutrition. Kupffer cell (macrophage) activation attracts neutrophils promoting inflammation, endotoxins accumulate from translocation of gut bacteria, and cell-mediated immunity is suppressed. Cellular damage initiates an inflammatory response that, along with necrosis, results in activation of hepatic stellate cells and excessive collagen formation. Fibrosis and scarring alter the structure of the liver and obstruct biliary and vascular channels.

**Clinical manifestations**

Fatty infiltration causes no specific symptoms or abnormal liver function test results. The liver is usually enlarged, however, and the individual has a history of continuous alcohol intake during the previous weeks or months. Anorexia, nausea, jaundice, and edema develop with advanced fatty infiltration or the onset of alcoholic steatohepatitis (Figure 36-15).
The clinical manifestations of alcoholic steatohepatitis can be mild or severe. Nonspecific symptoms include fatigue, weight loss, and anorexia. Manifestations of acute illness include nausea, anorexia, fever, abdominal pain, and jaundice. Cirrhosis is a multiple-system disease and causes hepatomegaly, splenomegaly, ascites, portal hypertension, gastrointestinal hemorrhage, hepatic encephalopathy, and esophageal varices. Anemia results from blood loss, malnutrition, and hypersplenism. Renal failure is often a late complication of hepatorenal syndrome. Toxic effects of alcohol also can cause testicular atrophy, reduced libido, azoospermia, and decreased testosterone levels in men. The presence of numerous and severe manifestations increases the risk of death. Cirrhosis increases the risk of hepatocellular carcinoma.

**Evaluation and treatment**

The diagnosis of alcoholic steatohepatitis or cirrhosis is based on the individual's
history and clinical manifestations. The results of liver function tests are abnormal, and serologic studies show elevated levels of serum enzymes and bilirubin, decreased levels of serum albumin, and prolonged prothrombin time that is not easily corrected with vitamin K therapy. Liver biopsy can confirm the diagnosis of cirrhosis, but biopsy is not necessary if clinical manifestations of cirrhosis are evident.

There is no specific treatment for alcoholic steatohepatitis or cirrhosis. Rest, vitamin supplements, a nutritious diet, corticosteroids, antioxidants, drugs that slow fibrosis, and management of complications (such as ascites, gastrointestinal bleeding, and encephalopathy) slow disease progression. Cessation of alcohol consumption slows the progression of liver damage, improves clinical symptoms, and prolongs life. Although the liver damage is irreversible, measures that halt the inflammation and destruction of liver cells prolong life. Liver transplantation is the treatment of end-stage liver disease. Artificial liver support systems continue to be evaluated and hepatocyte transplantation is being explored.158,159

**Nonalcoholic fatty liver disease and nonalcoholic steatohepatitis.**

**Nonalcoholic fatty liver disease (NAFLD)** is infiltration of hepatocytes with fat, primarily in the form of triglycerides, but it occurs in the absence of alcohol intake. It is associated with obesity (including obese children), high levels of cholesterol and triglycerides, metabolic syndrome, and type 2 diabetes mellitus. NAFLD is the most common chronic liver disease in the United States. Some individuals with NAFLD will develop **nonalcoholic steatohepatitis (NASH)** with hepatocellular injury, inflammation, and fibrosis. NASH is difficult to distinguish from alcohol-induced liver fibrosis. NAFLD is usually asymptomatic and may remain undetected for years. The most severe forms of NASH progress to cirrhosis and end-stage liver disease. Treatment is individualized and includes the use of behavioral modification, dietary counseling, and regular exercise.160,161

**Biliary cirrhosis.**

**Biliary cirrhosis** differs from alcoholic cirrhosis in that the damage and inflammation leading to cirrhosis begin in bile canaliculi and bile ducts, rather than in the hepatocytes. The two types of biliary cirrhosis are *primary* and *secondary*. Although both involve bile duct pathologic changes, they differ with respect to cause, risk factors, and mechanisms of obstruction and inflammation.

**Primary biliary cirrhosis** is a chronic, autoimmune, cholestatic liver disease. It is caused by autoimmune T-lymphocyte and highly specific antimitochondrial
antibody destruction of the small intrahepatic bile ducts and primarily affects middle-aged women. Primary biliary cirrhosis often accompanies other autoimmune diseases. Pathogenesis includes inflammation, destruction, fibrosis, and obstruction of the intrahepatic bile ducts. Primary biliary cirrhosis can be detected by biochemical evidence of cholestatic liver disease. Test findings include the presence of antinuclear antibodies, anticentromere antibodies, and the GP210 antinuclear antibody as well as elevated alkaline phosphatase levels for at least 6 months' duration. Ultrasound imaging of the liver, or liver biopsy, assists with diagnosis. Manifestations progress insidiously from pruritus, hyperbilirubinemia, jaundice, and light or clay-colored stools to cirrhosis, portal hypertension, and encephalopathy. Life expectancy is 5 to 10 years after onset of symptoms if not treated. Treatment with ursodeoxycholic acid slows disease progression and pruritus may be relieved by cholestyramine, which binds bile salts in the intestine. Liver transplant is highly effective.162

Secondary biliary cirrhosis is caused by prolonged partial or complete obstruction of the common bile duct or branches by gallstones, tumors, fibrotic strictures, or chronic pancreatitis; biliary atresia and cystic fibrosis are causative in children. Necrotic areas develop and lead to proliferation and inflammation of portal ducts, producing edema, fibrosis, and cirrhosis if not treated. Surgery or endoscopy relieves obstruction, prolongs survival, and diminishes or resolves symptoms.

Quick Check 36-6

1. How does alcohol damage the liver?

2. What kind of liver changes are common to alcoholic cirrhosis and nonalcoholic fatty liver disease?

3. What are the major pathologic differences between alcoholic and primary biliary cirrhosis?

Viral Hepatitis

Viral hepatitis is a relatively common systemic disease that affects primarily the liver. Different strains of viruses cause different types of hepatitis. The types and estimated incidence in the United States in 2013 were hepatitis A virus (HAV), 3473 cases; hepatitis B virus (HBV), 3050 cases; hepatitis D virus (HDV), associated with HBV unknown; hepatitis C virus (HCV), 2138 cases; and hepatitis E virus (HEV),
unknown. Hepatitis A formerly was known as infectious hepatitis and hepatitis B as serum hepatitis. Characteristics of the different types of viruses that cause hepatitis are presented in Table 36-8. Viral hepatitis in children is presented in Chapter 37.

**Pathophysiology**

All five types of viral hepatitis (A, B, C, D, and E) can cause acute, icteric illness. The pathologic lesions of hepatitis include hepatic cell necrosis, scarring (with chronic disease), and Kupffer cell hyperplasia, and infiltration by mononuclear phagocytes occurs with varying severity. Cellular injury is promoted by cell-mediated immune mechanisms (i.e., cytotoxic T cells, T-regulatory cells, and natural killer cells). Regeneration of hepatic cells begins within 48 hours of injury. The inflammatory process can damage and obstruct bile canaliculi, leading to
cholestasis and obstructive jaundice. In milder cases, the liver parenchyma is not damaged. Damage tends to be most severe in cases of hepatitides B and C. Acute fulminating hepatitis can cause acute liver failure and severe hepatic encephalopathy, which is manifested as confusion, stupor, coma, and coagulopathy. Hepatitides B and C are the most common causes as well as hepatitis E in pregnant women. \(^\text{164}\)

Coinfection of hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus (HDV), and human immunodeficiency virus (HIV) occurs because these viruses share the same route of transmission (contact between infected body fluids and broken skin or mucous membranes, or intravenously). Progression of liver disease is more rapid in these cases. \(^\text{165}\)

**Clinical manifestations**

The clinical manifestations of the various types of hepatitis are very similar. The spectrum of manifestations ranges from absence of symptoms to fulminating hepatitis, with rapid onset of liver failure and coma. Acute viral hepatitis causes abnormal liver function test results. The serum aminotransferase values, aspartate transaminase (AST) and alanine transaminase (ALT), are elevated but not consistent with the extent of cellular damage. The clinical course of hepatitis usually consists of three phases. The **incubation phase** and manifestations vary depending on the virus (see Table 36-8):

1. **Prodromal (preicteric) phase.** Begins about 2 weeks after exposure and ends with the appearance of jaundice; marked by fatigue, anorexia, malaise, nausea, vomiting, headache, hyperalgia, cough, and low-grade fever; infection is highly transmissible during this phase.

2. **Icteric phase.** Begins 1 to 2 weeks after the prodromal phase and lasts 2 to 6 weeks; jaundice, dark urine, and clay-colored stools are common; the liver is enlarged, smooth, and tender, and percussion or palpation of the liver causes pain; gastrointestinal and respiratory symptoms subside, but fatigue and abdominal pain may persist or become more severe. This is the actual phase of illness. Individuals who develop chronic HBV, HDV, or HCV infection do not become jaundiced and may not be diagnosed.

3. **Recovery phase.** Begins with resolution of jaundice, about 6 to 8 weeks after exposure; symptoms diminish, but the liver remains enlarged and tender; liver function returns to normal 2 to 12 weeks after the onset of jaundice.
**Chronic active hepatitis** is the persistence of clinical manifestations and liver inflammation after acute stages of HBV, HBV/HDV coinfection, and HCV infection. Liver function tests remain abnormal for longer than 6 months, and hepatitis B surface antigen (HBsAg) persists. Chronic, active HBV and HCV is a predisposition to cirrhosis and primary hepatocellular carcinoma.\(^{166,167}\) Chronic active hepatitis constitutes a carrier state, and HBV and HCV can be transmitted from mothers to infants.

**Evaluation and treatment**

Diagnosis of HAV and HCV is based on the presence of anti-HAV and anti-HCV antibodies. The most specific diagnostic test for HBV is serologic analysis for specific hepatitis virus antigens (i.e., HBsAg, which is the marker for HBV). There are other markers for HBV including anti-HBs, HBeAg and anti-HBe, and anti-HBc IgM and IgG.\(^{168}\) The assay for HDV is the measurement of total antibody to hepatitis D antigen (anti-HDV) and serum HDV RNA.\(^{169}\) HCV RNA quantification is important for evaluation of viral load to evaluate antiviral therapy for chronic HCV. HEV is diagnosed from the presence of serum anti-HEV IgG and HEV RNA. HEV is usually a self-limiting disease except in undeveloped countries, where it causes chronic hepatitis with increased risk in pregnant women. Liver enzyme levels and function tests also can indicate other viral liver diseases, drug toxicity, or alcoholic hepatitis.\(^{170}\)

Treatments for different types of viral hepatitis are summarized in Table 36-8. Physical activity may be restricted and a low-fat, high-carbohydrate diet is beneficial if bile flow is obstructed. For chronic hepatitis, treatment is directed at suppressing viral replication before irreversible liver cell damage or hepatic carcinoma occurs. Cyclic and combination therapy may prevent drug resistance, and new agents are being developed.\(^{171,172}\)

After ingestion and gastrointestinal uptake, HAV replicates in the liver and is secreted into the bile, feces, and sera. To prevent transmission of hepatitis A, proper hand hygiene and the use of gloves for disposing of bedpans and fecal matter are imperative. HAV may be shed in the feces for up to 3 months after onset of symptoms. Molecular procedures are available for direct surveillance of HAV in food.\(^{173}\) Direct contact with blood or body fluids of individuals with HBV or HBV/HDV coinfection or HCV should be avoided. The administration of immune globulin before exposure or early in the incubation period can prevent hepatitis A and hepatitis B. A combined vaccine is available to protect against HAV and HBV infection. There is no vaccine for HCV.\(^{174}\) A vaccine for HEV is available in China, but no vaccine has been approved for use in the United States.\(^{175}\) Preexposure vaccination is recommended for healthcare workers, liver transplant recipients, and
others who are at risk for contact with infected body fluids, particularly children.

**Quick Check 36-7**

1. How does hepatitis A virus (HAV) differ from hepatitis B virus (HBV)?
2. What vaccines are available to prevent viral hepatitis?
3. What are the three phases of hepatitis viral infection?
4. What complications are associated with chronic active viral hepatitis?

**Disorders of the Gallbladder**

Obstruction and inflammation are the most common disorders of the gallbladder. Obstruction is caused by **gallstones**, which are aggregates of substances in the bile. The gallstones may remain in the gallbladder or be ejected, with bile, into the cystic duct. Gallstones that become lodged in the cystic duct obstruct the flow of bile into and out of the gallbladder and cause inflammation. Gallstone formation is termed **cholelithiasis**. Inflammation of the gallbladder or cystic duct is known as **cholecystitis**.

**Cholelithiasis (Gallstones)**

Cholelithiasis (gallstones) is a prevalent disorder in developed countries, where the incidence is 10% to 15% in white adults and 60% to 70% in Native Americans. Risk factors include obesity, middle age, female gender, use of oral contraceptives, rapid weight loss, Native American ancestry, genetic predisposition, and gallbladder, pancreatic, or ileal disease.¹⁷⁶

**Pathophysiology**

Gallstones are formed from impaired metabolism of cholesterol, bilirubin, and bile acids. All gallstones contain cholesterol, unconjugated bilirubin, bilirubin calcium salts, fatty acids, calcium carbonates and phosphates, and mucin glycoproteins. Gallstones are of three types depending on chemical composition: **cholesterol** (70% cholesterol and the most common [70% to 80%]); **pigmented** (black [hard] and brown [soft] with less than 30% cholesterol); and **mixed**.¹⁷⁷ **Cholesterol gallstones** form in bile that is supersaturated with cholesterol produced by the liver. Supersaturation sets the stage for cholesterol crystal formation, or the formation of
“microstones.” More crystals then aggregate on the microstones, which grow to form “macrostones.” This process usually occurs in the gallbladder, which may have decreased motility. The stones may lie dormant or become lodged in the cystic or common duct, causing pain when the gallbladder contracts and cholecystitis. The stones can accumulate and fill the entire gallbladder (Figure 36-16). Pigmented brown gallstones form from calcium bilirubinate and fatty acid soaps that bind with calcium. They are associated with biliary stasis, bacterial infections, and biliary parasites. They are more common in East Asia. Black gallstones are rare. They are associated with chronic liver disease and hemolytic disease, and are composed of calcium bilirubinate with mucin glycoproteins.¹⁷⁸

![Resected Gallbladder Containing Mixed Gallstones](image)

**FIGURE 36-16**  Resected Gallbladder Containing Mixed Gallstones. (From Kissane JM, editor: Anderson’s pathology, ed 9, St Louis, 1990, Mosby)

**Clinical manifestations**

Cholelithiasis is often asymptomatic. Epigastric and right hypochondrium pain and intolerance to fatty foods are the cardinal manifestations of cholelithiasis. Vague symptoms include heartburn, flatulence, epigastric discomfort, and food intolerances, particularly to fats and cabbage. The pain (biliary colic) occurs 30 minutes to several hours after eating a fatty meal. It is caused by the lodging of one or more gallstones in the cystic or common duct during contraction of the gallbladder. It can be intermittent or steady and usually occurs in the right upper quadrant, radiating to the mid-upper area of the back. Jaundice indicates that the stone is located in the common bile duct.

**Evaluation and treatment**
Diagnosis is based on the medical history, physical examination, and imaging evaluation. An oral cholecystogram usually outlines the stones. Intravenous cholangiography is used to differentiate cholelithiasis from other causes of extrahepatic biliary obstruction if the cholecystogram is negative. Endoscopic or percutaneous cholangiography and endoscopic or transabdominal ultrasonography are diagnostic options. Oral bile acids (ursodeoxycholic acid or chenodeoxycholic acid) may prevent or dissolve cholesterol stones, but the stones may recur when the drug is discontinued. Dietary factors may prevent the development of gallstones, including reducing the intake of polyunsaturated fat, monounsaturated fat, and caffeine and increasing the consumption of fiber. Endoscopic removal of gallstones by sphincterotomy or endoscopic papillary balloon dilation is the preferred treatment for uncomplicated gallstones causing obstruction of the bile ducts. Large stones may be managed by lithotripsy.

Cholecystitis

Cholecystitis can be acute or chronic, but both forms are almost always caused by a gallstone lodged in the cystic duct. Obstruction causes the gallbladder to become distended and inflamed. The pain is similar to that caused by gallstones. Pressure against the distended wall of the gallbladder decreases blood flow and may result in ischemia, necrosis, and perforation. Fever, leukocytosis, rebound tenderness, and abdominal muscle guarding are common findings. Serum bilirubin and alkaline phosphatase levels may be elevated. Cholescintigraphy is the most sensitive imaging for cholecystitis. The acute abdominal pain of cholecystitis must be differentiated from that caused by pancreatitis, myocardial infarction, and acute pyelonephritis of the right kidney. Narcotics may be required to control pain, and antibiotics often are prescribed to manage bacterial infection in severe cases. Acute attacks usually require laparoscopic gallbladder resection (cholecystectomy). Obstruction also may lead to reflux of bile into the pancreatic duct, causing acute pancreatitis.

Disorders of the Pancreas

Pancreatitis, or inflammation of the pancreas, is a relatively rare (15 cases per 100,000 people in the United States) and potentially serious disorder. The incidence is about equal in men and women, is more common between 50 and 60 years of age, and is more likely to occur in blacks. Risk factors include obstructive biliary tract disease (particularly cholelithiasis), alcoholism, obesity, peptic ulcers, trauma, hyperlipidemia, hypercalcemia, smoking, certain drugs, and genetic factors (hereditary pancreatitis, cystic fibrosis). The cause is unknown in 15% to 25% of cases. Pancreatitis can be acute or chronic.
Acute Pancreatitis

Acute pancreatitis is usually a mild disease and resolves spontaneously, but about 20% of those with the disease develop a severe, acute pancreatitis requiring hospitalization. Pancreatitis develops because of obstruction to the outflow of pancreatic digestive enzymes caused by bile and pancreatic duct obstruction (e.g., gallstones). Acute pancreatitis also results from direct cellular injury from alcohol, drugs, or viral infection.\textsuperscript{184}

Pathophysiology

In obstructive disease, there is backup of pancreatic secretions and activation and release of enzymes (activated trypsin activates chymotrypsin, lipase, and elastase) within the pancreatic acinar cells. The activated enzymes cause autodigestion of pancreatic cells and tissues, resulting in inflammation. The autodigestion causes vascular damage, coagulation necrosis, fat necrosis (see Chapter 4), and formation of pseudocysts (walled-off collections of pancreatic secretions). Edema within the pancreatic capsule leads to ischemia and can contribute to necrosis. There also may be independent activation of inflammation within acinar cells contributing to the local and systemic responses occurring in acute pancreatitis\textsuperscript{185} (Figure 36-17). In cases of alcohol abuse, the pancreatic acinar cell metabolizes ethanol with the generation of toxic metabolites that injure pancreatic acinar cells, causing release of activated enzymes. Chronic alcohol use may also cause formation of protein plugs in pancreatic ducts and spasm of the sphincter of Oddi, resulting in obstruction. The obstruction leads to intrapancreatic release of activated enzymes, autodigestion, inflammation, and pancreatitis.
Systemic effects of acute pancreatitis are related to release of proinflammatory cytokines (e.g., interleukin-6, tumor necrosis factor-alpha, and platelet-activating factor) into the bloodstream. There is activation of leukocytes, injury to vessel walls, and coagulation abnormalities with development of vasodilation, hypotension, and shock. Complications can include acute respiratory distress syndrome; ATN, acute tubular necrosis; SIRS, systemic inflammatory response syndrome.
syndrome (ARDS), heart failure, renal failure, coagulopathies, intra-abdominal hypertension, and systemic inflammatory response syndrome (SIRS) (see Chapter 24). Paralytic ileus and gastrointestinal bleeding can occur. Translocation of intestinal bacteria to the bloodstream may cause peritonitis or sepsis. Recurrent inflammation activates pancreatic stellate cells, causing pancreatic fibrosis, strictures, and duct obstruction that lead to chronic pancreatitis. 186

**Clinical manifestations**

The cardinal manifestation of acute pancreatitis is epigastric or midabdominal constant pain ranging from mild abdominal discomfort to severe, incapacitating pain. The pain may radiate to the back. Pain is caused by (1) edema, which distends the pancreatic ducts and capsule; (2) chemical irritation and inflammation of the peritoneum; (3) irritation or obstruction of the biliary tract; and (4) inflammation of nerves. Fever and leukocytosis accompany the inflammatory response. Nausea and vomiting are caused by paralytic ileus secondary to the pancreatitis or peritonitis. Jaundice can occur from obstruction of the bile duct (e.g., a gallstone) or from pancreatic edema pressing on the duct. Abdominal distention accompanies bowel hypomotility and the accumulation of fluids in the peritoneal cavity. Hypovolemia, hypotension, tachycardia, myocardial insufficiency, and shock occur because plasma volume is lost as inflammatory mediators released into the circulation increase vascular permeability and dilate vessels. Tachypnea and hypoxemia develop secondary to ascites, pulmonary edema, atelectasis, or pleural effusions. Hypovolemia can decrease renal blood flow sufficiently to impair renal function and can cause renal failure. Tetany may develop as a result of hypocalcemia when calcium is deposited in areas of fat necrosis or as a decreased response to parathormone. Transient hyperglycemia also can occur if glucagon is released from damaged alpha cells in the pancreatic islets. In severe acute pancreatitis, some individuals develop flank or periumbilical ecchymosis, a sign of poor prognosis. Multiple organ failure or SIRS accounts for most deaths of those with severe acute pancreatitis.

**Evaluation and treatment**

Diagnosis is based on clinical findings, identification of associated disorders, laboratory studies, and imaging results. Elevated serum amylase concentration is characteristic but is not diagnostic of severity or specificity of disease. Elevated serum lipase level is the primary diagnostic marker for acute pancreatitis.

The goal of treatment for acute pancreatitis is to stop the process of autodigestion and prevent systemic complications. Narcotic medications may be needed to relieve pain. To decrease pancreatic secretions and “rest the gland,” oral food and fluids
may be withheld initially and continuous gastric suction instituted. Nasogastric suction may not be necessary with mild pancreatitis, but it helps to relieve pain and prevent paralytic ileus in individuals who are nauseated and vomiting. Feeding is usually initiated within 24 to 48 hours if ileus is not present. Parenteral fluids are essential to restore blood volume and prevent hypotension and shock. In severe pancreatitis enteral nutrition with use of jejunal tube feeding usually is well tolerated, may decrease pancreatic enzyme secretion, prevents gut bacterial overgrowth, and maintains gut barrier function. Drugs that decrease gastric acid production (e.g., H2-receptor antagonists) can decrease stimulation of the pancreas by secretin. Antibiotics are used if there is infection. The risk of mortality increases significantly with the development of infection or pulmonary, cardiac, and renal complications. 

**Chronic Pancreatitis**

**Chronic pancreatitis** is a process of progressive fibrotic destruction of the pancreas. Chronic alcohol abuse is the most common cause. Obstruction from gallstones, smoking, and genetic factors increase the risk of chronic pancreatitis. Toxic metabolites and chronic release of inflammatory cytokines contribute to the destruction of acinar cells and islets of Langerhans. The pancreatic parenchyma is destroyed and replaced by fibrous tissues, strictures, calcification, ductal obstruction, and pancreatic cysts. The cysts are walled-off areas or pockets of pancreatic juice, necrotic debris, or blood within or adjacent to the pancreas. New imaging techniques have advanced evaluation of disease severity.

Continuous or intermittent abdominal pain and weight loss are common. The pain is difficult to manage and is associated with increased intraductal pressure, ischemia, neuritis, intra-abdominal hypertension (compartment syndrome), ongoing injury, and both peripheral and central pain sensitization. Manifestations of pancreatic enzyme deficiency, such as steatorrhea or a malabsorption syndrome, are present in late stages of chronic pancreatitis. To correct enzyme deficiencies and prevent malabsorption, oral enzyme replacements are taken before and during meals. Loss of islet cells can cause insulin-dependent diabetes and requires treatment. Cessation of alcohol intake is essential for the management of both acute and chronic pancreatitis. Endoscopic or surgical drainage of cysts or partial resection of the pancreas may be required to relieve pain and to prevent cystic rupture. Chronic pancreatitis is a risk factor for pancreatic cancer.
Cancer of the Digestive System

Cancer of the Gastrointestinal Tract

Table 36-9 contains information on the various gastrointestinal cancers by organ, percentage of death compared with all cancer deaths, risk factors, type of cell, and common manifestations. The biology of cancer is presented in Chapter 10.

Cancer of the Esophagus

Carcinoma of the esophagus is a rare type of cancer with an estimated incidence of 16,980 new cases and 15,590 deaths in the United States in 2015.\(^{192}\) Risk factors are summarized in Risk Factors: Esophageal Cancer.
Risk Factors

Esophageal Cancer

• Age greater than 65 years
• Male
• Tobacco use
• Alcoholism
• Dietary factors: deficiencies of trace elements and vitamins
• Malnutrition associated with poor economic conditions or special dietary habits (e.g., very hot drinks, fish preserved in lye; diet deficient in fruits and vegetables)
• Reflux esophagitis with dysplasia
• Sliding hiatal hernia
• Obesity

Pathophysiology

Carcinoma of the esophagus includes squamous cell carcinoma and adenocarcinoma, which is more prevalent in the United States. Squamous cell esophageal carcinoma is more prevalent in Asia. Risk factors include chronic alcohol use combined with smoking or chewing tobacco, hot and irritant (alcohol) drinks, food containing nitrosamines, and achalasia. Squamous cell carcinomas are more common in the thoracic and cervical areas of the esophagus.

Adenocarcinomas are more prevalent in males and are associated with cigarette smoking, obesity, and gastroesophageal reflux disease (GERD). Adenocarcinoma development is often secondary to infiltration by a gastric carcinoma or to the presence of Barrett dysplasia, also known as Barrett esophagus (columnar rather than squamous epithelium in the lower esophagus), and can progress to metaplasia. Adenocarcinoma is more common at the gastroesophageal junction. The CagA-positive strain of *H. pylori* may be a protection against esophageal carcinoma.
Clinical manifestations

The two frequent symptoms of esophageal carcinoma are chest pain and dysphagia. The most common type of pain is heartburn. It is initiated by eating spicy or highly seasoned foods and by assuming the recumbent position. Odynophagia (pain on swallowing) may be initiated by the swallowing of cold liquids. Spontaneous chest pain is more difficult to diagnose positively. Some individuals with esophageal cancer complain of a constant retrosternal pain that radiates to the back. Dysphagia (difficulty swallowing) is usually pressure-like and may radiate posteriorly between the scapulae. Dysphagia usually progresses rapidly. Esophageal carcinoma is asymptomatic during the early stages and presents at an advanced stage. Esophageal cancer metastasizes rapidly and, therefore, has a poor prognosis.

Evaluation and treatment

Individuals with dysphagia undergo endoscopy so that specimens can be obtained and examined for neoplastic change. Endoscopic ultrasound and CT studies of the thorax are used for diagnosis and staging. Prevention of gastroesophageal reflux and removal of high-grade dysplasia are essential to the management of Barrett esophagus. It is impossible to remove all lymph nodes with the tumor, but removal of the primary lesion and the local lymph nodes can benefit the individual with esophageal cancer. If the malignancy has not spread beyond these sites, cure is likely. If metastasis has occurred, however, an incomplete resection is of little survival benefit. Treatment is combined radiation and chemotherapy.

Cancer of the Stomach

The incidence of gastric adenocarcinoma is estimated at 24,590 new cases and 10,720 deaths in the United States in 2015. The case fatality rate is 75%. The incidence is greater in males and it is more common in Asia, particularly China. Loss of tumor-suppressor genes and other genetic alterations may be important in gastric cancer.

Pathophysiology

Gastric adenocarcinomas are associated with atrophic gastritis and Helicobacter pylori that carry the CagA gene product cytotoxin-associated vacuolating antigen A (VacA). It also causes gastric B-cell mucosa-associated lymphoid tissue lymphoma. Hereditary diffuse adenocarcinoma is rare and occurs at a younger age. Most adenocarcinomas are sporadic and associated with consumption of heavily salted and preserved foods (e.g., nitrates in pickled or salted foods such as bacon), low intake of fruits and vegetables, and use of tobacco and alcohol. Dietary salt enhances
the conversion of nitrates to carcinogenic nitrosamines in the stomach. Salt and nitrates converted to nitrites are caustic to the stomach, delay gastric emptying, and can cause chronic atrophic gastritis. Insufficient acid secretion by the atrophic mucosa creates a relatively alkaline environment that permits bacteria to multiply and act on nitrates. The resulting increase in nitrosamines damages the deoxyribonucleic acid (DNA) of mucosal cells, further prompting metaplasia and neoplasia.

Gastric adenocarcinoma usually begins in the glands of the distal stomach mucosa. Duodenal reflux also may contribute to an intestinal-like metaplasia. The reflux contains caustic bile salts that destroy the mucosal barrier that normally protects the stomach.

Clinical manifestations
The early stages of gastric cancer are generally asymptomatic or produce vague symptoms such as loss of appetite (especially for meat), malaise, and indigestion. Later manifestations of gastric cancer include unexplained weight loss, upper abdominal pain, vomiting, change in bowel habits, and anemia caused by persistent occult bleeding. The prognosis is poor because symptoms do not occur until the tumor has spread and caused distant metastases, particularly to the liver and peritoneal structures. Generally, the first manifestations of carcinoma are caused by distant metastases, and the disease is already in an advanced stage.

Evaluation and treatment
There are no specific biomarkers for gastric cancer. Micro RNAs are being evaluated as a specific diagnostic and prognostic marker. Most symptoms suggest a problem in the upper gastrointestinal tract, and a barium x-ray film shows the lesion. Direct endoscopic visualization, lavage, and cellular examination or biopsy establish the diagnosis. Screening and treatment for H. pylori infection is the best preventive approach to gastric cancer. Surgery is the usual treatment for early stages of disease. Staging is determined by pathologic findings after resection. Early diagnosis and chemotherapy combined with radiation improves postsurgical outcomes.

Quick Check 36-8
1. How do gallstones form?
2. Compare acute and chronic pancreatitis.
3. What factors are associated with cancer of the esophagus?

4. What dietary factors are associated with gastric cancer?

**Cancer of the Colon and Rectum**

Colorectal cancer (CRC) is the second most common cause of cancer and cancer death with an estimated 132,700 new cases and 49,700 deaths in the United States in 2015. The incidence has been declining over the past several years because of successful screening programs. CRC tends to occur in individuals older than 50 years and is rare in children. Worldwide, the prevalence and death rate of CRC are highest in black populations, possibly because of lack of access to screening and treatment. CRC occurs in women 10 years later than in men. Risk factors for CRC can be reviewed in *Risk Factors: Cancer of the Colon and Rectum*. Small intestinal carcinoma is very rare and is usually located in the duodenum.

**Risk Factors**

**Cancer of the Colon and Rectum**

- Advanced age
- High-fat (especially egg consumption), red and processed meat, low-fiber diet
- High consumption of alcohol
- Cigarette smoking
- Obesity
- Familial polyposis or family history of colorectal cancer
- Low levels of physical activity
- Inflammatory bowel disease
- Type 2 diabetes mellitus

**Pathophysiology**

Most CRCs are sporadic (acquired) or associated with a family history of colorectal
cancer. They are caused by multiple gene alterations and environmental interactions (see Chapter 3 for epigenetics and Chapter 10 for mechanisms of oncogenesis). **Familial adenomatous polyposis (FAP)** is a mutation of the *APC* gene (adenomatous polyposis coli, a tumor-suppressor gene) and is the most common hereditary cause of colorectal cancer. **Hereditary nonpolyposis colorectal cancer (HNPCC), or Lynch syndrome,** is associated with several DNA mismatch repair (MMR). Both FAP and HNPCC have a rare, family-linked autosomal dominant inheritance trait that accounts for about 3% to 5% of colorectal cancers.\textsuperscript{207,208} Sporadic tumors are also thought to involve the loss of function or mutation of tumor-suppressor genes (i.e., *APC, kRAS, p53* genes). CRC begins with the formation of an adenoma and is termed “tumor initiation.” The progression to carcinoma is termed “tumor progression” and is a multistep process of genetic mutations that may take 8 to 10 years.

**Colorectal polyps** are closely associated with development of cancer. A polyp, or papilloma, is a projection arising from the mucosal epithelium. The most common types of polyps are hyperplastic (a nonneoplastic, or benign, polyp). Adenomatous polyps are neoplastic. They can be pedunculated (have a stalk) or sessile (flat with no stalk). **Neoplastic polyps** are premalignant lesions and are further classified as tubular (the most prevalent), villous (usually sessile), or tubulovillous adenomas (Figure 36-18). Serrated sessile polyps have a sawtooth appearance and can be difficult to detect. Serrated sessile polyps are associated with oncogene mutations and should be removed.\textsuperscript{209} The larger the polyp, the greater the risk of colorectal cancer. Although lesions larger than 1.5 cm occur less often, they are more likely to be malignant than those smaller than 1.0 cm. Thus, screening colonoscopy with polypectomy is performed when polyps are found.
Adenocarcinomas of the colon and rectum usually arise from adenomatous polyps and undergo a multistep cascade of genetic events that leads to carcinoma and metastasis\(^\text{210}\) (see Figure 10-6). Most colorectal cancers are moderately differentiated adenocarcinomas. These tumors have a long preinvasive phase and when they invade, they tend to grow slowly. Colorectal carcinoma begins from epithelial stem cells located in the glands at the base of the intestinal crypts. Because the lymphatic channels are located under the muscularis mucosae, the lesions must traverse this layer before the multistep process of metastasis can occur. Once the malignant cells of an adenoma traverse the muscularis mucosae, tumor cells enter the bloodstream and lymphatics and become invasive, spreading to other organs. Adenomas can be detected early, however, because the submucosa may not be penetrated for several years.

**Clinical manifestations**

Symptoms of colorectal cancer depend on the location, size, and shape of the lesion
and are silent in the early stages (Figure 36-19). Tumors of the right (ascending) colon and left (descending) colon evolve into two distinct tumor types. On the right side (proximal colon), the lesions are polypoid and extend along one wall of the cecum and ascending colon. These tumors may be silent, evolving to pain, palpable mass in the lower right quadrant, anemia, fatigue, and dark red or mahogany-colored blood mixed with the stool. These tumors can become large and bulky with necrosis and ulceration, contributing to persistent blood loss and anemia. Obstruction is unusual because the growth does not readily encircle the colon. These tumors are more common in women.

Tumors of the left, or descending, colon (distal colon) start as small, elevated, button-like masses. This type grows circumferentially, encircling the entire bowel wall, and eventually ulcerating in the middle as the tumor penetrates the blood supply. Obstruction is common but occurs slowly and stools become narrow and pencil shaped. Manifestations include progressive abdominal distention, pain, vomiting, constipation, need for laxatives, cramps, and bright red blood on the surface of the stool. These tumors are more common in men.

Systematic lymphatic distribution occurs along the aorta to the mesenteric and pancreatic lymph nodes. Liver metastasis is common and follows invasion of the mesenteric veins (left colon) or superior veins (right colon), which drain into the
Rectal carcinomas (about 30% of colorectal carcinomas) are defined as tumors occurring up to 15 cm from the anal opening. Tumors of the rectum can spread through the rectal wall to nearby structures: the prostate in men and the vagina in women. Penetration occurs more readily in the lower third of the rectum because it has no serosal covering. Systemic and pulmonary metastases occur through the hemorrhoidal plexus, which drains into the vena cava.

**Evaluation and treatment**

Individuals with hereditary polyposis should begin screening at an early age (10 to 12 years) using colonoscopy with removal of polyps when they are found. Specific, sensitive, and affordable molecular markers are being evaluated to assist with early diagnosis and evaluation of therapy. Carcinoembryonic antigen (CEA) is evaluated during and after cancer treatment. Screening procedures for detection of nonhereditary CRC are summarized in Box 36-4. Aspirin and celecoxib may reduce the incidence of CRC in the general population, but risk of GI bleeding must be considered. Vitamin D, calcium, fiber, folate, dietary modification, weight control, exercise, and other nondietary lifestyle changes can decrease the risk of colorectal cancer.²¹²

**Box 36-4**

**Screening for Colorectal Cancer**

Beginning at age 50, both men and women should follow one of these testing schedules:

**Tests That Find Polyps and Cancer**

Flexible sigmoidoscopy every 5 years,* or

Colonoscopy every 10 years, or

Double-contrast barium enema every 5 years,* or

CT colonography (virtual colonoscopy) every 5 years*

**Tests That Primarily Find Cancer**

Yearly fecal occult blood test (gFOBT),† or
Yearly fecal immunochemical test (FIT),† or

Stool DNA or RNA tests (sDNA, sRNA), interval uncertain†

*All positive tests should be followed up with colonoscopy.
†The multiple stool take-home test should be used.

The staging of colorectal cancer involves imaging and operative exploration. Physical examination of the abdomen detects liver enlargement and ascites; appropriate lymph nodes are palpated. Imaging is useful for pretreatment staging. Operative staging consists of careful exploration during surgery and biopsy of possible metastases. The National Cancer Institute TNM classification is widely used for staging of colorectal cancer (available at: www.cancer.gov/cancertopics/pdq/treatment/colon/HealthProfessional; also see Chapter 10).

Treatment for all stages of cancer of the colon is surgical. Chemotherapy and radiation therapy may be given before surgery in the hope that they will shrink the tumor or alter the malignant cells, or both, so that these cells will not survive after surgery. Resection and anastomosis can be performed for cancer of the ascending, transverse, descending, or sigmoid colon and upper rectum. These surgeries are performed through abdominal incisions and assisted with radiofrequency ablation. Natural defecation is preserved. Growths in the lower portion of the rectum require removal of the entire rectum with the formation of a permanent colostomy. Chemotherapy, including immunotherapy, is used to treat metastatic disease and cases with a high risk of recurrence. New chemotherapeutic agents are improving personalized, first-line therapy. Immunotherapy, vaccines, and viral vectors for the treatment of colon cancer are under continuing investigation. Resection of liver metastases or hepatic intra-arterial chemotherapy may prolong survival.

Cancer of the Accessory Organs of Digestion

Cancer of the Liver

Cancer of the liver is a leading cause of cancer death worldwide and is highest in Eastern and Southeastern Asia. The estimated number of new cases is 35,660 with
24,550 deaths in the United States in 2015. In the United States, the incidence of primary liver cancer is higher in blacks than in whites and higher in males than in females. Primary liver cancer is rare before the age of 40 years and is most common after 60 years. Cancer in the liver is usually caused by metastatic spread from a primary site elsewhere in the body. Risk factors for primary liver cancer are summarized in Risk Factors: Primary Liver Cancer. Risks associated with HBV and HCV are decreasing with antiviral therapy.

**Risk Factors**

**Primary Liver Cancer**

- Exposure to mycotoxins (aflatoxins), particularly those produced by *Aspergillus flavus*, a mold found on spoiled corn, peanuts, and grain
- Alcohol abuse
- Obesity
- Chronic liver disease, especially cirrhosis
- Infection with hepatitis B virus (HBV), hepatitis C virus (HCV), and hepatitis D virus (HDV), particularly in conjunction with cirrhosis; these infections act either as carcinogens or as co-carcinogens in chronically infected hepatocytes

**Pathophysiology**

Primary carcinomas of the liver are hepatocellular or cholangiocellular. **Hepatocellular carcinoma (HCC)** develops in the hepatocytes and can be nodular (consisting of multiple, discrete nodules), massive (consisting of a large tumor mass having satellite nodules), or diffuse (consisting of small nodules distributed throughout most of the liver). It is closely associated with chronic hepatitis and cirrhosis. Because carcinoma of the liver invades the hepatic and portal veins, it often spreads to the heart and lungs. Other sites of metastases are the brain, kidney, and spleen.

**Cholangiocellular carcinoma (cholangiocarcinoma)** is rare (less than 1% of liver cancers) and develops in the bile ducts; in the United States, it occurs less often than hepatocellular carcinoma. It is associated with primary sclerosing cholangitis (a rare autoimmune disease often associated with ulcerative colitis) and
is geographically associated with areas where liver fluke infestation is prevalent, such as Southeast Asia. Cholangiocellular carcinoma can occur anywhere along the bile duct and extend directly into the liver, usually as a solitary lesion. A combined form of HCC is known as combined (mixed) hepatocellular-cholangiocellular carcinoma. It is difficult to distinguish an invasion of cholangiocellular carcinoma from a metastatic adenocarcinoma except by neoplastic changes found in nearby ducts.

**Clinical manifestations**

HCC is usually asymptomatic. Manifestations can develop slowly or abruptly and include vague abdominal symptoms, such as nausea and vomiting, fullness, pressure, and dull ache in the right hypochondrium. In individuals with cirrhosis, deepening jaundice or abrupt lack of appetite is a sign of hepatocellular carcinoma. Obstruction by the tumor can cause sudden worsening of portal hypertension and development of ascites. As the tumor enlarges, it causes pain. Cholangiocellular carcinoma more commonly presents insidiously as pain, loss of appetite, weight loss, and gradual onset of jaundice. Some carcinomas of the liver rupture spontaneously, causing hemorrhage. Others are discovered accidentally during laboratory evaluation, imaging, or surgery for other diseases or trauma.

**Evaluation and treatment**

There is no specific test for the diagnosis of liver cancer. Biopsy is not recommended because of the risk for tumor seeding. For high-risk individuals, alpha fetoprotein associated with HBV and abdominal ultrasound are common screening tools. Diagnosis is based on clinical manifestations, laboratory findings, imaging, and exploratory laparotomy. In individuals without cirrhosis, liver scans can document filling defects. CT or ultrasonography is used to detect solid tumors, but neither can distinguish benign from malignant tumors. Primary prevention may be achieved by vaccinating against HBV, preventing and treating HBV and HCV, screening all donated blood for the presence of HBV, and reducing contamination of food with aflatoxins.\(^{222}\)

Surgical resection is possible only if the tumor is localized to a removable lobe of the liver. Surgery is hazardous and usually not undertaken if the individual has cirrhosis. Radiofrequency (thermal) ablation has emerged as the most effective method for local tumor destruction. Most individuals develop metastases after surgical resection, but long-term survival is possible. Chemotherapeutic agents, immunotherapy, and radiotherapy are treatment options.\(^{223}\) Liver transplant offers a cure if the waiting time is short. The prognosis for those with symptomatic liver cancer is poor.\(^{224}\)
Cancer of the Gallbladder

In 2015 in the United States, there were an estimated 10,910 new cases and 3700 deaths attributable to gallbladder cancer. Risk factors include gallstones, advancing age, female gender (2 : 1), anomalous pancreaticobiliary ductal junction, and obesity. It occurs rarely before the age of 40 years and is most common between the ages of 50 and 60 years. Primary carcinoma of the gallbladder is rare and associated with larger gallstones. Most gallbladder cancer is caused by metastasis.

Pathophysiology

Most primary carcinomas of the gallbladder are adenocarcinomas, and more rarely squamous cell carcinomas. The pathogenesis is not clear. Chronic inflammation may trigger dysplasia and progression to metaplasia. The molecular mechanisms involve mutation of several genes, including tumor-suppressor genes and oncogenes, and alterations in the extracellular matrix. Invasion of the liver and lymph nodes occurs early. Direct invasion of the stomach and the duodenum can cause pyloric obstruction. Infection often accompanies cancer of the gallbladder. Generalized peritonitis, gangrene, perforation, and liver abscesses are potential complications of infection.

Clinical manifestations

Early stages of gallbladder carcinoma are asymptomatic and the disease usually presents at an advanced stage. When symptoms develop, there is usually steady, upper right quadrant pain for about 2 months. Other manifestations include diarrhea, belching, weakness, loss of appetite, weight loss, and vomiting. Obstructive jaundice can occur if an enlarging tumor presses on the extrahepatic ducts.

Evaluation and treatment

Early diagnosis of cancer of the gallbladder is rare and is often found incidentally. Therefore, older adults with gallstones, particularly women, are evaluated for disease. Inflammatory disorders, such as cholangitis (bile duct inflammation) and peritonitis, often obscure an underlying malignancy. Diagnostic procedures include ultrasonography and further imaging with suspicious findings. Complete surgical resection of the gallbladder is the only effective treatment for early stages of disease, and recurrence is common. Complete removal of tumor tissue and lymph nodes with chemoradiation therapy is performed for more advanced stages. Because advanced malignancies cannot be resected, gallbladders containing stones are
removed as a preventive measure. The prognosis of unresectable gallbladder cancer is extremely poor. Molecular therapies are under development.227

**Cancer of the Pancreas**

Pancreatic cancer is the fourth leading cause of cancer deaths in the United States. An estimated 48,960 new cases and 40,560 deaths occurred in the United States in 2015.192 The incidence of pancreatic cancer rises steadily with age. Males are affected slightly more often than females, and blacks more often than whites. Mortality is nearly 100%. The cause of pancreatic cancer is not known, but there are modest risks associated with tobacco smoking, certain dietary factors (e.g., high-fat foods and processed meat), obesity, diabetes mellitus, chronic pancreatitis, family history of pancreatic cancer, hereditary nonpolyposis colon cancer (HNPCC) (Lynch syndrome), and BRCA1 and BRCA2 mutations.192

**Pathophysiology**

Pancreatic cancer can arise from exocrine or endocrine cells. Most pancreatic tumors arise from metaplastic exocrine cells in the ducts and are called ductal adenocarcinomas. Chronic pancreatitis and inflammatory cytokines support tumor growth.228 There is significant expansion of the extracellular matrix (stroma) from activation of pancreatic stellate cells, a type of fibroblast in the pancreas, that contributes to therapeutic resistance.229 Tumors arising in small ducts invade nearby glandular tissue, penetrate the covering of the pancreas, and extend into surrounding tissues.230 Tumors of the head of the pancreas quickly spread to obstruct the common bile duct and portal vein. These tumors can then infiltrate the superior mesenteric artery, the vena cava, and the aorta and form emboli. Tumors of the body and tail of the pancreas infiltrate the posterior abdominal wall. Lymphatic invasion occurs early and rapidly. Venous invasion causes metastases to the liver. Tumor implants on the peritoneal surface can obstruct veins and promote development of ascites.

**Clinical manifestations**

Early stages of pancreatic cancer are asymptomatic. When symptoms occur there usually has been a malignant transformation. Typically, vague upper abdominal pain that radiates to the back develops. Jaundice arises in most cases, usually caused by obstruction of the bile duct. Because obstruction impairs enzyme secretion and flow to the duodenum, pancreatic cancer causes fat and protein malabsorption, resulting in weight loss. Distant metastases are found in the cervical lymph nodes, the lungs, and the brain. Most individuals die of hepatic failure, malnutrition, or systemic
diseases.

**Evaluation and treatment**

There is no specific biomarker for pancreatic cancer and the diagnosis is usually made after the tumor has spread. Several molecular markers are under investigation.²³¹ Endoscopic ultrasound and CT are used initially for diagnosis.²³¹ Laparotomy is often used to establish a definitive diagnosis, evaluate the extent of disease, and determine whether palliative bypass surgery (i.e., cholecystojejunostomy and gastrojejunostomy) is needed. Many surgeons recommend a total pancreatectomy because cancer of the pancreas seldom consists of a single lesion. Adjuvant chemotherapy, immunotherapy, radiochemotherapy, and combination therapy may produce favorable controls in locally advanced cancer.²³² Pain management includes opioids and celiac plexus nerve block. Supportive therapy involves an interdisciplinary team.²³³ Five-year survival is about 20% with resectable disease (a small subset) and less than 6% for metastatic disease. There is a need for new approaches for earlier diagnosis and more effective treatment.

**Quick Check 36-9**

1. What are the primary risk factors for colorectal carcinoma?

2. Compare tumors of the right colon with those of the left colon.

3. What is the most common cause of liver cancer?
Did You Understand?

Disorders of the Gastrointestinal Tract

1. Anorexia is lack of a desire to eat despite physiologic stimuli that would normally produce hunger.

2. Vomiting is the forceful emptying of the stomach effected by gastrointestinal contraction and reverse peristalsis of the esophagus. It is usually preceded by nausea and retching, with the exception of projectile vomiting, which is associated with direct stimulation of the vomiting center in the brain.

3. Constipation is difficult or infrequent defecation often caused by unhealthy dietary and bowel habits combined with lack of exercise. Constipation can result from a disorder that impairs intestinal motility or obstructs the intestinal lumen.

4. Diarrhea is the presence of frequent loose, watery stools and can be caused by excessive fluid drawn into the intestinal lumen by osmosis (osmotic diarrhea), excessive secretion of fluids by the intestinal mucosa (secretory or infectious diarrhea), or excessive gastrointestinal motility (motility diarrhea).

5. Abdominal pain is caused by stretching, inflammation, or ischemia (insufficient blood supply). Abdominal pain originates in the organs themselves (visceral pain) or in the peritoneum (parietal pain) and can be acute or chronic. Visceral pain is often referred to the back.

6. Obvious manifestations of gastrointestinal bleeding are hematemesis (vomiting of blood), melena (dark, tarry stools), and hematochezia (frank bleeding from the rectum). Occult bleeding can be detected only by testing stools or vomitus for the presence of blood.

7. Dysphagia is difficulty swallowing. It can be caused by a mechanical or functional obstruction of the esophagus. Functional obstruction is an impairment of esophageal motility.

8. Achalasia is a form of functional dysphagia caused by loss of esophageal innervation.

9. Gastroesophageal reflux disease is the regurgitation of chyme from the stomach into the esophagus, resulting in an inflammatory response (reflux esophagitis) when
the esophageal mucosa is repeatedly exposed to acids and enzymes in the regurgitated chyme.

10. Hiatal hernia is the protrusion of the upper part of the stomach through the hiatus (esophageal opening in the diaphragm) at the gastroesophageal junction. Hiatal hernia can be sliding or paraesophageal.

11. Gastroparesis is delayed gastric emptying in the absence of mechanical gastric outlet obstruction.

12. Pyloric obstruction is the narrowing or blockage of the pylorus, which is the opening between the stomach and the duodenum. It can be caused by a congenital defect, inflammation and scarring secondary to a gastric ulcer, or tumor growth.

13. Intestinal obstruction prevents the normal movement of chyme through the intestinal tract. It can be mechanical (i.e., caused by torsion, herniation, or tumor) or functional as a result of paralytic ileus.

14. The most severe consequences of intestinal obstruction are fluid and electrolyte losses, hypovolemia, shock, intestinal necrosis, and perforation of the intestinal wall.

15. Gastritis is an acute or chronic inflammation of the gastric mucosa.

16. Regurgitation of bile, use of anti-inflammatory drugs or alcohol, Helicobacter pylori infection, and some systemic diseases are associated with gastritis.

17. Chronic gastritis of the fundus (immune) and antrum (nonimmune) is the most severe form of gastritis. It can result in gastric atrophy and decreased secretion of hydrochloric acid, pepsinogen, and intrinsic factor.

18. Chronic gastritis of the antrum, the most common type, is not usually associated with impaired secretion or gastric atrophy.

19. A peptic ulcer is a circumscribed area of mucosal inflammation and ulceration caused by excessive secretion of gastric acid, disruption of the protective mucosal barrier, or infection with Helicobacter pylori.

20. Zollinger-Ellison syndrome is a rare syndrome associated with peptic ulcers caused by a gastrin-secreting neuroendocrine tumor or multiple tumors (gastrinoma) of the pancreas or duodenum.
21. There are three types of peptic ulcers: duodenal, gastric, and stress ulcers.

22. Duodenal ulcers, the most common peptic ulcers, are associated with *H. pylori* infection, chronic use of NSAIDs, increased numbers of parietal (acid-secreting) cells in the stomach, elevated gastrin levels, and rapid gastric emptying. Pain occurs when the stomach is empty, and it is relieved with food or antacids. Duodenal ulcers tend to heal spontaneously and recur frequently.

23. Gastric ulcers develop near parietal cells, generally in the antrum, and tend to become chronic. Gastric secretions may be normal or decreased, and pain may occur after eating.

24. Stress ulcers develop suddenly after severe illness, systemic trauma, or neural injury. Ulceration follows mucosal damage caused by ischemia (decreased blood flow to the gastric mucosa).

25. Cushing ulcer is a stress ulcer caused by head trauma. Ulceration follows hypersecretion of hydrochloric acid caused by overstimulation of the vagal nuclei.

26. Curling ulcer is associated with burn trauma.

27. Postgastrectomy syndromes are long-term complications that follow gastrectomy—the resection of all or part of the stomach. The postgastrectomy syndromes include dumping syndrome, alkaline reflux gastritis, afferent loop obstruction, diarrhea, weight loss, and anemia.

28. Dumping syndrome is the rapid emptying of chyme into the small intestine. It causes an osmotic shift of fluid from the vascular compartment to the intestinal lumen, which decreases plasma volume.

29. Alkaline reflux gastritis is stomach inflammation caused by the reflux of bile and pancreatic secretions from the duodenum into the stomach. These substances disrupt the mucosal barrier and cause inflammation.

30. Afferent loop obstruction is an obstruction of the duodenal stump on the proximal side of a gastrojejunostomy. Biliary and pancreatic secretions accumulate in the stump, causing distention, intermittent pain, and vomiting.

31. Malabsorption syndromes result in impaired digestion or absorption of nutrients and usually cause diarrhea.
32. Pancreatic exocrine insufficiency causes malabsorption associated with impaired digestion. The pancreas does not produce sufficient amounts of the enzymes that digest protein, carbohydrates, and fats into components that can be absorbed by the intestine.

33. Deficient lactase production in the brush border of the small intestine inhibits the breakdown of lactose. This prevents lactose absorption and causes osmotic diarrhea.

34. Bile salt deficiency causes fat malabsorption and steatorrhea (fatty stools). Bile salt deficiency can result from inadequate secretion of bile, excessive bacterial deconjugation of bile, or impaired reabsorption of bile salts caused by ileal disease.

35. Ulcerative colitis is a chronic inflammatory bowel disease that causes ulceration, abscess formation, and necrosis of the colonic and rectal mucosa. Cramping pain, bleeding, frequent diarrhea, dehydration, and weight loss accompany severe forms of the disease. A course of frequent remissions and exacerbations is common.

36. Crohn disease is similar to ulcerative colitis but it affects the GI tract from the mouth to the anus and tends to involve all the layers of the intestinal lumen. “Skip lesion” fissures and granulomata are characteristic of Crohn disease. Abdominal tenderness, diarrhea, and weight loss are the usual symptoms.

37. Microscopic colitis is an inflammation that involves either mucosal lymphocytic infiltration or a thickened subepithelial collagen layer with symptoms of watery diarrhea.

38. Irritable bowel syndrome (IBS) is described as a functional disorder with recurring abdominal pain and bloating. IBS can be diarrhea prevalent or constipation prevalent or may alternate between diarrhea and constipation. Alterations in the brain-gut axis, gut microflora, gut immune responses, gut neuroendocrine cell function, genetic susceptibility, and epigenetic factors contribute to intestinal hypersensitivity, intestinal inflammation, increased permeability, and symptoms caused by alterations in motility and secretion.

39. Diverticula are outpouchings of colonic mucosa through the muscle layers of the colon wall. Diverticulosis is the presence of these outpouchings; diverticulitis is inflammation of the diverticula.

40. Appendicitis is the most common surgical emergency of the abdomen.
Obstruction of the lumen leads to increased pressure, ischemia, and inflammation of the appendix. Without surgical resection, inflammation may progress to gangrene, perforation, and peritonitis.

41. Vascular insufficiency in the intestine is most often associated with occlusion or obstruction of the mesenteric vessels or insufficient intestinal arterial blood flow. The resulting ischemia and necrosis produce abdominal pain, fever, bloody diarrhea, hypovolemia, and shock.

42. Obesity is a metabolic disorder with an increase in body fat mass and a BMI greater than 30.

43. The causes of obesity are complex and involve the interaction of adipokines produced by fat cells and other body weight control signals at the level of the hypothalamus. Metabolic dysregulation includes leptin resistance, insulin resistance, and a proinflammatory state that contribute to the complications of obesity.

44. Visceral obesity and normal weight obesity increase the risk of developing systemic inflammation, dyslipidemia, and insulin resistance with predisposition to atherosclerosis, hypertension, cardiovascular disease, cancer, and type 2 diabetes mellitus. Metabolically healthy obesity delays obesity-related complications until an older age.

45. Malnutrition is lack of nourishment from inadequate amounts of calories, protein, vitamins, or minerals. Starvation is an extreme state of malnutrition. Cachexia is physical wasting associated with chronic disease.

46. Short-term starvation, or lack of dietary intake for 3 or 4 days, stimulates mobilization of stored glucose by two metabolic processes: glycogenolysis (splitting of glycogen into glucose) and gluconeogenesis (formation of glucose from noncarbohydrate molecules).

47. Long-term starvation triggers the breakdown of ketone bodies and fatty acids. Eventually proteolysis (protein breakdown) begins, and death ensues if nutrition is not restored.

**Disorders of the Accessory Organs of Digestion**

1. Portal hypertension, ascites, hepatic encephalopathy, jaundice, and hepatorenal syndrome are complications of many liver disorders.
2. Portal hypertension is an elevation of portal venous pressure to at least 10 mm Hg. It is caused by increased resistance to venous flow in the portal vein and its tributaries, including the sinusoids and hepatic vein.

3. Portal hypertension is the most serious complication of liver disease because it can cause potentially fatal complications, such as bleeding varices, ascites, and hepatic encephalopathy.

4. Varices (esophageal, gastric, hemorrhoidal) are distended, tortuous, collateral veins resulting from prolonged elevation of pressure in the portal vein.

5. Splenomegaly is enlargement of the spleen caused by increased pressure in the splenic vein, which branches from the portal vein.

6. Hepatopulmonary syndrome and portopulmonary hypertension are complications of portal hypertension caused by release of nitric oxide and carbon monoxide in the presence of liver injury.

7. Ascites is the accumulation and sequestration of fluid in the peritoneal cavity, often as a result of portal hypertension and decreased concentrations of plasma proteins.

8. Hepatic encephalopathy (portal-systemic encephalopathy) is impaired cerebral function caused by blood-borne toxins (particularly ammonia) not metabolized by the liver. Toxin-bearing blood may bypass the liver in collateral vessels opened as a result of portal hypertension, or diseased hepatocytes may be unable to carry out their metabolic functions.

9. Manifestations of hepatic encephalopathy range from confusion and asterixis (flapping tremor of the hands) to loss of consciousness, coma, and death.

10. Jaundice (icterus) is a yellow or greenish pigmentation of the skin or sclera of the eyes caused by increases in plasma bilirubin concentration (hyperbilirubinemia).

11. Obstructive jaundice is caused by obstructed bile canaliculi (intrahepatic obstructive jaundice) or obstructed bile ducts outside the liver (extrahepatic obstructive jaundice). Bilirubin accumulates proximal to the sites of obstruction, enters the bloodstream, and is carried to the skin and deposited.

12. Hemolytic jaundice is caused by destruction of red blood cells at a rate that
exceeds the liver's ability to metabolize unconjugated bilirubin.

13. Hepatorenal syndrome is functional kidney failure caused by advanced liver disease, particularly cirrhosis with portal hypertension. Renal failure is caused by a sudden decrease in blood flow to the kidneys usually caused by massive gastrointestinal hemorrhage, liver failure, or inadequate circulating blood volume associated with ascites. The chief clinical manifestation is oliguria.

14. Acute liver failure is severe impairment or necrosis of liver cells with or without preexisting liver disease or cirrhosis. It is commonly associated with acetaminophen overdose or as a complication of viral hepatitis.

15. Cirrhosis is an inflammatory disease of the liver that causes disorganization of lobular structure, fibrosis, and nodular regeneration. Cirrhosis can result from hepatitis or exposure to toxins, such as acetaldehyde (a product of alcohol metabolism). The disease causes progressive irreversible liver damage, usually over a period of years.

16. Alcoholic liver disease includes fatty liver and alcoholic steatohepatitis from accumulations of fat in the liver and is a precursor to alcoholic cirrhosis.

17. Alcoholic cirrhosis impairs the hepatocytes' ability to oxidize fatty acids, synthesize enzymes and proteins, degrade hormones, and clear portal blood of ammonia and toxins. The inflammatory response includes excessive collagen formation, fibrosis, and scarring, which obstruct bile canaliculi and sinusoids. Bile obstruction causes jaundice. Vascular obstruction causes portal hypertension, shunting, and varices.

18. Nonalcoholic fatty liver disease and nonalcoholic steatohepatitis involve accumulation of fat in the liver not associated with alcohol intake and are commonly associated with obesity.

19. Primary biliary cirrhosis is an autoimmune inflammatory destruction of intrahepatic bile ducts. Its cause is unknown.

20. Secondary biliary cirrhosis develops from prolonged obstruction of bile flow with increased pressure in the hepatic bile ducts that causes pooling of bile and necrosis of tissue. Relief of obstruction allays symptoms of jaundice and pruritus. Continued obstruction causes cirrhosis and liver failure.
21. Viral hepatitis is an infection of the liver caused by a strain of the hepatitis virus (i.e., hepatitis A virus [HAV], hepatitis B virus [HBV], hepatitis C virus [HCV], hepatitis E virus [HEV], and HBV transmitted with HBV). Although they differ with respect to modes of transmission and severity of acute illness, all can cause hepatic cell necrosis, Kupffer cell hyperplasia, and infiltration of liver tissue by mononuclear phagocytes. These changes obstruct bile flow and impair hepatocyte function.

22. The clinical manifestations of viral hepatitis depend on the stage of infection. Fever, malaise, anorexia, and liver enlargement and tenderness characterize the prodromal phase (stage 1). Jaundice and hyperbilirubinemia mark the icteric phase (stage 2). During the recovery phase (stage 3), symptoms resolve. Recovery takes several weeks.

23. Cholelithiasis (the formation of gallstones) is a common disorder of the gallbladder. Gallstones form in the bile as a result of the aggregation of cholesterol crystals (cholesterol stones) or precipitates of unconjugated bilirubin (pigmented stones). Gallstones that fill the gallbladder or obstruct the cystic or common bile duct cause abdominal pain and jaundice.

24. Cholecystitis is an acute or chronic inflammation of the gallbladder usually associated with obstruction of the cystic duct by gallstones.

25. Acute pancreatitis (pancreatic inflammation) is a serious but relatively rare disorder. Pancreatic duct obstruction and injury permits leakage of digestive enzymes into pancreatic tissue, where they become activated and begin the process of autodigestion, inflammation, and destruction of tissues. Release of pancreatic enzymes into the bloodstream or abdominal cavity causes damage to other organs.

26. Chronic pancreatitis results from structural or functional impairment of the pancreas. It causes recurrent abdominal pain and digestive disorders.

**Cancer of the Digestive System**

1. Cancer of the esophagus is rare and tends to occur in people older than 60 years of age. Alcohol and tobacco use, reflux esophagitis, and nutritional deficiencies are associated with esophageal carcinoma.

2. Dysphagia and chest pain are the primary manifestations of esophageal cancer.
Early treatment of tumors that have not spread into the mediastinum or lymph nodes results in a good prognosis.

3. Gastric adenocarcinoma is associated with *Helicobacter pylori* that carries the *CagA* gene product cytotoxin-associated vacuolating antigen A, a diet high in salt and food preservatives (nitrates, nitrites), and atrophic gastritis.

4. Approximately 50% of all gastric cancers are located in the prepyloric antrum. Clinical manifestations (weight loss, upper abdominal pain, vomiting, hematemesis, anemia) develop only after the tumor has penetrated the wall of the stomach.

5. Cancer of the colon and rectum (colorectal cancer) is the third most common cause of cancer death in the United States. Preexisting polyps are highly associated with adenocarcinoma of the colon. Familial adenomatous polyposis accounts for about 3% to 5% of colorectal cancer cases.

6. Tumors of the right (ascending or proximal) colon are usually large and bulky; tumors of the left (descending, sigmoid or distal) colon develop as small, button-like masses. Manifestations of colon tumors include pain, bloody stools, and a change in bowel habits.

7. Rectal carcinoma is located up to 15 cm from the opening of the anus. The tumor spreads transmurally to the vagina in women or the prostate in men.

8. Metastatic invasion of the liver is more common than primary cancer of the liver.

9. Primary liver cancers are associated with chronic liver disease (cirrhosis, hepatitis B). Hepatocellular carcinomas arise from the hepatocytes, whereas cholangiocellular carcinomas arise from the bile ducts. Primary liver cancer spreads to the heart, lungs, brain, kidney, and spleen through the circulation.

10. Cancer of the gallbladder is relatively rare and tends to occur in women older than 50 years. Adenocarcinoma is most common. Because clinical manifestations occur late in the disease, metastases to lymph channels have usually occurred by the time of diagnosis and the prognosis is poor.

11. Cancer of the pancreas is the fourth cause of cancer deaths. Most tumors are adenocarcinomas that arise in the exocrine cells of ducts in the head, body, or tail of the pancreas. Symptoms may not be evident until the tumor has spread to surrounding tissues. Treatment is palliative, and mortality is nearly 100% at 5 years.

Disorders of the gastrointestinal tract, liver, and pancreas in children include congenital anomalies with structural and functional alterations, enzyme deficiencies, and infections. These disorders lead to impairment of motility, digestion, absorption, nutrition, and normal growth and development.
Disorders of the Gastrointestinal Tract

Congenital Impairment of Motility

Cleft Lip and Cleft Palate

There are numerous types of congenital orofacial anomalies, the most common of which is cleft lip (CL) or cleft palate (CP), or both (CL/P). The incidence of cleft lip, with or without cleft palate, is about 1 in 1000 live births. In the United States, the incidence varies significantly by racial group,\textsuperscript{1,2} with Asian and Native American populations having the highest prevalence and African-derived populations having the lowest.\textsuperscript{3} CL and CP can occur in isolation or as part of a broad range of chromosomal, mendelian, or teratogenic syndromes. When this occurs, the defect may be referred to as syndromic CLP. If CP occurs alone, the defect may be referred to as nonsyndromic or isolated CP and is more common in females. CL with or without CP is more common in males. Both anomalies can be unilateral or bilateral, or partial or complete.\textsuperscript{4} Periconceptional intake of B vitamins, folate, and folic acid and reduced tobacco and alcohol use may prevent orofacial clefts.\textsuperscript{5}

Pathophysiology

Cleft lip (CL) and cleft palate (CP) are embryonic developmental anomalies and vary in severity (Figure 37-1). There may be genetic and environmental triggers for syndromic and nonsyndromic CLP. Epigenetic influences include maternal smoking, alcohol steroid or statin use; folate deficiency, or disordered metabolism. Cleft lip and cleft palate also may be associated with other malformations (i.e., cardiac, skeletal, or central nervous system). This phenomenon, called multifactorial inheritance, is discussed in Chapter 2. Together, the genetic and epigenetic factors reduce the amount of neural crest mesenchyme that migrates into the area that will develop into the face of the embryo.\textsuperscript{6}
Cleft lip is caused by the incomplete fusion of the nasomedial or intermaxillary process beginning the fourth week of embryonic development, a period of rapid development. The cleft causes structures of the face and mouth to develop without the normal restraints of encircling lip muscles. The facial cleft may affect not only the lip but also the external nose, nasal cartilages, nasal septum, and alveolar processes. The cleft is usually just beneath the center of one nostril. The defect may occur bilaterally and may be symmetric or asymmetric. The more complete the cleft
lip, the greater the chance that teeth in the line of the cleft will be missing or malformed.

*Cleft palate* is often associated with cleft lip but may occur without it. The fissure may affect only the uvula and soft palate or may extend forward to the nostril and involve the hard palate and the maxillary alveolar ridge. It may be unilateral or bilateral, with the cleft occupying the midline posteriorly and as far forward as the alveolar process, where it deviates to the involved side. Clefts involving the palate only are usually but not necessarily in the midline. In some cases, the vomer and nasal septum are partly or completely undeveloped. When these facial bones are involved, the nasal cavity may freely communicate with the oral cavity. Teeth in the cleft palate area may be missing or deformed. There is increased risk for middle ear infections.

**Clinical manifestations**

Clefts of the lip or palate, or both, are immediately recognizable disruptions of normal facial structure. Feeding difficulty is the most significant clinical manifestation because of the oronasal communication and inability to generate negative pressure needed for normal sucking. There also may be swallowing difficulty.

**Evaluation and treatment**

Prenatal diagnosis is made by ultrasound, and postnatal imaging confirms the extent of bone deformity. Soft tissue alterations are evaluated by history and physical examination. The nature and extent of the cleft, the infant's condition, and the method of surgical correction proposed determine the course of treatment. Surgical correction is planned at about the third to sixth month and may be performed in stages. There are limited long-term outcome studies.

Feeding the infant with cleft lip usually presents no difficulty if the cleft lip is simple and the palate intact. A baby with a complete cleft palate requires consultation with a feeding and swallowing specialist to ensure adequate and safe nutritional intake. Bottles with nipples specialized for feeding an infant with a cleft palate are required. Breast-feeding may be possible for some infants. An orthodontic prosthesis for the roof of the mouth may facilitate sucking for some infants. Parental education and support is required for the long-term care of children with cleft palate. Longitudinal monitoring requires a cleft/orofacial multidisciplinary team including a plastic surgeon, speech therapist, orthodontist, and nurse.

**Esophageal Atresia**
Congenital malformations of the esophagus occur in 1 of 3000 to 4500 live births. **Esophageal atresia (EA)** is the most common congenital atresia of the esophagus. The esophagus ends in a blind pouch. EA is usually accompanied by a fistula between the esophagus and the trachea (tracheoesophageal fistula [EA/TEF]).

 Either defect can occur alone (Figure 37-2). There is a high frequency of anomalies and syndromes associated with esophageal atresias. Environmental risk factors include maternal exposure to methimazole, exogenous sex hormones, infectious diseases, alcohol, or smoking; maternal diabetes; advanced maternal age; and maternal employment in agriculture. Many genes and chromosomal abnormalities have been implicated; 10% to 30% of infants with EA/TEF have associated vertebral, anal, cardiovascular, tracheoesophageal, renal, and limb anomalies (VACTERL).

**Pathophysiology**

The pathogenesis of esophageal abnormalities is unknown. Defective growth of endodermal cells and impaired embryonic foregut development of the trachea and esophagus lead to atresia.

**Clinical manifestations**
Antenatal diagnosis of EA/TEF increases with the findings of polyhydramnios (excessive amniotic fluid).\(^{13,14}\) Swallowed amniotic fluid is usually absorbed into the placental circulation; therefore if the fetus cannot swallow, amniotic fluid accumulates in the uterus. EA will be diagnosed at birth on the basis of drooling, inability to swallow secretions or choking with feeding, and respiratory distress. Confirmation is established by inability to pass a gastric tube into the stomach. If a fistula connects the trachea with the distal esophagus, the abdomen fills with air and becomes distended, possibly interfering with breathing (see Figure 37-2, C to E). Intermittent cyanosis may result.

Pulmonary complications are compounded by reflux of air and gastric secretions into the tracheobronchial tree through the fistula, causing severe chemical irritation. Infants with esophageal atresia but no fistulae have scaphoid (boat-shaped), gasless abdomens. In infants with fistulae but without atresia (see Figure 37-2, E), the usual symptoms are recurrent aspiration, pneumonia, and atelectasis that remains unexpressed for days or even months.

**Evaluation and treatment**

Infants presenting with esophageal atresia are evaluated with ultrasound, echocardiogram, and vertebral and limb radiographs. Following diagnosis, a tube should be placed into the upper pouch and continuous suction applied to decrease risk of aspiration. The head of the bed should be elevated slightly to assist drainage of the upper pouch. The infant should not be fed orally. Surgical repair is completed in the majority of cases.\(^{16}\) The overall survival rate for infants with esophageal defects is 95%.\(^{17}\)

**Infantile Hypertrophic Pyloric Stenosis**

**Infantile hypertrophic pyloric stenosis (IHPS)** is an acquired narrowing and distal obstruction of the pylorus and a common cause of postprandial vomiting. The incidence of pyloric stenosis is approximately 2 to 5 in 1000 live births for males and 1 in 1000 live births for females.\(^{18}\) The etiology is unclear but probably multifactorial, involving genetic and environmental factors.

**Pathophysiology**

Individual muscle fibers thicken, so the entire pyloric sphincter becomes enlarged and inflexible. The mucosal lining of the pyloric opening is folded and narrowed by the encroaching muscle. Because of the extra peristaltic effort necessary to force the gastric contents through the narrow pylorus, the muscle layers of the stomach may become hypertrophied as well.
Clinical manifestations

Between 2 and 8 weeks after birth, an infant who has fed well and gained weight begins forceful, nonbilious vomiting immediately after feeding. The infant then demands to be refed. Constipation occurs because little food reaches the intestine.

In severe, untreated cases, increased gastric peristalsis and vomiting lead to severe fluid and electrolyte imbalances, malnutrition, and weight loss that can be fatal within 4 to 6 weeks. Infants with pyloric stenosis are irritable because of hunger, and they may have esophageal discomfort caused by repeated vomiting and esophagitis. The vomitus may be blood-streaked because of rupture of gastric and esophageal vessels.

Evaluation and treatment

Diagnosis is based on the history, clinical manifestations, and findings on abdominal ultrasound. The force and timing of the vomiting can help distinguish IHPS from gastroesophageal reflux, for which episodes of vomiting are not forceful and occur 10 minutes or more after a feeding. The hypertrophied pylorus is palpable as a firm, small, movable mass, approximately the size of an olive, and is felt in the right upper quadrant in 70% to 90% of infants with pyloric stenosis. The hypertrophied pyloric muscles and narrowed pyloric channel are identified with ultrasound and radiographs.

The standard treatment for hypertrophic pyloric stenosis is a laparoscopic pyloromyotomy, in which the muscles of the pylorus are split and separated. Preoperative and postoperative medical management to correct fluid and electrolyte imbalance has been the key to the high success rate and low complication rates associated with this surgery.

Obstructions of the Duodenum, Jejunum, and Ileum

High intestinal obstruction should be considered whenever persistent vomiting occurs. With duodenal obstruction there will be upper abdominal distention, visible peristaltic waves, a decrease in the size and frequency of meconium stools, progressive weight loss, persistent vomiting, and dehydration. Congenital obstruction of the duodenum can be caused by intrinsic malformations, such as atresia (complete blockage), stenosis (partial obstruction or narrowing), or external pressure, and occurs in 2.5 to 10 per 100,000 live births. The obstruction may be partial or complete and is usually located at or near the major duodenal papilla. The classic “double bubble” sign is seen on imaging of the abdomen and represents duodenal obstruction. The larger, proximal “bubble” is air in a dilated stomach. The more distal, smaller “bubble” is air in a dilated proximal duodenum. There is
usually little or no air in the bowel distal to the obstruction. Double bubble also may be seen on prenatal ultrasounds. An annular pancreas—a defect in which the head of the pancreas surrounds part of the duodenum—can obstruct the duodenum. Congenital obstructions of the jejunum and ileum can be attributable to atresia, stenosis, meconium ileus, megacolon (Hirschsprung disease), intussusception, Meckel diverticulum, intestinal duplication, or strangulated hernia. In ileal or jejunal atresia, the intestine ends blindly, proximal and distal to an interruption in its continuity, with or without a gap in the mesentery. Stenosis (narrowing of the lumen) causes dilation proximal to the obstruction and luminal collapse distal to it.

**Malrotation**

Malrotation is the term used to describe the spectrum of abnormalities of embryonic development of the midgut associated with abnormal intestinal rotation or fixation, or both. The incidence is between 1 in 500 and 1 in 600 live births.\(^{22}\)

**Pathophysiology**

In malrotation, the small intestine lacks a normal posterior attachment. The mobile loops of intestine can twist upon themselves (volvulus), leading to symptoms of bowel obstruction (see Figure 36-4). The twisting can partly or completely occlude the superior mesenteric artery, causing infarction and necrosis of the entire midgut. Peritoneal (Ladd) bands may press against and obstruct the duodenum.

**Clinical manifestations**

Most cases of malrotation-associated volvulus and infarction develop during the neonatal period (90% are younger than 1 year). Some develop during childhood or adulthood. Classic symptoms in infants are intermittent or persistent bile-stained vomiting after feedings and epigastric distention. Dehydration and electrolyte imbalance may occur rapidly. Fever usually ensues with pain and scanty stools. Diarrhea and bloody stools are associated with progressive volvulus, vascular compression, and infarction of the intestine. Intermittent or partial volvulus is more common in older children and adults. It may be asymptomatic or cause minor abdominal discomfort and be discovered during unrelated abdominal surgery.

**Evaluation and treatment**

Diagnosis of malrotation with volvulus and infarction is based on clinical manifestations. Radiographic films of the abdomen and barium studies show intestinal gas bubbles and distention proximal to the site of obstruction. Treatment includes laparoscopic or open surgery to reduce the volvulus.\(^{23}\)
Necrotic bowel may be resected and a primary anastomosis performed. An enterostomy may be created. Most children have a good outcome; however, there is risk for adhesion-related bowel obstruction in about 15% of cases. Resection of large segments of the small intestine results in short bowel syndrome and its long-term sequelae.\textsuperscript{24,25}

**Meckel Diverticulum**

Diverticula are small outpouches, or sacs, that have formed and pushed outward through weak spots of the intestinal wall. **Meckel diverticulum** is a remnant of the embryonic yolk sac and the most prevalent congenital abnormality of the small bowel (usually in the ileum). It is a true diverticulum in that it contains all layers of the intestinal wall. Ectopic gastric mucosal cells are contained in the diverticuli and may cause peptic ulcer and painless bleeding or mimic colonic diverticulitis. Often referred to as “the rule of 2s,” a Meckel diverticulum occurs in approximately 2% of the general population, is typically located within 2 feet of the ileocecal valve (on the antimesenteric border of the ileum), is 2 inches in length on average, and its clinical symptomatology often occurs before 2 years of age.\textsuperscript{26} Although most Meckel diverticuli are asymptomatic, the most common symptom is painless rectal bleeding. Intestinal obstruction, intussusception, and volvulus can occur, more commonly in adults. Diagnosis is made by symptom presentation and radionucleotide scintigraphy. The scan shows the gastric mucosal cells in the diverticuli. Treatment in those with symptoms is surgical resection.\textsuperscript{27-30}

**Meconium Syndromes**

**Meconium** is a substance that fills the entire intestine before birth. It is a dark greenish mass of desquamated cells, mucus, and bile that accumulates in the bowel of a fetus and is typically discharged during the first 12 to 48 hours after birth. **Meconium ileus (MI)** is an intestinal obstruction in the neonatal period caused by meconium formed in utero that is abnormally thick and sticky, which leads to a partial or complete obstruction at the level of the terminal ileum. There are two
forms of MI: simple and complex. Complex MI is a surgical emergency and there is usually an associated gastrointestinal pathology, such as bowel atresia, necrosis, or perforation. MI occurs in up to 20% of infants with cystic fibrosis, and is thought to result from abnormal mucus production in the intestine or impaired pancreatic enzymes, or both\textsuperscript{31,32} (see Chapter 28 and p. 956).

**Meconium plug syndrome (MPS),** also termed functional immaturity of the colon, is a transient disorder of the newborn colon characterized by delayed passage (>24 to 48 hours) of meconium and intestinal dilatation. **Meconium disease (MD)** is often associated with severe prematurity and low birth weight. It results from a combination of extremely sticky meconium in the colon or terminal ileum and poor intestinal motility, resulting in mechanical bowel obstruction. In both MPS and MD, plugs of meconium are found in the distal ileum and proximal colon, resulting in obstruction of passage of meconium from the rectum.

**Distal intestinal obstruction syndrome (DIOS),** formerly called meconium ileus equivalent, is seen in about 7.4% of children and adults with cystic fibrosis.\textsuperscript{33} It is characterized by complete or incomplete intestinal obstruction of viscid fecal accumulation in the terminal ileum and proximal colon.\textsuperscript{34}

**Pathophysiology**

The terminal ileum is plugged with thick, viscous meconium resulting from the formation of an insoluble, calcium-glycoprotein compound in abnormal mucus. The segment of the ileum proximal to the obstruction is distended with liquid contents, and its walls may be hypertrophied. The segment distal to the obstruction is collapsed and filled with small pellets of pale-colored stool. Meconium in the obstructed segment has the consistency of thick syrup or glue. Peristalsis fails to propel this viscus material through the ileum, and it becomes impacted. Volvulus, atresia, or perforation of the bowel sometimes accompanies meconium ileus.

**Clinical manifestations**

Abdominal distention usually develops during the first few hours after birth. As air is swallowed, the distention increases and the infant begins to vomit bile-stained material. Infants with cystic fibrosis may have signs of pulmonary involvement, such as tachypnea, intercostal retractions, and grunting respirations. The distended abdomen shows patterns of dilated intestinal loops that feel doughlike when palpated. Some of the loops contain scattered, firm, movable masses. Despite hyperactive peristalsis, the rectal ampulla is empty.

**Evaluation and treatment**

Radiologic examination confirms the presence of meconium in the ileum or
ileocecum. The sweat test measures the amount of chloride in the sweat, is performed to detect or rule out cystic fibrosis, and is accurate in 90% of infants. Defective chloride channels in cystic fibrosis cause increased chloride concentration in sweat. About 50% of cases are complicated with volvulus or perforation. In most cases, the obstruction is relieved by intestinal lavage and administration of oral laxatives.\textsuperscript{34,35} If this is not possible, the meconium is removed surgically.\textsuperscript{36} Survival of infants with simple meconium ileus is improving, with rates approaching 100%. Mortality of infants with complex meconium ileus with perforation and subsequent peritonitis or septicemia is about 70%.\textsuperscript{31,35} DIOS is treated with hydration and stool softeners.

**Idiopathic Intestinal Pseudo-obstruction**

**Idiopathic intestinal pseudo-obstruction** is a disorder of impaired intestinal motility. The pseudo-obstruction is caused by nerve or peristaltic muscle dysfunction that affects the movement of food, fluid, or air through the intestine. Children present with abdominal swelling or bloating, crampy abdominal pain, nausea, vomiting, constipation, or diarrhea. Idiopathic intestinal pseudo-obstruction is difficult to diagnose and treatment includes intestinal decompression, nutritional support, and symptom management.\textsuperscript{37-39}

**Hirschsprung Disease**

**Hirschsprung disease**, or aganglionic megacolon, is a functional obstruction of the colon. It is the most common cause of colon obstruction, accounting for about one third of all gastrointestinal obstructions in infants. The incidence is approximately 1 in 5000 live births, and varies among ethnic groups. There is a predominance in males. Hirschsprung disease is a multifactorial malformation.\textsuperscript{40-42}

**Pathophysiology**

Hirschsprung disease is characterized by the absence of parasympathetic intrinsic ganglion cells in the submucosal and myenteric plexuses along with the absence of peristaltic movement in the bowels (see Figure 35-13 for normal colon structure). In 80% of cases, the aganglionic segment is limited to the rectal end of the sigmoid colon. In rare cases, the entire colon lacks ganglion cells. The abnormally innervated colon impairs fecal movements, causing the proximal colon to become distended—hence the term megacolon (Figure 37-3).
Clinical manifestations
The infant typically becomes symptomatic during the first 24 to 72 hours after birth with delayed passage of meconium. Mild to severe constipation is the usual manifestation of Hirschsprung disease, with poor feeding, poor weight gain, and progressive abdominal distention. However, diarrhea may be the first sign because only water can travel around the impacted feces.

The most serious complication in the neonatal period is enterocolitis related to fecal impaction. Bowel dilation stretches and partly occludes the encircling blood and lymphatic vessels, causing edema, ischemia, infarction of the mucosa, and significant outflow of fluid into the bowel lumen. Copious liquid stools result. Infarction and destruction of the mucosa enable enteric microorganisms to penetrate the bowel wall. Frequently, gram-negative sepsis occurs, accompanied by fever and vomiting. Severe and rapid fluid and electrolyte changes may take place, causing hypovolemic or septic shock or death.

Evaluation and treatment
Radiocontrast enema and anorectal manometry are screening tools for the diagnosis
of Hirschsprung disease. The definitive diagnosis is made by rectal biopsy showing an absence of ganglion cells in the submucosa of the colon. Surgery is the definitive treatment in all cases of Hirschsprung disease. In general, the prognosis of congenital megacolon is satisfactory for children who undergo surgical treatment. Bowel training may be prolonged; most children achieve bowel continence before puberty but some have long-term constipation or fecal incontinence.

Anorectal Malformations

Anorectal malformations (ARMs) represent a spectrum of anomalies of the anus and rectum (Figure 37-4). ARMs include anorectal stenosis, imperforate anus, anorectal atresia, and rectal atresia. Persistent cloaca is the most severe type of anorectal malformation and occurs exclusively in girls. The rectum, urethra, and vagina fail to develop separately; instead, they drain through a single, common channel onto the perineum. Approximately 40% of infants with anorectal malformations have other developmental anomalies (i.e., Down syndrome, Hirschsprung disease, and duodenal atresia).
Most ARMs are identified in routine physical examination during the neonatal period. Types of imperforate anus include an anal opening that is narrow or misplaced, a membrane (covering) may be present over the anal opening, the rectum may not connect to the anus, the rectum may connect to part of the urinary tract or to the reproductive system through an opening called a fistula, or the anal opening is not present. Treatment recommendations depend on the type of imperforate anus, the presence and type of associated abnormalities, and the child's overall health status. Anal stenosis can be treated by dilations. Infants with an imperforate anus and other anorectal malformations require surgical correction. Overall mortality is approximately 10%. Lower lesions have better functional outcomes than higher lesions.\textsuperscript{51,53}

**Acquired Impairment of Motility**

**Gastroesophageal Reflux**

Gastroesophageal reflux (GER) is the passage of gastric contents into the esophagus independent of swallowing. GER is normal and nonpathologic in healthy
infants and may be asymptomatic or exhibited by regurgitation and vomiting. The frequency of GER is highest in premature infants and occurs in about 70% of healthy infants; however, GER resolves without treatment in 95% of infants by 12 to 14 months of age. Gastroesophageal reflux disease (GERD) is different from GER and occurs when it is the cause of troublesome symptoms or complications, or both, described as esophageal or extraesophageal in nature. Children at greatest risk for complicated GERD are those with prematurity, neurologic impairment, esophageal atresia, obesity, hiatal hernia, achalasia, chronic lung diseases, and certain genetic disorders, including cystic fibrosis.

**Pathophysiology**

GERD is influenced by genetic, environmental, anatomic, hormonal, and neurogenic factors. Although transient lower esophageal sphincter relaxations (TLESRs) are the most common pathophysiologic cause of GER, inadequate adaptation of sphincter tone to changes in abdominal pressure also may be implicated. Factors that maintain lower esophageal sphincter integrity in children include the location of the gastroesophageal junction in a high-pressure zone within the abdomen, mucosal gathering within the sphincter, and the angle at which the esophagus is inserted into the stomach. Reflux persists if any one of these pressure-maintaining factors is altered. Other mediators of GER are esophageal peristalsis or clearance, mucosal resistance that mediates the noxiousness of the refluxate, and delayed gastric emptying. Reflux of acidic gastric contents results in inflammation of the esophageal epithelium (esophagitis) and stimulation of the vomiting reflex.

Esophageal inflammation resulting from GERD is differentiated from eosinophilic esophagitis (EoE), which can occur in children. EoE is thought to be an allergic esophageal disease involving both immediate and delayed hypersensitivity reactions to food ingestion. An eosinophilic infiltrate is associated with inflammation of the entire esophagus that is nonresponsive to acid-suppression therapy. The hallmark symptoms of EoE are dysphagia, food refusal or impaction, and throat and chest pain. Treatment involves food elimination and oral steroids.

**Clinical manifestations**

The clinical manifestations of GERD include excessive regurgitation or vomiting; food refusal/anorexia; unexplained crying, choking, or gagging; sleep disturbance; dysphagia; and abdominal or epigastric pain, or both. Esophageal complications of GER can be significant, such as esophagitis, hemorrhage, stricture, Barrett esophagus (metaplasia) (see Chapter 36), and, rarely, adenocarcinoma. Extraesophageal symptoms include cough and wheezing, laryngitis, pharyngitis, dental erosions, sinusitis, recurrent otitis media, and Sandifer syndrome (a
neurologic disorder).\textsuperscript{58} This constellation of symptoms is often indistinguishable from those of cow's milk protein allergy, which may coexist with or overlap GERD.

**Evaluation and treatment**

The clinical manifestations are often adequate to confirm a diagnosis of GERD. Esophageal pH monitoring with a probe for 24 hours and endoscopy are routinely used for diagnosis.

Normal physiologic GER resolves without treatment. In breast-fed babies, maternal elimination of cow's milk protein is recommended whereas formula-fed infants may require feeding volume and frequency adjustments using extensively hydrolyzed protein or amino acid–based formulas. Using thickened feedings has shown to improve symptoms of GER. Prone positioning is only recommended for infants older than 1 year of age because of the risk of sudden infant death syndrome. Lifestyle changes for children and adolescents include weight loss, smoking cessation, and avoidance of caffeine, chocolate, alcohol, and spicy foods.

Medications are used to buffer or decrease gastric acid secretion, increase motility, or increase lower esophageal sphincter pressure to treat GER.\textsuperscript{59} If no improvement is seen with medical management or the child has life-threatening events with reflux, an antireflux surgical procedure, including gastropexy and fundoplication, is performed. More evidence is needed to evaluate long-term surgical outcomes.\textsuperscript{60}

**Intussusception**

**Intussusception** is the telescoping of a proximal segment of intestine into a distal segment, causing an obstruction. It is the most common cause of small bowel obstruction in children and occurs in about 56 of 100,000 children yearly in the United States.\textsuperscript{61} Most cases occur between 5 and 7 months of age. Intussusception is more common in males and can occur in children with polyps or tumors (lead points), cystic fibrosis, Meckel diverticulum, intestinal adhesions, or immediately after abdominal surgery.\textsuperscript{62} There is a small risk of intussusception associated with rotovirus vaccination but the vaccine is generally safe.\textsuperscript{63}

**Pathophysiology**

In intussusception, the ileum commonly telescopes into the cecum and part of the ascending colon by collapsing through the ileocecal valve, although intussusception can occur anywhere from the duodenum to the rectum. The proximal portion of the intestine (the intussusceptum) collapses into the distal portion (the intussuscipiens) in the direction of peristaltic flow (Figure 37-5). The intussusceptum then drags its
Blood vessels drawn in between layers

FIGURE 37-5 Ileocolic Intussusception.

Clinical manifestations
The classic symptoms of intussusception include colicky abdominal pain, irritability, knees drawn to the chest, abdominal mass, vomiting, and bloody
(currant-jelly) stools. All of these symptoms may not occur, and intussusception has been discovered incidentally by computed tomography (CT) or magnetic resonance imaging (MRI) scan for other indications. Abdominal tenderness and distention develop as intestinal obstruction becomes more acute.

**Evaluation and treatment**

Diagnosis is based on clinical manifestations, onset of symptoms, and ultrasonographic or radiologic imaging studies. An enema reduction is usually effective for large bowel intussusception and avoids the progression to ischemia and perforation. Laparotomy remains the treatment of choice for small bowel intussusception.\(^6^4\) Untreated intussusception in infants is nearly always fatal. Most infants recover if the intussusception is reduced within 24 hours.\(^6^5\)

**Appendicitis**

Appendicitis is common in children between the ages of 10 and 11 years.\(^6^6\) The mechanisms of disease, symptoms, and treatment are similar to those for adults and can be reviewed in Chapter 36.

**Impairment of Digestion, Absorption, and Nutrition**

**Cystic Fibrosis**

*Cystic fibrosis* (CF) is an autosomal recessive disease that involves multiple organ systems and leads to death at an earlier age, although new treatments are extending life expectancy. This section focuses on gastrointestinal complications of CF; **Chapter 28** discusses CF's epidemiology and pulmonary involvement.

**Pathophysiology**

The gastrointestinal presentation of CF is caused by a dysfunction of the CF transmembrane regulator (CFTR) protein, which is located on epithelial membranes and regulates chloride and sodium ion channels. It is found throughout the airways,
sweat glands, digestive tract, pancreas, hepatobiliary system, and reproductive system (also called *mucoviscidosis* or *fibrocystic disease of the pancreas*). The hallmark pathophysiologic triad of CF includes obstruction, infection, and inflammation that are evident throughout the gastrointestinal tract and within the airways. The full spectrum of involvement is summarized in Table 37-1.

Dysfunction of the CFTR protein results in altered sodium, chloride, and potassium resorption, all of which remain external to the surface of the epithelial membrane with reduced clearance from tubular structures lined by affected epithelia. Maldigestion of proteins, carbohydrates, fats, and fat-soluble vitamins occurs because mucus obstruction of the pancreatic ducts blocks the flow of pancreatic enzymes, causing intestinal malabsorption and degenerative and fibrotic
changes in the pancreas and gastrointestinal tract. Diabetes mellitus commonly develops from damage to insulin-producing beta cells and insulin resistance.⁶⁸

**Clinical manifestations**

Clinical manifestations are summarized in Table 37-1. Gastrointestinal symptoms often precede pulmonary manifestations. Approximately 85% of those with CF present early in life with pancreatic insufficiency (PI). PI is the cause of nutrient malabsorption and failure to thrive in children with CF. Steatorrhea and abdominal distention are common symptoms with potential sequelae that include distal intestinal obstruction syndrome (DIOS) (see p. 953), fibrotic colonopathy, or focal biliary cirrhosis. Children who are pancreatic sufficient (PS) are at greater risk of developing pancreatitis.⁶⁹ Those with CF are at greater risk for many gastrointestinal complications, including gastrointestinal cancers and hepatobiliary abnormalities, which may lead to pancreatic transplant or death.

**Evaluation and treatment**

All states in the United States screen newborns for cystic fibrosis using a blood test to detect immunoreactive trypsinogen. Genetic screening and the sweat test are required for diagnosis. Evaluation of pancreatic sufficiency also is essential. The extent of pancreatic function is determined by 72-hour fecal fat measurements, which are not easily obtained. Therefore, the most common measurement of fat malabsorption is fecal elastase. A serum test for trypsinogen also can be used to detect pancreatic insufficiency in children older than 8 years of age.

The goal of treatment for PI is to reduce malabsorption of nutrients and improve growth. Most children with CF take pancreatic enzyme replacement therapy (PERT) for the rest of their lives. PERT is administered before or with every meal, snack, or enteral feeding supplementation. High doses of PERT are associated with DIOS; therefore, minimal effective doses are indicated. High-caloric, high-protein diets with frequent snacks and vitamin supplements are used to treat malnutrition. Nutritional status and growth should be carefully monitored, and growth hormone may be included with nutritional supplements.⁷⁰

**Celiac Disease**

**Celiac disease (CD)**, formerly called **celiac sprue**, is an autoimmune disease that damages small intestinal villous epithelium when there is ingestion of gluten (gliadin), the protein component of cereal grains. CD is a common multiorgan disease with a strong genetic predisposition associated with human leukocyte antigen DQ2 (HLA-DQ2) and HLA-DQ8.⁷¹ The disease has a prevalence of about
1% worldwide, although evidence suggests only 10% to 15% of the population have been diagnosed and treated. Nonceliac gluten sensitivity (GS), or wheat allergy, should not be confused with CD; although it presents similarly after the ingestion of gluten, the individual does not have positive autoantibodies or classic intestinal villous atrophy but instead has variable HLA status with similar symptoms as CD.

The pathogenesis of CD is complex and involves genetic and immunologic factors. Environmental factors include early infections, gut microbiota in infants, feeding patterns, and timing and amount of gluten. CD presents with greater frequency in children with type 1 diabetes mellitus, autoimmune thyroid or liver disease, Down syndrome, Turner syndrome, Williams syndrome, selective IgA deficiency, Addison disease, and first-degree relatives with CD.

**Pathophysiology**

The major pathophysiologic characteristic of celiac disease is T-cell–mediated autoimmune injury to the small intestinal epithelial cells of genetically susceptible individuals. There is atrophy and flattening of villi, crypt hyperplasia in the upper small intestine, and malabsorption of most nutrients in the presence of cereal gluten, particularly wheat, rye, and barley (**Figure 37-6**).
Damage to the mucosa of the duodenum and jejunum exacerbates malabsorption. The secretion of intestinal hormones, such as secretin and cholecystokinin-pancreozymin, may be diminished; consequently, secretion of pancreatic enzymes and expulsion of bile from the gallbladder decrease, contributing to malabsorption.

Destruction of mucosal cells causes inflammation, and water and electrolytes are secreted, leading to watery diarrhea. Potassium loss leads to muscle weakness. Magnesium and calcium malabsorption can cause seizures or tetany. Unabsorbed fatty acids combine with calcium, and secondary hyperparathyroidism increases phosphorus excretion, resulting in bone reabsorption. Calcium is no longer able to bind oxalate in the intestine and is absorbed, which causes hyperoxaluria. Gallbladder function may be abnormal, and bile salt conjugation may decrease.

Fat malabsorption in the jejunum is the major cause of steatorrhea (fatty stools). Deficiencies of fat-soluble vitamins are common in children with CD. Vitamin K malabsorption leads to hypoprothrombinemia. In one third of cases, iron and folic acid malabsorption is manifested as cheilosis, anemia, and a smooth red tongue. Vitamin B_{12} absorption is impaired in those with extensive ileal disease, and folate and iron deficiencies are common.

**Clinical manifestations**
The onset of clinical manifestations of celiac disease depends on the age of the infant when gluten-containing substances are added to the diet. Although in 50% of affected children onset occurs by 18 months of age, it is not uncommon to be diagnosed later in life. Severity of symptoms can vary tremendously and many children older than 3 years of age present with nongastrointestinal symptoms.\textsuperscript{72} Gastrointestinal and extraintestinal symptoms of CD are listed in Box 37-1.

An unusual complication of celiac disease in infancy is celiac crisis. **Celiac crisis** is characterized by severe diarrhea, dehydration, and hypoproteinemia as a result of malabsorption and protein loss.

**Evaluation and treatment**

Diagnosis includes confirmation with serologic autoantibody measurement against tissue transglutaminase IgA (tTG IgA) (most sensitive and specific), anti-endomysium (EMA) IgA, or deaminated gliadin peptides (DGP\textsubscript{S}), which are more sensitive in children younger than 2 years of age. A negative genetic screening for HLA haplotypes would rule out CD.\textsuperscript{75} Currently, there is controversy regarding treatment for those children who are HLA-positive but asymptomatic. If an autoantibody or genetic screen is positive, a small intestinal biopsy is obtained to detect the classic mucosal changes caused by gluten-induced enteropathy. A wide variety of screening tests for malabsorption also may be useful. Even though there are very useful screening tools to diagnose CD, many children remain undiagnosed.

Treatment consists of lifelong adherence to a gluten-free diet (GFD), which includes elimination of wheat, rye, barley, and malt. Lactose intolerance also may be present from damage to villi; therefore, lactose (milk sugar) also may be excluded.
from the diet but should be resumed after treatment. Infants are routinely given vitamin D, iron, and folic acid supplements to treat deficiencies. Bone mineral density (BMD) screening is required. For most children the long-term prognosis is excellent. There is an increased incidence of malignant disease, particularly lymphoma, in individuals who fail to respond or are nonadherent to a GFD. \(^{76}\)

**Malnutrition**

Pediatric malnutrition is an imbalance between nutrient requirements and intake that results in energy, protein, and micronutrient deficits that negatively impact growth and development. Malnutrition also involves impaired absorption and altered nutrient utilization. Kwashiorkor (deficiency of dietary protein) and marasmus (all forms of inadequate nutrient intake) are the two most common types of malnutrition in children. Collectively they are known as **protein-energy malnutrition (PEM)**. PEM describes the effects of malnutrition but not the etiology or interactions that contribute to nutrient depletion.

Both kwashiorkor and marasmus are states of long-term starvation and are the result of widespread nutritional deficiencies among children in developing countries and economically destitute populations, particularly when associated with human immunodeficiency virus (HIV) infection. \(^{77}\) Kwashiorkor usually occurs in infants or children from 1 to 4 years of age who have been weaned from breast milk to a high-starch, protein-deficient diet. The death rate of kwashiorkor is higher than that for marasmus.

Marasmus can occur at any age but it is common in children younger than 1 year. In marasmus, starvation is attributable to lack of protein and carbohydrates, and in neglected children it can have a psychogenic basis. In developing countries and impoverished populations, early weaning of breast-fed infants to overdiluted commercial formulas is a risk factor for marasmus.

Although PEM is common in developing countries, it is underestimated in hospitalized children. A new paradigm used to define pediatric malnutrition and includes etiology (illness or environmental), identification of pathogenesis and chronicity, associations with inflammation, and resulting impact on functional outcomes. \(^{78}\) PEM is a known complication of chronic diseases, such as chronic fever; infectious diseases like tuberculosis; malignancy; digestive and malabsorptive disorders; cardiac, pulmonary, renal, and neurologic diseases; burns or hypermetabolic states; anorexia and bulimia; and psychogenic illness. Treatments such as radiation therapy and chemotherapy also can contribute to malnutrition. PEM contributes to hospital-acquired conditions (HACs), longer time on mechanical ventilation, increased hospital length of stay, and increased morbidity
Pathophysiology
The pathogenesis of kwashiorkor is uncertain but includes inadequate dietary protein, leaky gut syndrome (compromised gut barrier), and intestinal inflammation. Recent studies are now implicating alterations in gut microbiota as the central cause of kwashiorkor. There is evidence that children with kwashiorkor show stunting of gut microbiota maturation, which may generate products, such as inhibitors of enzymes in the tricarboxylic acid cycles, that compromise energy metabolism. Support for this theory of causation includes an antibiotic treatment study that demonstrated significant improvement in recovery and mortality rates of malnourished Malawian children.

The lack of sufficient plasma proteins results in generalized edema with a substantial loss of potassium. The liver swells with stored fat because no hepatic proteins are synthesized to form and release lipoproteins. Pancreatic atrophy and fibrosis may be present. Kwashiorkor also causes malabsorption, reduced bone density, and impaired renal function. If the condition is not reversed, the prognosis is very poor.

The metabolic response in marasmus is different, allowing sustained protein and lipid supply during periods of decreased dietary intake. Metabolic processes, including liver function, are preserved, but growth is severely retarded. Caloric intake is too low to support protein synthesis for growth or the storage of fat. Muscle and fat wasting occur and anemia is common and can be severe.

Clinical manifestations
Children with kwashiorkor have appropriate stores of protein and fat that are mobilized inadequately. They have marked generalized edema, dermatoses, hypopigmented hair, distended abdomen, hepatomegaly, and almost normal weight for age (because of edema). Children with marasmus demonstrate greater wasting of protein and fat stores yet have improved survival. Marasmus is characterized by muscle wasting, fatty liver and hepatomegaly, diarrhea, dermatosis, low hemoglobin level, and infection. There is loss of subcutaneous fat and an absence of edema. Both conditions lead to delays in physical, behavioral, and cognitive development and academic performance. Lastly, micronutrient deficiencies, especially with zinc, selenium, iron, and antioxidant vitamins, can lead to immune deficiency and infections. Severe vitamin A deficiency commonly results in blindness.

Evaluation and treatment
Evaluation of PEM is based on nutritional history and clinical manifestations, including anthropometric measurements. Laboratory monitoring is used to assess for macro- and micronutrient deficiencies, aminotransaminase alterations, and response to refeeding. The provision of deficient nutrients will resolve clinical symptoms in 4 to 6 weeks. Use of antibiotics has been shown to improve recovery of PEM and decrease mortality. Developmental sequelae of PEM may be irreversible; therefore early intervention is recommended. Nutritional rehabilitation with appropriate environmental stimulation for infants and young children has been shown to resolve or improve cerebral shrinkage, physical growth, and psychomotor development.

**Failure to Thrive or Growth Faltering**

*Failure to thrive (FTT)* or *growth faltering (GF)* is a physical sign demonstrating that a child is receiving inadequate nutrition for optimal growth and development. It is manifested as a deceleration in weight gain, a low weight/height or BMI ratio, or a low weight/height/head circumference ratio. FTT is a common problem and can present at any time in childhood. Approximately 80% of children with FTT present before 18 months of age.

**Pathophysiology**

Currently, there is a move away from describing FTT as organic versus nonorganic; instead, it is considered a multifactorial condition that includes biologic, psychosocial, and environmental contributions that are illness related or nonillness related (*Box 37-2*). An underlying medical condition is never found in more than 80% of cases of FTT. Categories of FTT include inadequate caloric intake, inadequate caloric absorption, or excessive caloric expenditure. Infants and children are at risk for FTT if their parents or primary caregivers are unable to provide nurturance.

**Box 37-2**

**Factors Associated with Failure to Thrive or Growth Faltering**

- Mechanical feeding difficulties (oromotor dysfunction, congenital anomalies, central nervous system disorders)
- Inadequate caloric intake or caloric absorption: infant feeding problems, underlying
chronic disease or malabsorption syndromes

Incorrect preparation of formula (too diluted, too concentrated)

Unsuitable feeding habits (food fads, excessive juice)

Behavior problems affecting eating

Disturbed parent-child relationship; parental stress, parental lack of knowledge; child neglect

**Clinical manifestations**

Clinical manifestations of FTT are delayed growth accompanied by manifestations of malnutrition or an underlying disease, or both. Infants who present with FTT frequently have feeding problems. Symptoms include delayed growth; pallid or dry, cracked skin; sparse hair; poorly developed musculature; decreased subcutaneous fat; and swollen abdomen with malabsorption, diarrhea, anorexia, and signs of vitamin deficiencies such as rickets. Social or emotional manifestations include reduced energy level, reduced responsiveness and interaction with the environment, social isolation, spasticity and rigidity when held or touched, inability to make eye contact or smile, refusal to eat, and rejection of foods. There may be long-term adverse effects on cognitive, behavioral, and academic performance.86

**Evaluation and treatment**

FTT is suggested if a child falls below the 3rd percentile for weight, or shows stagnation in length or weight.87 Underlying medical conditions are evaluated. If illness is ruled out, a thorough review of psychosocial, emotional, and environmental components of care is necessary. Screening tools are available to assist with evaluation of nutrition status and to guide therapy, particularly in hospitalized children.88

Treatment of FTT includes treating an underlying illness if found, increasing volume or caloric density of formula, increasing frequency of breast-feeding (if found to be insufficient), structuring meals and snacks, and adding high-calorie foods and additives. Eliminating fruit juice, soda, or excessive milk also will improve appetite and absorption of nutrients. Medications are used to stimulate appetite. Nutrient deficiencies are supplemented. If unable to gain weight, an oral enteral supplement may be added to the diet or a nasogastric or gastrostomy tube
can be used to supplement oral intake.

If the cause is not medical, management then involves the immediate total care of the child and measures to address (1) the psychosocial and emotional problems of the caregivers and (2) parent-child interactions. Counseling, parental modeling, and long-term family support are sometimes required. ⁸⁹

Hospital admission and evaluation is recommended if the diagnosis is unclear or the child is in nutritional or emotional jeopardy. Eating patterns, food preferences, caloric intake, and family interactions can be assessed and treatment plans implemented during the hospital stay.

**Necrotizing Enterocolitis**

**Necrotizing enterocolitis (NEC)** is an ischemic, inflammatory condition that causes bowel necrosis and perforation. NEC is not a specific diagnosis but a constellation of signs and symptoms with several proposed etiologies. It is the most common severe neonatal gastrointestinal emergency that predominantly affects the smallest and most premature infants. ⁹⁰, ⁹¹ Approximately 12% of infants born weighing less than 1500 g will develop NEC; of those, about 30% will not survive. ⁹² Isolated or focal intestinal perforation is sometimes confused with NEC and generally is not accompanied by an inflammatory component or by diffuse necrosis. ⁹³

**Pathophysiology**

The exact etiology of NEC is unclear. Factors contributing to the development of NEC include infections, abnormal bacterial colonization, intestinal ischemia, immature immune responses, exaggerated inflammatory responses, immature intestinal motility and barrier function, perinatal stress, effects of medications and feeding practices, and genetic predisposition. The immature mucosal barrier delays digestion and motility is slower, allowing for the accumulation of noxious substances that damage the intestine, increase permeability, and increase the risk for infection. Translocation of intestinal bacteria and other substances contributes to injury, inflammation, and development of systemic inflammatory disease. Immature intestinal innate immunity and an unfavorable balance between normal and pathogenic bacteria promote intestinal inflammation and release of proinflammatory cytokines. Accumulation of gas in the intestine can cause pressure that decreases blood flow, and an imbalance between vasodilator and vasoconstrictor inputs in the immature gut may lead to vasoconstriction promoting ischemia, injury, and necrosis. ⁹⁴

**Clinical manifestations**
Manifestations of NEC usually appear suddenly and within weeks of premature birth, and sooner for term neonates. Signs and symptoms of “classic” NEC include feeding intolerance, abdominal distention and bloody stools after 8 to 10 days of age, septicemia with elevated white blood cell count, and falling platelet levels. Unstable temperature, bradycardia, and apnea are nonspecific signs. In late preterm or term infants, NEC is more likely to be associated with other predisposing factors, such as low Apgar scores, chorioamnionitis, exchange transfusions, prolonged rupture of membranes, congenital heart disease, or neural tube defects.

**Evaluation and treatment**

Abdominal radiographs show pneumatosis intestinalis or portal venous gas, or both. Symptoms usually progress rapidly, often within hours, from subtle signs to abdominal discoloration, intestinal perforation, and peritonitis or even death. Systemic hypotension requires intensive medical support or bowel resection, or both. A study is in progress to identify predictive biologic markers for early diagnosis. Preventive strategies include encouragement of breast milk feeding, judicious fluid management to prevent vascular fluid overload, confirmation of patent ductus arteriosus (see Chapter 25), administration of arginine and glutamine supplements to support intestinal epithelial cell growth, and utilization of enteral probiotics to support normal gut bacteria. The rapid onset of symptoms makes primary prevention difficult.

Treatments include cessation of feeding, implementation of gastric suction to decompress the intestines, maintenance of fluid and electrolyte balance, and administration of antibiotics to control sepsis. Surgical resection is the treatment of choice for perforation, and peritoneal drainage may be used as an adjunct to laparotomy. Overall mortality is high, particularly for infants who have surgery.

**Quick Check 37-3**

1. Why do individuals with cystic fibrosis have pancreatic insufficiency?

2. Why does loss of villi occur with gluten-sensitive enteropathy?

3. Compare kwashiorkor and marasmus.

**Diarrhea**

**Diarrhea** is an increase in the water content, volume, or frequency of stools and can be acute or chronic. Diarrhea is usually defined as three or more watery or loose
stools in 24 hours. Children with acute gastroenteritis often remain mildly symptomatic for up to 4 weeks; therefore, diarrhea that persists longer than 4 weeks is considered chronic. Diarrhea is a common gastrointestinal problem during infancy and early childhood and is the leading cause of death in young children, particularly among preterm infants and children in developing countries, with 760,000 deaths per year. Severe, acute infectious diarrhea occurs one to three times during the first 3 years of life. Most episodes are self-limiting and resolve within 72 hours.

The pathophysiologic mechanisms of diarrhea in children are similar to those described for adults—osmotic, secretory, intestinal dysmotility, or inflammatory (see Chapter 36). Prolonged diarrhea is more dangerous in infants and children, however, because they have much smaller fluid reserves and more rapid peristalsis and metabolism than adults. Therefore dehydration can develop rapidly if any disturbance increases fluid secretion into the gastrointestinal lumen (secretory diarrhea), draws fluid into the lumen by osmosis (osmotic diarrhea), reduces intestinal transit time with luminal fluid retention (intestinal dysmotility), or causes inflammation that results in malabsorption and increased luminal osmotic load from nutrients, fluid, and blood, which may increase gut motility (inflammatory diarrhea).

**Diarrhea in Infants and Children**

There are numerous causes of diarrhea in infants and young children, including bacterial and systemic infections, malabsorption syndromes, autoimmune disorders, congenital malformations, and genetic disorders. Acute infection is a common cause of childhood diarrhea worldwide.

*Acute infectious diarrhea* in infants and young children is usually associated with viral or bacterial gastroenteritis. Viruses include rotaviruses, noroviruses, and adenoviruses. **Rotavirus** is the most common cause in young children and is associated with a higher death rate in low-income countries. Rotavirus vaccine is an effective preventive strategy. Numerous bacteria or parasites can contaminate food or water and cause diarrhea. Specific bacteria can be identified using molecular analysis or stool culture. **Clostridium difficile** is often associated with previous antibiotic therapy.

Infectious diarrhea has a rapid onset, with watery stools sometimes mixed with blood, abdominal cramping, fever, vomiting, and weight loss. Severe dehydration, acidosis, and shock can occur quickly from diarrhea and vomiting. Hemolytic uremic syndrome and renal failure can develop when diarrhea is associated with **Shigella** toxin and **Escherichia coli** infection (see Chapter 31). Other causes of acute...
diarrhea in the older child include antibiotic therapy, appendicitis, chemotherapy, inflammatory bowel disease, parasitic infestation, parenteral infections, and ingestion of toxic substances.

Treatment of diarrhea requires evaluation of cause through history, stool testing for common pathogens, and laboratory analysis. Treatment of underlying illness is warranted when identified. Other treatments include fluid and electrolyte replacement, and antibiotics if a pathogen is found. Antispasmodics may relieve abdominal cramping, and probiotics can reduce duration and improve morbidity and mortality. Intravenous solutions are used only when oral solutions are not tolerated. Prevention includes clean water, environmental sanitation, and good hygiene.

Primary lactose intolerance.

Lactose malabsorption and intolerance, the inability to digest milk sugar, is caused by inadequate production or impaired activity of the enzyme lactase. It is a common cause of diarrhea, particularly in nonwhite children under the age of 7 years. The malabsorption of lactose results in osmotic diarrhea accompanied by abdominal pain, bloating, and flatulence. Systemic manifestations include skin disease, rheumatologic complaints, chronic fatigue, and failure to thrive. Diagnosis includes elimination of dietary lactose or implementation of hydrogen lactose breath testing. Treatment consists of reducing milk consumption or supplementing the diet with oral lactase. Some children can tolerate lactose in fermented forms, such as cheese and yogurt, or by adding soy food. Utilization of a diet low in fermentable oligosaccharides, disaccharides, and monosaccharides and polyols (FODMAPs) or administration of probiotics to alter intestinal flora has been found to be effective in lactose-intolerant irritable bowel syndrome children with persistent symptoms.
Disorders of the Liver

Disorders of Biliary Metabolism and Transport

Neonatal Jaundice

Jaundice (icterus) is a yellow pigmentation of the skin caused by an increased level of bilirubin in the bloodstream (total serum bilirubin [TSB]) that exceeds the 95th percentile for the infant’s age in hours or greater than 20 mg/dl, except in the low birth weight population. Jaundice usually becomes clinically apparent when the serum bilirubin concentration is greater than 2 mg/dl (34 µmol/L). Physiologic jaundice (hyperbilirubinemia) of the newborn, or neonatal bilirubinemia, is a frequently encountered problem in otherwise healthy newborns caused by lack of maturity of bilirubin uptake and conjugation. Poor caloric intake or dehydration, or both, associated with inadequate breast-feeding also may contribute to the high levels of bilirubin. Although up to 60% of term newborns have clinical jaundice in the first week of life, with a higher percentage in the preterm population, few have significant underlying disease. High bilirubin levels in the newborn period can be associated with hemolytic disease, metabolic and endocrine disorders, anatomic abnormalities of the liver, and infections. For older infants and children, the most common causes of unconjugated hyperbilirubinemia are hemolytic processes resulting in bilirubin overproduction. Pathologic jaundice is a bilirubin concentration greater than 20 mg/dl in the newborn period associated with a severe illness, or a total serum bilirubin level that rises by more than 5 mg/dl during the newborn period.

Risk factors for development of pathologic jaundice include fetal-maternal blood type incompatibility (ABO and Rh incompatibility, hemolytic disease in the newborn), premature birth, exclusive breast-feeding in some infants, maternal age greater than or equal to 25 years, male gender, delayed meconium passage, glucose-6-phosphate dehydrogenase deficiency, and excessive birth trauma such as bruising or cephalohematomas.106,107

Pathophysiology

Pathologic jaundice results from the complex interaction of factors that cause (1) increased bilirubin production (e.g., hemolysis), (2) impaired hepatic uptake or excretion of unconjugated bilirubin, or (3) delayed maturation of liver bilirubin conjugating mechanisms.108 The most common cause is hemolytic disease of the newborn (ABO blood incompatibility) (see Chapters 8 and 22), and all pregnant women should be tested for ABO and Rh incompatibility. Unconjugated bilirubin (indirect bilirubin) is lipid soluble and bound to albumin in the blood, and in the
free form it readily crosses the blood-brain barrier in infants. Chronic bilirubin encephalopathy (kernicterus) is caused by the deposition of toxic, unconjugated bilirubin in brain cells and usually does not occur in healthy, full-term infants. The mechanism of injury is not clearly known. Elevated conjugated bilirubin level is a sign of underlying disease.

**Clinical manifestations**

Physiologic jaundice develops during the second or third day after birth and usually subsides in 1 to 2 weeks in full-term infants and in 2 to 4 weeks in premature infants. After this, increasing bilirubin values and persistent jaundice indicate pathologic hyperbilirubinemia. Manifestations include yellowing of skin, dark urine, light-colored stools, and weight loss. Premature infants with respiratory distress, acidosis, or sepsis are at greater risk for kernicterus (brain damage related to unconjugated hyperbilirubinemia) and the development of athetoid cerebral palsy and speech and hearing impairment.¹⁰⁹

**Evaluation and treatment**

Jaundice is detected by clinical assessment. Both total and direct (conjugated) bilirubin levels are monitored as described previously. Other causes of jaundice must be eliminated to confirm physiologic jaundice. Treatment depends on the degree of hyperbilirubinemia. Physiologic jaundice is commonly treated by phototherapy and several techniques are available.¹¹⁰ Pathologic jaundice requires an exchange transfusion and treatment of the underlying disorder.

**Biliary Atresia**

Biliary atresia (BA) is a rare congenital malformation (from 1 in 8000 to 1 in 18,000 live births) characterized by the absence or obstruction of intrahepatic or extrahepatic bile ducts; the most common cause of BA is neonatal cholestasis.¹¹¹ The etiology of duct injury is not clear but is thought to be related to an embryonic, congenital, or genetic abnormality or an acquired, perinatal viral-induced progressive inflammation with innate autoimmune destruction. The disease expression is a continuum in which the principal process is one of bile duct destruction.¹¹² The atresia or obstruction of the bile ducts leads to plugging, inflammation, fibrosis of the bile canaliculi, and cholestasis. Progressive obstruction leads to secondary biliary cirrhosis (see Chapter 36), portal hypertension, or liver failure.

Jaundice is the primary clinical manifestation of biliary atresia, along with hepatomegaly and acholic (clay-colored) stools. Fat absorption is impaired because
of the lack of bile salts. Abdominal distention caused by hepatomegaly and ascites may cause anorexia and failure to thrive. Fat-soluble vitamin (A, D, E, K) deficiencies require supplementation. Manifestations of cirrhosis and liver failure include ascites, hypoalbuminemia, hypercoagulation, pruritus, esophageal varices, and gastrointestinal bleeding that may lead to death.

Early diagnosis of biliary atresia is essential with the best outcome occurring when diagnosed and treated in the first 30 to 45 days of life. Late diagnosis of BA does not respond well to current surgical treatment. Diagnosis of BA is based on clinical manifestations, abnormal liver function tests, liver biopsy results, and intraoperative cholangiogram. Serum aminotransaminase and alkaline phosphatase levels are elevated and conjugated (direct) serum bilirubin levels rise progressively. BA can be relieved by hepatopancreatobiliary surgery (HPE or Kasai procedure). Even with initial restoration of bile flow, however, obliteration of intrahepatic bile ducts can continue and cirrhosis results. Liver transplantation is a successful long-term therapy for biliary atresia. Eighty percent of children with biliary atresia die before the age of 3 years if not treated.

Inflammatory Disorders

Hepatitis

Details related to viral hepatitis are presented in Chapter 36, including differentiation of types of viruses (see Table 36-8).

Hepatitis A virus (HAV).

Approximately 30% to 50% of the reported cases of hepatitis A virus (HAV) occur in children, particularly children of nursery school age. Outbreaks tend to occur in day-care centers with large numbers of children who are not toilet trained and staff members who practice poor handwashing techniques. Vertical transmission from mother to newborn or from a transfusion is rare. HAV in children is usually mild and asymptomatic, but it may involve nausea, vomiting, and diarrhea. Jaundice appears in more than 70% of older children. Almost all children recover from hepatitis A without residual liver damage. Relapse HAV occurs in 3% to 20% of individuals. Vaccination programs have successfully reduced the incidence of HAV in the United States by 92% since their introduction.

Hepatitis B virus (HBV).

Risk factors for hepatitis B virus (HBV) include infants of mothers who are chronic hepatitis B virus (HBV) surface antigen (HBsAg) carriers, children from
families that immigrated to the United States or are adopted from endemic areas, infection from HBsAg-positive household contacts, and children who abuse parenteral drugs or engage in unprotected sex. Ninety percent of newborns are infected by their mothers (vertical transmission); 25% to 50% of children between the ages of 1 and 5 years of age who are acutely infected will develop chronic infection. Chronic hepatitis may develop because the infant's immune system is immature. Infected infants are at risk for cirrhosis and hepatocellular carcinoma. The most serious consequence of HBV infection is fulminant hepatitis, which occurs in 1% of cases. **Hepatitis D virus (HDV)** infection depends on active infection with HBV. Exacerbation of HBV is more common in children with superinfected HDV. There is evidence that the risk of fulminant hepatitis is higher in individuals with combined infection of HBV and HDV than in those with HBV infection alone. There also is a higher risk of hepatocellular carcinoma and increased mortality in this group. Aggressive HBV vaccination programs have reduced the incidence of HBV; HDV reduction has mirrored this response. To prevent perinatal transmission of HBV, immunoprophylaxis and HBV vaccination within the first 12 hours of birth are recommended with close follow-up visits. Treatment is conservative and antivirals are used for chronic disease. Children ages 2 to 17 years who are hepatitis B surface antigen (HBsAg) seropositive for more than 6 months with elevated serum alanine transaminase (ALT) and HBV DNA levels for more than 3 months may be eligible for treatment with antivirals. Maternal antiviral therapy may be given during the third trimester when there is impending liver decompensation.

**Hepatitis C virus (HCV).**

**Hepatitis C virus (HCV)** in children is most commonly transmitted vertically and is enhanced with maternal coinfection with human immunodeficiency virus (HIV). Risk factors for vertical transmission include internal fetal monitoring, prolonged rupture of membranes, and fetal anoxia. HCV transmission also can occur through exposure to infected blood or contaminated materials (as in injection drug use or tattooing and body piercing) and, less commonly, following sexual encounters with HCV-infected partners. Transmission from blood transfusions has become a negligible risk with universal HCV screening of blood. With vertical transmission, spontaneous resolution of HCV is high, up to 40%; otherwise, the disease is usually mild in children and cirrhosis is rare. Because of adverse drug events, only children with persistently elevated serum aminotransferases or those with progressive liver disease are treated with antiviral drugs.
Chronic hepatitis.

Hepatitis B virus (HBV) and hepatitis C virus (HCV) are the main causes of chronic hepatitis in children. Manifestations of chronic hepatitis include malaise, anorexia, fever, gastrointestinal bleeding, hepatomegaly, edema, and transient joint pain. Often there are no symptoms. Serum alanine aminotransferase and bilirubin levels are elevated. There may be evidence of impairment of synthetic functions of the liver: prolonged prothrombin time, thrombocytopenia, and hypoalbuminemia. Diagnosis is based on the clinical manifestations and liver biopsy results. There is no curative therapy for chronic HBV or chronic HCV. Children are treated with antiviral drugs and should continue to be monitored. Liver transplant may ultimately be required for chronic hepatitis.

There also is an autoimmune form of chronic hepatitis, known as autoimmune hepatitis (AIH) or autoimmune primary sclerosing cholangitis (PSC), with unknown etiology. The pathogenic mechanism is thought to be immunologic, environmental, or genetic in nature. These diseases present with elevations in the levels of aminotransferases, autoantibodies, and immunoglobulin G (IgG). AIH is more common in female children, and both are treated with immunosuppressive therapy; about 50% to 80% will achieve remission and long-term survival.

Cirrhosis

Cirrhosis is fibrotic scarring of the liver in response to inflammation and tissue damage resulting in obstruction to the flow of blood and bile. Most forms of chronic liver diseases in children can progress to cirrhosis, but they seldom do so. The complications of cirrhosis in children are the same as those in adults: portal hypertension, the opening of collateral vessels between the portal and systemic veins, and varices. In addition, children with cirrhosis experience growth failure caused by nutritional deficits, as well as developmental delay, particularly in gross motor function because of ascites and weakness. The cause of cirrhosis may influence its severity and course. Some types of cirrhosis can be stabilized if the cause is identified and treated early. The risk of cirrhosis is increasing in obese children with nonalcoholic fatty liver disease (see Health Alert: Childhood Obesity and Nonalcoholic Fatty Liver Disease).

Health Alert

Childhood Obesity and Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is the most common cause of chronic
Liver disease in children and is associated with obesity, insulin resistance, genetic predisposition, the gut microbiome, and environmental factors. The rise in childhood obesity worldwide is contributing to the increasing prevalence of NAFLD. The disease usually presents in prepubertal children and is predominant in males and in children of Hispanic origin. Diagnosis is made by exclusion of other disease causes. Liver biopsy is required for definitive diagnosis of steatosis (hepatic fat accumulation greater than 5%), and there are differences in the extent of fat, inflammation, and fibrosis in children compared with adults. There is no consensus regarding treatment. Exercise and slow, consistent weight loss with a low glycemic index diet have been shown to be more effective than a low-fat diet in lowering body weight. Pharmacologic agents are being evaluated to control insulin resistance and prevent progression of liver disease, and cirrhosis and vitamin E may be a specific therapy. Research is in progress to define the pathophysiology, noninvasive diagnostic procedures, and prevention of this disease.

Portal Hypertension

Portal hypertension is increased pressure in the portal venous system (see Chapter 36) and a major cause of morbidity and mortality in children with liver disease. There are two basic causes of portal hypertension in children: (1) increased resistance to blood flow within the portal system and (2) increased volume of portal blood flow. The second cause is rare in children and is not discussed here. Increased resistance to flow can occur anywhere in the portal circulatory system. Portal hypertension can accompany cirrhosis, intra-abdominal infections, portal vein thrombosis, congenital anomalies of the portal vein, and congenital hepatic fibrosis.

Types of Portal Hypertension

Extrahepatic portal hypertension.

Extrahepatic (prehepatic) portal venous obstruction causes 50% to 70% of the cases of extrahepatic portal hypertension in children. In approximately two thirds of these children, no specific cause can be found. Obstruction is almost always in the portal vein and is usually caused by thrombosis as a complication of abdominal trauma, pancreatitis, abdominal infections, and some systemic disorders; however, these causes are rare. Life-threatening bleeding and coagulation disorders can occur. Mesoportal bypass (anastomosis of portal vein to mesenteric vein) restores
normal physiologic portal flow to the liver and corrects portal hypertension.\textsuperscript{129}

**Intrahepatic portal hypertension.**

Liver fibrosis is the primary cause of \textit{intrahepatic portal hypertension}. The fibrosis can lead to cirrhosis with increased resistance to portal blood flow by constricting and reducing the compliance of hepatic sinusoids. Chronic hepatitis, biliary atresia, nonalcoholic fatty liver disease, and congenital hepatic fibrosis are causes of liver fibrosis in children.\textsuperscript{130-132}

The clinical manifestations of portal hypertension are (1) splenomegaly, (2) upper gastrointestinal tract bleeding, (3) ascites, (4) hepatopulmonary syndrome, (5) hepatorenal syndrome, and (6) hepatic encephalopathy (see \textit{Chapter 36}).

The objectives of the clinical investigation are to (1) locate the site of the venous block and (2) identify the disease responsible for the portal hypertension. Thorough physical examination; laboratory evaluation of liver function, white blood count, and platelet count; ultrasonographic imaging; endoscopic evaluation; and biopsy may be included in the diagnostic evaluation. Treatment in children is the same as that in adults (see \textit{Chapter 36}).

The outcome of portal hypertension depends almost entirely on its cause. Children with extrahepatic disease are expected to recover with little morbidity. For children with intrahepatic disease, the prognosis varies.

**Metabolic Disorders**

More than 5000 genetically determined metabolic pathways have been identified in liver tissue. The earliest possible identification of metabolic disorders is essential because (1) early treatment may prevent permanent damage to vital organs, such as the liver or brain; (2) precise genetic counseling may be possible with prenatal diagnosis; and (3) complications can be minimized, even if cure is not possible. \textit{Galactosemia, fructosemia, glycogen storage disease (GSD)}, and \textit{Wilson disease} are treatable metabolic disorders that have hepatic clinical manifestations. The mechanisms of disease, clinical manifestations, and evaluation and treatment of these disorders are presented in Table 37-2.

**Quick Check 37-4**

1. Why is diarrhea such a serious disorder in infants and children?

2. What is biliary atresia?
3. What are the three most common metabolic disorders that cause liver damage in children?

1. Alterations of digestive function in children include congenital obstructions of the intestinal tract; disorders of digestion, absorption, or nutrition; or liver disease.

2. Cleft lip and cleft palate (failure of the bony palate to fuse in the midline) may occur separately or together. The fissure may affect the uvula, soft palate, hard palate, nostril, and maxillary alveolar ridge, with difficulty sucking and swallowing.

3. Esophageal atresia, a condition in which the esophagus ends in a blind pouch, may occur with or without tracheoesophageal fistula. As the infant swallows oral secretions or ingests milk, the pouch fills, causing either drooling or aspiration into the lungs.

4. Infantile hypertrophic pyloric stenosis is an obstruction of the pyloric outlet caused by hypertrophy of circular muscles in the pyloric sphincter.

5. In intestinal malrotation, the small intestine lacks a normal posterior attachment during fetal development, causing volvulus (twisting of the bowel on itself) that may partly or completely occlude the gastrointestinal tract and its blood vessels.

6. Meckel diverticulum is a congenital malformation of the gastrointestinal tract involving all layers of the small intestinal wall; it usually occurs in the ileum.

7. Meconium ileus is a newborn condition in which intestinal secretions and amniotic waste products produce a thick, tarry plug that obstructs the intestine; it occurs in 10% to 15% of newborns with cystic fibrosis.

8. Idiopathic intestinal pseudo-obstruction is a disorder of impaired intestinal motility.

9. Congenital aganglionic megacolon (Hirschsprung disease) is caused by a malformation of the parasympathetic nervous system in a segment of the colon needed for peristalsis, resulting in colon obstruction.

10. Malformations of the anus and rectum range from mild congenital stenosis of the anus to complex deformities, all of which are classified as imperforate anus.
11. Intussusception is a condition in which one portion of the bowel telescopes, or invaginates, into another, most commonly in the area of the ileocecal junction, and causes obstruction.

12. Gastroesophageal reflux disease is the presence of symptoms related to the return of stomach contents into the esophagus caused by relaxation or incompetence of the lower esophageal sphincter that results from immaturity of the gastroesophageal sphincter.

13. Intussusception is the telescoping of a proximal segment of intestine into a distal segment, causing an obstruction.

14. Cystic fibrosis is an inherited fibrocystic disease that involves mucosal chloride and sodium ion channels in many organs, including the GI tract and pancreas; CF causes pancreatic enzyme deficiency with maldigestion.

15. Celiac disease is caused by hypersensitivity to gluten protein, with autoimmune injury and loss of the villous epithelium. It results in malabsorption and growth failure.

16. Pediatric malnutrition is an imbalance between nutrient requirements and intake that results in energy, protein, and micronutrient deficits, which negatively impact growth and development.

17. Kwashiorkor is a severe protein deficiency. Marasmus is a deficiency of all dietary nutrients, including carbohydrates.

18. Failure to thrive or growth faltering is a multifactorial condition that includes biologic, psychosocial, and environmental contributions; may or may not be illness related; and results in inadequate physical growth and development of a child.

19. Necrotizing enterocolitis is an ischemic, inflammatory disorder in neonates, particularly premature infants, thought to result from immaturity, infection, stress, and anoxia of the bowel wall.

20. Acute diarrhea in infants and children is three or more watery or loose stools in 24 hours; it is commonly caused by viral or bacterial enterocolitis.

21. Chronic diarrhea (diarrhea persisting longer than 4 weeks) can be caused by a wide variety of underlying conditions and often leads to growth failure and slow
development.

22. Primary lactose intolerance is the inability to digest milk sugar because of a lack of the enzyme lactase, resulting in osmotic diarrhea.

Disorders of the Liver

1. Physiologic jaundice of the newborn is caused by mild hyperbilirubinemia that subsides in 1 or 2 weeks. Pathologic jaundice is caused by severe hyperbilirubinemia and can cause brain damage (kernicterus).

2. Biliary atresia is a congenital malformation of the bile ducts that obstructs bile flow and causes jaundice, cirrhosis, and liver failure.

3. Acute hepatitis is usually caused by a virus, and hepatitis A is the most common form of childhood hepatitis. Chronic hepatitis B or C usually occurs by maternal transmission.

4. Cirrhosis results from fibrotic scarring of the liver and is rare in children, but it can develop from most forms of chronic liver disease.

5. Portal hypertension in children usually is caused by extrahepatic obstruction and the cause is often unknown. Intrahepatic obstruction is related to diseases that cause liver fibrosis.

6. The four most common metabolic disorders that cause liver damage in children are galactosemia, fructosemia, glycogen storage disease, and Wilson disease. All three are inherited as genetic traits and allow toxins to accumulate in the liver.

The way an individual functions in daily life, moves about, or manipulates objects physically depends on the integrity of the musculoskeletal system. The musculoskeletal system is actually two systems: (1) the skeleton composed of bones and joints and (2) soft tissues (skeletal muscles, tendons, and ligaments). Each system contributes to mobility. The skeleton supports the body and provides leverage to the skeletal muscles so that movement of various parts of the body is possible. Contraction of the skeletal muscles and bending or rotation at the joints facilitate movements of the various body parts.
Structure and Function of Bones

Bones give form to the body, support tissues, and permit movement by providing points of attachment for muscles. Many bones meet in movable joints that determine the type and extent of movement possible. Bones also protect many of the body's vital organs. For example, the bones of the skull, thorax, and pelvis are hard exterior shields that protect the brain, heart and lungs, and reproductive and urinary organs, respectively.

The marrow cavities within certain bones serve as sites of blood cell formation. In adults, blood cells originate exclusively in the marrow cavities of the skull, vertebrae, ribs, sternum, shoulders, and pelvis. The development of blood cells is discussed in Chapter 20. Bones also have a crucial role in mineral homeostasis (storing minerals [i.e., calcium, phosphate, carbonate, magnesium] that are essential for the proper performance of many delicate cellular mechanisms), play a role in hormone homeostasis, and assist in maintaining normal immunologic function.

Elements of Bone Tissue

Mature bone is a rigid connective tissue consisting of cells, fibers, a gelatinous material termed ground substance, and large amounts of crystallized minerals, mainly calcium, that give bone its rigidity. Ground substance consists of proteoglycans and hyaluronic acid secreted by chondroblasts. The structural elements of bone are summarized in Table 38-1.

Bone cells enable bone to grow, repair itself, change shape, and continuously synthesize new bone tissue and **resorb** (dissolve or digest) old tissue. The fibers in bone are made of collagen, which gives bone its tensile strength (the ability to hold itself together). Ground substance acts as a medium for the diffusion of nutrients, oxygen, metabolic wastes, biochemicals, and minerals between bone tissue and blood vessels.

Bone formation begins during fetal life with the growth of cartilage—the precursor of bone tissue. In mature bone, the formation of new tissue begins with the production of an organic matrix by the bone cells. This **bone matrix** consists of ground substance, collagen, and other proteins (see Table 38-1) that take part in bone formation and maintenance.

The next step in bone formation is **calcification**, in which minerals are deposited and then crystallize. Minerals bind tightly to collagen fibers, producing tensile and
compressional strength in bone and allowing it to withstand pressure and weightbearing.

**Bone Cells**

Bone contains three types of cells: osteoblasts, osteocytes, and osteoclasts (Figure 38-1). Both osteoblasts and osteocytes originate from osteoprogenitor cells found in the mesenchymal stem cell lineage. Unlike osteoblasts and osteocytes, osteoclasts originate from hematopoietic stem cells. Osteoblasts are the bone-forming cells. Once this function is complete, osteoblasts become osteocytes. Osteocytes, the most numerous cells within bone, are osteoblasts that have become imprisoned within the mineralized bone matrix. They have multiple important duties in maintaining bone homeostasis, including synthesizing new bone matrix molecules and initiating osteoclast function. Osteoclasts primarily resorb (remove) bone during processes of growth and repair.

![Bone Cells](image)

**FIGURE 38-1 Bone Cells.** A, Osteoblasts are responsible for the production of collagenous and noncollagenous proteins that compose osteoid. Active osteoblasts are aligned on the osteoid. Note the eccentrically located nuclei. B, Electron photomicrograph of an osteocyte. Osteocytes reside within the lacunae of compact bone. C, Osteoclasts actively resorb mineralized tissue. The scalloped surface in which the multinucleated osteoclasts rest is termed Howship lacuna. (A and C from Damjanov I, Linder J, editors: Anderson’s pathology, ed 10, St Louis, 1996, Mosby; B from Wikimedia Commons, courtesy Robert M. Hunt.)

**Osteoblasts.**

Originating from mesenchymal stem cells (MSCs), osteoblasts are the primary bone-producing cells, and are involved in many functions related to the skeletal system (see Table 38-1). Osteoblasts are responsive to parathyroid hormone (PTH) and produce osteocalcin when stimulated by 1,25-dihydroxy-vitamin D₃.¹ Osteoblasts are active on the outer surfaces of bones, where they form a single layer
of cells. Osteoblasts initiate new bone formation by their synthesis of osteoid (nonmineralized bone matrix). Osteoblasts also mineralize newly formed bone matrix. Stimulation of new bone formation and orderly mineralization of bone matrix occur by concentrating some of the plasma proteins (growth factors) found in the bone matrix and by facilitating the deposit and exchange of calcium and other ions at the site. Enzymes, signaling proteins, and growth factors, including bone morphogenic proteins (BMPs) and other members of the transforming growth factor-beta (TGF-β) superfamily, are critical components of bone formation, maintenance, and remodeling (Table 38-2).

<tr>
<td>Activin</td>
<td>Important in differentiating osteoblasts, bone formation; has overlapping effects with BMPs, helps regulate bone formation and remodeling; crosstalks with other signaling pathways</td>
</tr>
</tbody>
</table>
Osteoblasts use intercellular calcium signaling to include osteoclastic activity. One of the most important discoveries linking osteoblast and osteoclast function is that of the cytokine receptor activator nuclear factor kappa-B ligand, or RANKL (see below). RANKL is expressed by osteoblasts and osteocytes and is necessary for forming osteoclasts²⁻⁴ (see Osteoclasts). Thus, the cells of the osteoblastic lineage (osteoblasts, osteocytes) form a network of cells in bone that sense the shape and structure of bone and determine where it is appropriate that bone be formed or resorbed, according to Wolff law (bone is shaped according to its function).

Osteoblasts synthesize and secrete osteoid when active, and in the resting state they are termed satellite cells. If appropriately stimulated, however, the resting osteoblasts are capable of resuming activity.

**Osteocytes.**

Osteocytes, the most abundant cells in bone, are transformed osteoblasts trapped or surrounded in osteoid as it hardens because of minerals that enter during calcification (see Figure 38-1, B). The osteocyte is within a space in the hardened bone matrix called a lacuna. Each osteocyte contains long, thin cytoplasmic extensions, called processes, which run through the canaliculi, providing communication with osteoblasts lying on the bone surface. Another form of extracellular communication used by osteocytes is through transmembrane channels called gap junctions, which connect the cytoplasm of adjacent cells.

Osteocytes are the most abundant cells found in bone and have numerous functions, including acting as mechanoreceptors and synthesizing certain matrix molecules, playing a major role in controlling osteoblast differentiation and...
production of growth factors, and maintaining bone homeostasis.\textsuperscript{5} As the major source of sclerostin, RANKL, and osteoprotegerin (OPG), osteocytes are thought to be key regulators of both bone formation and bone resorption.\textsuperscript{6-8} They also help concentrate nutrients in the matrix. Osteocytes obtain nutrients from capillaries in the canaliculi, which contain nutrient-rich fluids. Through exchanges among these cells, hormone catalysts, and minerals, optimal levels of calcium, phosphorus, and other minerals are maintained in blood plasma.

One of the osteocyte's primary functions is to act as a mechanoreceptor, responding to changes in weightbearing or other stressors (“loading”) on bone. Lying within the lacunae are the osteocyte's primary cilia, which are likely the primary mechanoreceptors in bone.\textsuperscript{9,10} Once changes in bone, such as mechanical stress, hormonal imbalance, loading, or unloading, are detected by the osteocyte's mechanoreceptors, multiple molecular signals are produced and the process of bone remodeling begins.\textsuperscript{4,11} Remodeling is described on p. 974.

**Osteoclasts.**

Osteoclasts are large (typically 20 to 100 µm in diameter), multinucleated cells that develop from the hematopoietic monocyte-macrophage lineage. Osteoclasts are the major resorptive cells of bone. They migrate over bone surfaces to resorption areas that have been prepared and stripped of osteoid by enzymes, such as collagenases produced by osteoblasts in the presence of PTH, which is necessary for the resorptive process. Osteoclasts travel over the prepared bone surfaces, creating irregular, scalloped cavities known as *Howship lacunae* or *resorption bays*, as they resorb bone areas and then acidify hydroxyapatite in order to dissolve it.

A specific area of the cell membrane forms adjacent to the bone surface and develops multiple infoldings to permit intimate contact with the resorption bay. These infoldings, known as the **ruffled border**, greatly increase the surface areas of cells under their scalloped or ruffled borders. Osteoclasts resorb bone by secretion of hydrochloric acid, acid proteases (such as cathepsin K), and matrix metalloproteinases (MMPs) that help digest collagen, along with the action of cytokines (see Table 38-2). Osteoclasts also resorb bone through the action of lysosomes (digestive vacuoles) filled with hydrolytic enzymes in their mitochondria.

Osteoclasts bind to the bone surfaces through attachments called **podosomes**, which are foot-like structures that cluster together along a sealing membrane that forms a “belt” containing multiple proteins, enzymes, and **integrin** receptors.\textsuperscript{12,13} Once resorption is complete, the osteoclasts retract and loosen from the bone surface under the ruffled border through the action of calcitonin. Calcitonin binds to
receptor areas of the osteoclasts' cell membranes to effectively loosen the osteoclasts from the bone surfaces. Once resorption is completed, osteoclasts disappear by the process of degeneration, either by reverting to the form of their parent cells or by undergoing cell movements away from the site, in which the osteoclast becomes an inactive or resting osteoclast.

In addition to resorption of bone, osteoclasts assist the endocrine and renal systems in maintaining appropriate serum calcium and phosphorus levels. Osteoclasts also appear to have a role in the body's immune response.\textsuperscript{12}

**OPG/RANKL/RANK System**

**Osteoprotegerin (OPG)** is a glycoprotein belonging to the tumor necrosis factor superfamily and inhibits bone remodeling/resorption, inhibiting osteoclast formation. Numerous cells, including osteoblasts and osteocytes, produce it. OPG is key in the interaction between osteoblasts and osteoclasts.\textsuperscript{14} Osteoblasts and osteoclasts cooperate (a process called *coupling*) to maintain normal bone homeostasis. RANKL is an essential cytokine needed for the formation and activation of osteoclasts. RANKL, like an automobile's accelerator, increases bone loss. OPG, similar to an automobile's brakes, decreases bone loss because when it is activated it promotes bone formation. When RANKL binds to its receptor RANK on osteoclast precursor cells, it triggers their proliferation and increases bone resorption. OPG is secreted by osteoblasts and B lymphocytes\textsuperscript{15} and serves as a decoy by binding to RANK, preventing RANKL binding to RANK, and thus preventing bone resorption. Therefore, the overall balance between RANKL and OPG determines the amount of bone loss. The balance between RANKL and OPG is regulated by cytokines and hormones.\textsuperscript{16} Alterations of the RANKL/RANK/OPG system can lead to dysregulation and pathologic conditions, including primary osteoporosis, immune-mediated bone diseases, malignant bone disorders, and inherited skeletal diseases (see Figure 38-5).

**Bone Matrix**

Bone matrix is made of the *extracellular elements* of bone tissue, specifically collagen fibers, structural proteins (such as proteoglycans and certain glycoproteins), carbohydrate-protein complexes, ground substance, and minerals.

**Collagen fibers.**

**Collagen fibers** make up the bulk of bone matrix. They are formed as follows:

1. Osteoblasts synthesize and secrete type I collagen and osteocalcin.
2. Collagen molecules assemble into three thin chains (alpha chains) to form fibrils.

3. Fibrils organize into the staggered pattern, with each fibril overlapping its nearest neighbor by about one fourth its length. This creates gaps into which mineral crystals are deposited.

4. After mineral deposition, fibrils interlink and twist to form ropelike fibers.

5. The fibers join to form the framework that gives bone its tensile and supportive strength.

**Proteoglycans.**

Proteoglycans are large complexes of numerous polysaccharides attached to a common protein core. They strengthen bone by forming compression-resistant networks between the collagen fibers. Proteoglycans also control the transport and distribution of electrically charged particles (ions), particularly calcium, through the bone matrix, thereby playing a role in bone calcium deposition and calcification. Proteoglycans are important constituents of ground substance.

**Glycoproteins.**

Glycoproteins are carbohydrate-protein complexes that control the collagen interactions that lead to fibril formation. They also may function in calcification. Four glycoproteins are present in bone: sialoprotein, which binds easily with calcium; osteocalcin, which binds preferentially to crystallized calcium; bone albumin, which is identical to serum albumin and possibly transports essential nutrients to and from bone cells and maintains the osmotic pressure of bone fluid; and alpha-glycoprotein (α-glycoprotein), which probably plays a significant role in calcification and also may facilitate bone resorption by activating osteoclasts (see Table 38-1).

**Bone Minerals**

After collagen synthesis and fiber formation, mineralization, the final step, occurs in areas known as matrix vesicles that “bud” from the surfaces of osteoblasts, chondrocytes (cartilage cells), and odontoblasts (cells that form dentin in teeth). Mineralization has two distinct phases: (1) formation of the initial mineral deposit (initiation) and (2) proliferation or accretion of additional mineral crystals on the initial mineral deposits (growth). The majority of the minerals in the body are an analog of the naturally occurring mineral **hydroxyapatite (HAP)**. The HAP
crystals then penetrate the matrix vesicle membrane and enter into the extracellular space.\textsuperscript{17}

Table 38-3 lists the sequence in which calcium and phosphate form amorphous (fluid) calcium phosphate compounds that are converted, in stages, to solid hexagonal crystals of HAP. As the calcium and phosphorus concentrations increase in the bone matrix, the first precipitate to form is dicalcium phosphate dihydrate (DCPD). Once DCPD precipitation begins, the remaining phases of bone crystal formation proceed until insoluble HAP is produced, with approximately 80% to 90% of the HAP incorporated into the collagen fibers. Amorphous calcium phosphate is distributed throughout the bone matrix.

\textbf{TABLE 38-3}

\textbf{Sequence of Calcium and Phosphate Compound Formation and Crystallization*}

*Compounds are listed in the order in which precipitation and crystal formation occur.

\textbf{Types of Bone Tissue}

Bone is composed of two types of bony (osseous) tissue: \textbf{compact bone (cortical bone)} and \textbf{spongy bone (cancellous bone)} (Figure 38-2). Cortical bone is about 85% of the skeleton; cancellous bone makes up the remaining 15%. Both types of bone tissue contain the same structural elements, with a few exceptions. In addition, both compact tissue and spongy tissue are present in every bone. The major difference between the two types of tissue is the organization of the elements.
Compact bone is highly organized, solid, and extremely strong. The basic structural unit in compact bone is the **haversian system** (Figure 38-3). Each
haversian system consists of the following:

1. A central canal called the **haversian canal**
2. Concentric layers of bone matrix called **lamellae** (sing., **lamella**)
3. Tiny spaces (lacunae) between the lamellae
4. Bone cells (osteocytes) within the lacunae
5. Small channels or canals called **canaliculi** (sing., **canaliculus**)

**FIGURE 38-3** Structure of Compact and Cancellous Bone. A, Magnified view of compact bone. B, Longitudinal section of a long bone showing both cancellous and compact bone. C, Section of a flat bone. Outer layers of compact bone surround cancellous bone. Fine structure of compact and cancellous bone is shown in the electron photomicrograph. (From Patton KT, Thibodeau GA: Anatomy & physiology, ed 9, St Louis, 2016, Mosby. Photo courtesy Dennis Strete.)
Spongy bone is less complex and lacks haversian systems. In spongy bone, the lamellae are not arranged in concentric layers but in plates or bars termed **trabeculae** (sing., **trabecula**) that branch and unite with one another to form an irregular meshwork. The pattern of the meshwork is determined by the direction of stress on the particular bone. The spaces between the trabeculae are filled with red bone marrow. The osteocyte-containing lacunae are distributed between the trabeculae and interconnected by canaliculi. Capillaries pass through the marrow to nourish the osteocytes.

All bones are covered with a double-layered connective tissue called the **periosteum**. The outer layer of the periosteum contains blood vessels and nerves, some of which penetrate to the inner structures of the bone through channels called **Volkmann canals** (see **Figure 38-3**). The inner layer of the periosteum is anchored to the bone by collagenous fibers (Sharpey fibers) that penetrate the bone. Sharpey fibers also help hold or attach tendons and ligaments to the periosteum of bones.

**Characteristics of Bone**

The 206 bones of the human skeleton are distributed between the axial skeleton and the appendicular skeleton. The **axial skeleton**—the skull, vertebral column, and thorax—consists of 80 bones. The other 126 bones of the **appendicular skeleton** comprise the upper and lower extremities, the shoulder girdle (pectoral girdle), and the pelvic girdle (os coxae) (**Figure 38-4**). The skeleton contributes approximately 14% of an adult's body weight.
Bones can be classified by shape as long, flat, short (cuboidal), or irregular. **Long bones** are longer than they are wide and consist of a narrow tubular midportion (**diaphysis**) that merges into a broader neck (**metaphysis**) and a broad end (**epiphysis**) (see Figure 38-2).

The diaphysis consists of a shaft of thick, rigid compact bone that is able to tolerate bending forces. Contained within the diaphysis is the elongated marrow (medullary) cavity. The marrow cavity of the diaphysis contains primarily fatty tissue, which is referred to as yellow marrow. The yellow marrow assists red bone marrow in hematopoiesis only during times of stress. The yellow marrow cavity of the diaphysis is continuous with marrow cavities in the spongy bone of the metaphysis and diaphysis. The marrow contained within the epiphysis is red because it contains primarily blood-forming tissue (see Chapter 20). A layer of connective tissue, the **endosteum**, lines the outer surfaces of both types of marrow cavity.

The broadness of the epiphysis allows weightbearing to be distributed over a wide area. The epiphysis is made up of spongy bone covered by a thin layer of compact bone. In a child, the epiphysis is separated from the metaphysis by a cartilaginous growth plate (**epiphyseal plate**). After puberty, the epiphyseal plate calcifies and the epiphysis and metaphysis merge. By adulthood, the line of demarcation between the epiphysis and metaphysis is undetectable.

In **flat bones**, such as the ribs and scapulae, two plates of compact bone are nearly parallel to each other. Between the compact bone plates is a layer of spongy bone. **Short bones**, such as the bones of the wrist or ankle, are often cuboidal. They consist of spongy bone covered by a thin layer of compact bone.

**Irregular bones**, such as the vertebrae, mandibles, or other facial bones, have various shapes that include thin and thick segments. The thin part of an irregular bone consists of two plates of compact bone surrounding spongy bone. The thick part consists of spongy bone surrounded by a layer of compact bone.

**Maintenance of Bone Integrity**

**Remodeling**

The internal structure of bone is maintained by **remodeling**, a three-phase process in which existing bone is resorbed and new bone is laid down to replace it. Clusters of bone cells, termed **basic multicellular units**, carry out remodeling. The basic multicellular units are made up of bone precursor cells that differentiate into osteoclasts and osteoblasts. Precursor cells are located on the free surfaces of bones and along the vascular channels (especially the marrow cavities).

In phase 1 (activation) of the remodeling cycle, a stimulus (e.g., hormone, drug, vitamin, physical stressor) activates the cytokine system, particularly the tumor
necrosis factor (TNF) superfamily, to form osteoclasts.\textsuperscript{14} Osteoclasts attach to the bone matrix by actin microfilaments and multiple other proteins that form foot-like structures called podosomes. Once attached, the osteoclasts' integrin receptors anchor its microfilaments to the extracellular matrix, thus providing receptor pathways between the osteocyte and bone matrix. Lysosomal enzymes produced by osteoclasts “digest” bone; the osteoclasts then release the degraded bone products into the vascular system.\textsuperscript{12} After bone is resorbed, the osteoclast leaves behind an elongated cavity termed a \textit{resorption cavity}. The resorption cavity in compact bone follows the longitudinal axis of the haversian system, whereas the resorption cavity in spongy bone parallels the surface of the trabeculae.

New bone formation begins as osteoblasts lining the walls of the resorption cavity express osteoid and alkaline phosphatase, forming sites for calcium and phosphorus deposition. As the osteoid mineralizes, new bone is formed. Successive layers (lamellae) in compact bone are laid down, until the resorption cavity is reduced to a narrow haversian canal around a blood vessel. In this way, old haversian systems are destroyed and new haversian systems are formed. New trabeculae are formed in spongy bone. The entire process of remodeling takes about 3 to 6 months.

\textbf{Repair}

The remodeling process can repair microscopic bone injuries, but gross injuries, such as fractures and surgical wounds (osteotomies), heal by the same stages as soft tissue injuries, except that new bone, instead of scar tissue, is the final result (see Chapter 6). The stages of bone healing are listed here and shown in Figure 38-5:

1. Inflammation/hematoma formation

2. Procallus formation

3. Callus formation

4. Replacement, by basic multicellular units, of the callus with lamellar or trabecular bone

5. Remodeling of the periosteal and endosteal surfaces of the bone to the size and shape of the bone before injury
FIGURE 38-5 Bone Remodeling. All bone cells participate in bone remodeling. In the remodeling sequence bone sections are removed by bone-resorbing cells (osteoclasts) and replaced with a new section laid down by bone-forming cells (osteoblasts). Bone remodeling is necessary because it allows the skeleton to respond to mechanical loading, maintains quality control (repair and prevent microdamage), and allows the skeleton to release growth factors and minerals (calcium and phosphate) stored in bone matrix to the circulation. The cells work in response to signals generated in the environment (see F). Only the osteoclastic cells mediate the first phase of remodeling. They are activated, scoop out bone (A), and resorb it; then the work of the osteoblasts begins (B). They form new bone that replaces bone removed by the resorption process (C). The sequence takes 4 to 6 months. D, Micrograph of active bone remodeling seen in the settings of primary or secondary hyperparathyroidism. Note the active osteoblasts surmounted on red-stained osteoid. Marrow fibrosis is present. E, Bone remodeling cycle in normal bone with (F). Numerous signaling factors are necessary for remodeling. Factors most important for resorption include granulocyte macrophage-colony stimulating factor (GM-CSF), interleukin-1 (IL-1) and IL-6, receptor activator for nuclear factor-κB ligand (RANKL), prostaglandin E₂ (PGE₂), and tumor necrosis factor-alpha (TNF-α). Important factors for bone formation include osteoprotegerin (OPG), transforming growth factor-beta (TGF-β), and estrogen. (Adapted from Nucleus Medical Art. D from Damjanov I, Linder J, editors: Anderson’s pathology, ed 10, St Louis, 1996, Mosby.)

The speed with which bone heals depends on the severity of the bone disruption; the type and amount of bone tissue that need to be replaced (spongy bone heals faster); the blood and oxygen supply available at the site; the presence of growth and thyroid hormones, insulin, vitamins, and other nutrients; the existence of
systemic disease; the effects of aging (see *Osteoporosis* in Chapter 39 on p. 1000); and the availability of effective treatment, including immobilization and the prevention of complications such as infection. In general, however, hematoma formation occurs within hours of fracture or surgery, formation of procallus by osteoblasts within days, callus formation within weeks, and replacement and contour modeling within years—up to 4 years in some cases.

Structure and Function of Joints

The site where two or more bones are attached is called a **joint**, or **articulation** (Figure 38-6). The primary function of joints is to provide stability and mobility to the skeleton. A joint’s function depends on both its location and its structure. Generally, joints that stabilize the skeleton have a simpler structure than those that enable the skeleton to move. Most joints provide both stability and mobility to some degree.

![Various Kinds of Joints](image)

Joints are classified based on the degree of movement they permit or on the connecting tissues that hold them together. Based on movement, a joint is classified as a **synarthrosis** (immovable joint), an **amphiarthrosis** (slightly movable joint), or a **diarthrosis** (freely movable joint). On the basis of connective structures, joints are classified broadly as fibrous, cartilaginous, or synovial. Each of these three structural classifications can be subdivided according to the shape and contour of
the articulating surfaces (ends) of the bones and the type of motion the joint permits.

**Fibrous Joints**

A joint in which bone is united directly to bone by fibrous connective tissue is called a **fibrous joint**. These joints have no joint cavity and allow little, if any, movement.

Fibrous joints are further subdivided into three types: sutures, syndesmoses, and gomphoses. A **suture** has a thin layer of dense fibrous tissue that binds together interlocking flat bones in the skulls of young children. Sutures form an extremely tight union that permits no motion. By adulthood, the fibrous tissue has been replaced by bone. A **syndesmosis** is a joint in which the two bony surfaces are united by a ligament or membrane. The fibers of ligaments are flexible and stretch, permitting a limited amount of movement. The paired bones of the lower arm (radius and ulna) and the lower leg (tibia and fibula) and their ligaments are syndesmotic joints. A **gomphosis** is a special type of fibrous joint in which a conical projection fits into a complementary socket and is held in place by a ligament. The teeth held in the maxilla or mandible are gomphosis joints.

**Cartilaginous Joints**

There are two types of cartilaginous joints: symphyses and synchondroses. A **symphysis** is a cartilaginous joint in which bones are united by a pad or disk of fibrocartilage. A thin layer of hyaline cartilage usually covers the articulating surfaces of these two bones, and the thick pad of fibrocartilage acts as a shock absorber and stabilizer. Examples of symphyses are the symphysis pubis, which joins the two pubic bones, and the intervertebral disks, which join the bodies of the vertebrae. A **synchondrosis** is a joint in which hyaline cartilage, rather than fibrocartilage, connects the two bones. The joints between the ribs and the sternum are synchondroses. The hyaline cartilage of these joints is called **costal cartilage**. Slight movement at the synchondroses between the ribs and the sternum allows the chest to move outward and upward during breathing.

**Joint (Articular) Capsule**

The **joint (articular) capsule** is fibrous connective tissue that covers the ends of bones where they meet in a joint; Sharpey fibers firmly attach the proximal and distal capsule to the periosteum, and ligaments and tendons also may reinforce the capsule. It is composed of parallel, interlacing bundles of dense, white fibrous tissue richly supplied with nerves, blood vessels, and lymphatic vessels. Nerves in and around the joint capsule are sensitive to rate and direction of motion, compression,
tension, vibration, and pain.

**Synovial Membrane**

The *synovial membrane* is a smooth, delicate inner lining of joint capsule found in the nonarticular portion of the synovial joint and any ligaments or tendons that traverse this cavity. It is composed of two layers: the vascular subintima and the thin cellular intima. The vascular subintima merges with the fibrous joint capsule and is composed of loose fibrous connective tissue, elastin fibers, fat cells, fibroblasts, macrophages, and mast cells; the cellular intima consists of rows of synovial cells embedded in fiber-free intercellular matrix and contains two types of cells—A and B. A cells (macrophages) ingest and remove (phagocytose) bacteria and particles of debris in the joint cavity; B cells (fibroblasts) are the most numerous and secrete hyaluronate, which gives synovial fluid its viscous quality. The synovial membrane is richly supplied with blood and lymphatic vessels and is capable of rapid repair and regeneration.

**Joint (Synovial) Cavity**

The *joint (synovial) cavity* is an enclosed, fluid-filled space between articulating surfaces of two bones, also called *joint space*. It enables two bones to move “against” one another and is surrounded by synovial membrane and filled with synovial fluid.

**Synovial Fluid**

*Synovial fluid* is superfiltrated plasma from blood vessels that lubricates the joint surfaces, nourishes the pad of the articular cartilage, and covers the ends of the bones. Hyaluronic acid in the synovial fluid gives it important biomechanical properties. It also contains free-floating synovial cells and various leukocytes that phagocytose joint debris and microorganisms.

**Articular Cartilage**

*Articular cartilage* is a layer of hyaline cartilage that covers the end of each bone; it may be thick or thin, depending on the size of the joint, the fit of the two bone ends, and the amount of weight and shearing force the joint normally withstands. The function of articular cartilage is to reduce friction in the joint and to distribute the forces of weightbearing. Articular cartilage is composed of *chondrocytes* (cartilage cells) (about 2% of the tissue) and an intercellular matrix consisting of type II collagen (about 10% to 30% of weight), proteoglycans (about 5% to 10% of weight), and water. The water content ranges from 60% to almost 80% of the net
weight of the cartilage, and individual molecules rapidly enter or exit the articular cartilage to contribute to the resiliency of the tissue.

At the surface of articular cartilage, the collagen fibers run parallel to the joint surface and are closely compacted into a dense, protective mat. (Loss of this dense, compacted configuration at the surface subjects the underlying fibers to splitting and thinning, in which case the cartilage is unable to tolerate weightbearing.) In the middle layer (the proliferative zone) of the cartilage, the fibers are arranged tangential to the surface, which allows them to deform and absorb some of the weightbearing (Figure 38-7). In the bottom layer (the hypertrophic zone) of the cartilage, the fibers are perpendicular to the joint surface, allowing them to resist shear forces, and are embedded in a calcified layer of cartilage called the *tidemark*.

The *tidemark* anchors the collagen fibers to the underlying (subchondral) bone. Collagen fibers are important components of the cartilage matrix because they account for approximately 60% of the dry weight and because they (1) anchor the cartilage securely to underlying bone, (2) provide a taut framework for the cartilage, (3) control the loss of fluid from the cartilage, and (4) prevent the escape of protein polysaccharides (proteoglycans) from the cartilage. The proteoglycans give articular cartilage its stiff quality and regulate the movement of synovial fluid through the cartilage. The proteoglycans are macromolecules consisting of proteins, carbohydrates (glycosaminoglycans), and hyaluronic acid.
Synovial Joints

Structure of Synovial Joints

Synovial joints (diarthroses) are the most movable and the most complex joints in the body (Figure 38-8).
Movement of Synovial Joints

Synovial joints are described as uniaxial, biaxial, or multiaxial according to the shapes of the bone ends and the type of movement occurring at the joint (Figure 38-9). Usually, one of the bones is stable and serves as an axis for the motion of the other bone. The body movements made possible by various synovial joints are either circular or angular (Figure 38-10).

Quick Check 38-2

1. How do the following joints differ from each other: synarthrosis, amphiarthrosis, and diarthrosis?

2. Name at least two characteristics of each of the joints in the previous question that either facilitate or hinder movement.

3. Name three functions of articular cartilage.
FIGURE 38-9 Movements of Synovial (Diarthrodial) Joints.

Uniaxial (elbow)  Biaxial (finger)  Multiaxial (hip)
**Figure 38-10** Body Movements Made Possible by Synovial (Diarthrodial) Joints.
**Structure and Function of Skeletal Muscles**

Skeletal muscles arise from mesodermal precursor cells that then form myoblasts. The millions of individual fibers of skeletal muscle contract and relax to perform the work necessary to move the body (Figure 38-11). Muscle constitutes 40% of an adult's body weight and 50% of a child's weight. Muscle is 75% water, 20% protein, and 5% organic and inorganic compounds. Thirty-two percent of all protein stores for energy and metabolism are contained in muscle. Between the ages of 30 and 60, muscle mass decreases by about 0.5 pound of muscle each year. For each 0.5 pound of muscle lost, almost 1 pound of fat is typically gained.

**Whole Muscle**

There are more than 600 skeletal muscles in the body. The body's muscles vary dramatically in size and shape. They range from 2 to 60 cm in length and are shaped according to function. **Fusiform muscles** are elongated muscles shaped like straps.
and can run from one joint to another. The biceps brachii and psoas major are examples of fusiform muscles. **Pennate muscles** are broad, flat, and slightly fan shaped, with fibers running obliquely to the muscle's long axis. The multipennate deltoid muscle, which flexes and extends the arm, is a good example of a muscle shaped according to its function.

Each skeletal muscle is a separate organ, encased in a three-part connective tissue framework called **fascia**. The layers of connective tissue protect the muscle fibers, attach the muscle to bony prominences, and provide a structure for a network of nerve fibers, blood vessels, and lymphatic channels. The layers are as follows:

1. The outermost layer, the **epimysium**, is located on the surface of the muscle and tapers at each end to form the **tendon** (Figure 38-12, also see p. 986 for a discussion of tendons). Tendons allow short muscles to exert power on a distant joint, whereas a thick muscle would interfere with the joint's mobility.
2. The **perimysium** further subdivides the muscle fibers into bundles of connective tissue, or **fascicles**.
3. The smallest unit of muscle visible without a microscope is the **endomysium**, which surrounds the muscle.

The ligaments, tendons, and fascia are made up of connective tissue that also buffers the limbs from the effects of sudden strains or changes in speed. The rapid recovery necessary for strenuous exercise is supported by the elastic property of muscle and its connective tissue.

**Skeletal muscle** has been designated as **voluntary** (controlled directly by the nervous system), **striated** (has a striped pattern when viewed under a light microscope), or **extrafusal** (to distinguish from other contractile fibers in the sensory organ of the muscle). Components that are visible on gross inspection of the whole muscle include the motor and sensory nerve fibers. These function together with the muscle, innervating portions of it and providing the electrical impulses needed for motor function.

**Motor Unit**

From the anterior horn cell of the spinal cord, the axons of motor nerves branch to innervate a specific group of muscle fibers. Each anterior horn cell, its axon (part of the lower motor neuron; see Chapter 13), and the muscle fibers innervated by it are called a **motor unit** (Figure 38-13). The motor units are composed of lower motor neurons, which extend to skeletal muscles. Often termed the **functional unit** of the neuromuscular system, the motor unit behaves as a single entity and contracts as a whole when it receives an electrical impulse.

![Motor Units of a Muscle](image)

**FIGURE 38-13**

Motor Units of a Muscle. Each motor unit consists of a motor neuron and all the muscle fibers (cells) supplied by the neuron and its axon branches.

The whole muscle may be controlled by several motor nerve axons. These branch to innervate many motor units within the muscle. The whole muscle then may be
made up of many motor units. The number of motor units per individual muscle varies greatly. In the calf, for example, 1 motor axon innervates approximately 2000 muscle fibers, out of a total of 1,200,000 muscle fibers. This is a high innervation ratio of muscle fibers to axons, and it contrasts markedly with the low innervation ratio found in laryngeal muscles, where two to three muscle fibers constitute each motor unit and the innervation ratio can be of great functional significance. The greater the innervation ratio of a particular organ, the greater its endurance. Higher innervation ratios prevent fatigue, whereas lower innervation ratios allow for precision of movement.

**Sensory receptors.**

Although muscles function as effector organs, they also contain sensory receptors and are involved in sending different signals to the central nervous system. Among these are the muscle spindles and Golgi tendon organs. **Spindles** are mechanoreceptors that lie parallel to muscle fibers and respond to muscle stretching. **Golgi tendon organs** are dendrites that terminate and branch to tendons near the neuromuscular junction. The muscle spindles, Golgi tendon organs, and free nerve endings provide a means of reporting changes in length, tension, velocity, and tone in the muscle. This system of afferent signals is responsible for the muscle stretch response and maintenance of normal muscle tone.

**Muscle fibers.**

Each **muscle fiber** is a single **muscle cell** that is cylindrical in structure and surrounded by a membrane capable of excitation and impulse propagation. The muscle fiber contains bundles of **myofibrils**, the fiber's functional subunits, in a parallel arrangement along the longitudinal axis of the muscle ([Figure 38-14](#)). At birth, the muscle fibers have completed development from precursor cells called **myoblasts**. All **voluntary muscles** are derived from the mesodermal layer of the embryo. Genetic transcription factors, most notably MyoD, induce skeletal muscle differentiation. Myoblasts are the main cells responsible for muscle growth and regeneration. Myoblasts are termed **satellite cells** when in a dormant state. **Satellite cells** are crucial in muscle growth, maintenance, repair, and regeneration. Once muscle is injured, satellite cells become activated and increase the number of transcriptional factors necessary to form myoblasts and assist in repair.39
The type of peripheral nerve influences the muscle fiber and motor unit considerably. Whether motor nerves are fast or slow determines the type of muscle fibers in the motor unit. White muscle (type II fibers [white fast-twitch fibers]) is innervated by relatively large type II alpha motor neurons with fast conduction velocities. These fibers rely on a short-term anaerobic glycolytic system for rapid energy transfer. Red muscle (type I fibers [slow-twitch fibers]) depends on aerobic oxidative metabolism. Table 38-4 describes the specific characteristics of type I and type II fibers.

</table>

The overlap of muscle fibers that appears with staining gives a checkerboard appearance to muscle biopsy specimens. This overlap provides an equal distribution of fiber types throughout the muscle and also helps to compensate for muscle fiber loss and fatigue of individual motor units during activity. In spite of this, some muscles contain proportionally more of one fiber type than another. Postural muscles have more type I fibers, allowing them the high resistance to fatigue that is necessary to maintain the same position for extended periods. The ocular muscles have more type II muscle fibers, allowing them to respond rapidly to visual changes.

The number of muscle fibers varies according to location. Large muscles, such as the gastrocnemius, have more fibers (1,200,000) than smaller muscles, such as the lumbrical muscles in the hand (10,000). The diameter of muscle fibers also varies. The closely packed polygons are small (10 to 20 µm) until puberty, when they attain the normal adult diameter of 40 to 80 µm. Women usually have smaller-diameter fibers than men. Small muscles, such as the ocular muscles, are 15 µm in diameter; larger, more proximal muscles are 40 µm in diameter. Fiber size can have functional significance. Studies have shown that larger fiber diameter is associated with generation of greater forces. Fiber diameter can be increased by exercise or occupational overuse, activities that cause hypertrophied muscle.
The major components of the muscle fiber include the muscle membrane, myofibrils, sarcotubular system, sarcoplasm, and mitochondria (see Figure 38-14). The muscle membrane is a two-part membrane. It includes the sarcolemma, which contains the plasma membrane of the muscle cell, and the cell's basement membrane. The sarcolemma is 7.5 µm thick and is capable of propagating electrical impulses to initiate contraction. At the motor nerve end plate, where the nerve impulse is transmitted, the sarcolemma forms the highly convoluted synaptic cleft. The sarcolemma is made up of lipid molecules and protein systems. The protein systems perform special functions, such as transport of nutrients and protein synthesis. They also provide the sodium-potassium pump and include the cell's cholinergic receptor. The basement membrane is 50 µm thick and is composed primarily of proteins and polysaccharides. It also serves as the cell's microskeleton and maintains the shape of the muscle cell. The basement membrane also may function in some way to restrict further diffusion of electrolytes once they have crossed the sarcolemma.

The sarcoplasm is the cytoplasm of the muscle cell and contains myoglobin plus the intracellular components that are common to all cells (see Chapter 1). Myoglobin is a protein found primarily in skeletal and heart muscle. Related to hemoglobin in the blood, myoglobin stores oxygen and iron in the muscle. The sarcoplasm is an aqueous substance that provides a matrix that surrounds the myofibrils. It contains numerous enzymes and proteins that are responsible for the cell's energy production, protein synthesis, and oxygen storage. The mitochondria house enzyme systems for energy production, particularly those that regulate processes such as the citric acid cycle and adenosine triphosphate (ATP) formation. Many other structures are present in the sarcoplasm. The ribosomes are composed of primarily ribonucleic acid (RNA) and participate in the process of protein synthesis. The cell nucleus, satellite cells, glycogen granules, and lipid droplets are suspended in the sarcoplasmic matrix. Blood vessels, nerve endings, muscle spindles, and Golgi tendon organs are also directly located within this structure.

Unique to the muscle is the sarcotubular system, a network that includes the transverse tubules and the sarcoplasmic reticulum, which crosses the interior of the cell. The sarcoplasmic reticulum is constructed like the endoplasmic reticulum in other cells. The sarcoplasmic reticulum is composed of tubules that run parallel to the myofibrils. The longitudinal tubules are termed sarcotubules. In muscle cells, the sarcoplasmic reticulum contains a network of intracellular receptors known as ryanodine receptors (RyRs). In response to a nerve impulse, RyR1 (found in skeletal muscle cells) releases intracellular calcium and initiates muscle contraction at the sarcomere, a portion of the myofibril. The transverse tubules, which also contain calcium release channels and are closely associated with the sarcotubules, run
across the sarcoplasm and communicate with the extracellular space. Together, the tubules of this membrane system allow for uptake and regulation of intracellular calcium, release of calcium during muscle contraction, and storage of calcium during muscle relaxation.20-22

**Myofibrils.**

The myofibrils are the functional units of muscle contraction. Each myofibril contains sarcomeres, which appear at intervals (see Figure 38-14). The speed with which sarcomeres lengthen and shorten during movement directly influences the strength and function of skeletal muscles. Sprinters tend to have more fast-twitch (FT) fibers than slow-twitch (ST) fibers in their leg muscles, and endurance runners have more ST fibers in their leg muscles. Sarcomeres are composed of several proteins. The two most abundant are actin and myosin, but three other giant, muscle-specific proteins (titin, nebulin, and obscurin) play important roles in myofibril formation and function (see Table 38-5).

*Also may function as molecular scaffolds for myofibril formation.

ATP, Adenosine triphosphate; ATPase, adenosinetriphosphatase.

The myofibrils are the most abundant subcellular muscle component, equaling 85% to 90% of the total volume. On cross section, they are seen to be irregular polygons with a mean diameter of less than 1 µm. Each myofibril is composed of serially repeating sarcomeres, separated by Z bands, which give the muscle its
striped, cross-striated appearance. Each sarcomere has a dark A band and is flanked by two light I bands (Figure 38-15). The A band is 1.5 to 1.6 µm long and contains the thick myosin filaments. Included in the A band is a lighter zone called the H band, and in the center of the H band is the dark M band, or M line. The I band, which contains actin, is divided at the midpoint of each sarcomere by the Z band. Its length varies with the start of muscle contraction. The Z disk (made up of different layers of Z bands, depending on muscle type) marks the boundaries of the sarcomere.²³
Myofibrils are composed of myofilaments. Each myofilament is structured in a closely packed hexagonal arrangement, with two thin filaments for every thick filament. The thick filament, along with C protein and M line protein, is made up of myosin. Myosin has two subunits—heavy and light meromyosin, which resemble twisted golf club shafts. The thin filaments are twisted double strands consisting of actin, troponin, and tropomysin (see Chapter 23 and Figure 23-13).

**Muscle proteins.**

A multitude of muscle proteins have been identified and their functions are still being discovered. Table 38-5 summarizes the location and function of some of the important muscle proteins.

**Nonprotein constituents of muscle.**

Substances such as nitrogen, creatine, creatinine, phosphocreatine, purines, uric acid, and amino acids all serve in the complex process of muscle metabolism. Energy is provided by glycogen and its derivatives.

Creatine metabolism and creatinine metabolism have been used to measure muscle mass. Plasma creatine is taken up by muscle and converted into the high-energy phosphate compound phosphocreatine by the enzyme creatine kinase. Creatinine is formed in muscle from creatine at a constant rate of 2% per day. (Tests for measurement of plasma creatine level are discussed in Chapter 30.) Creatine excretion is increased in muscle wasting. This change reflects the reduction in total body creatine stores and the loss of muscle mass.

Inorganic compounds, anions (phosphate, chloride), and cations (calcium, magnesium, sodium, potassium) are important in the regulation of protein synthesis, muscle contraction, and enzyme systems as well as in the stabilization of cell membranes. Total body potassium (TBK) level, measured by the K40 method, has been used to measure muscle mass, also called lean body mass. Total body potassium levels reflect changes in muscle mass seen during growth, malnutrition, and muscle wasting.
**Components of Muscle Function**

The ultimate function of muscle is to accomplish work. Although variously expressed in such measures as foot-pounds or kilogram-meters, work usually refers to the amount of energy liberated or force exerted over a distance (work = force × distance). Muscles usually contract or tense while doing work. Muscle contraction occurs on the molecular level and leads to the observable phenomenon of muscle movement.

**Muscle Contraction at the Molecular Level**

The four steps of muscle contraction are (1) excitation, (2) coupling, (3) contraction, and (4) relaxation. The process involves the electrical properties of all cells and the movement of ions across the plasma membrane (see Chapter 1). The muscle fiber is an excitable tissue. At rest, an electrical charge of −90 mV is continually maintained across the sarcolemma. This resting potential, generated by the separation of positive and negative charges on either side of the membrane, creates an electrochemical equilibrium caused by the selective permeability of the sarcolemma to electrolytes in the intracellular and extracellular fluids, particularly potassium and sodium.

**Excitation**, the first step of muscle contraction, begins with the spread of an action potential from the nerve terminal to the neuromuscular junction. The rapid depolarization of the membrane initiates an electrical impulse in the muscle fiber membrane called the **muscle fiber action potential**. As the action potential advances along the sarcolemmal membrane, it spreads to the transverse tubules. (The velocity of conduction is much slower in muscle fibers than in myelinated nerve fibers—only 3 to 5 m/sec compared with 54 to 90 m/sec in nerve fibers.) A receptor on the transverse tubule opens, allowing calcium to enter the cell.

The second stage, **coupling**, follows the depolarization of the transverse tubules. This triggers the release of calcium ions from the sarcoplasmic reticulum through RyR1 channels into the sarcoplasm. The calcium then binds to a protein on the actin filament. (Calcium affects troponin and tropomyosin, muscle proteins that bind with actin when the muscle is at rest.) In the presence of calcium, however, both these proteins are attracted to calcium ions, leaving the actin free to bind with myosin. The release of intracellular calcium ions is the critical link between a nerve impulse (electrical excitation) and muscle contraction.

**Contraction** begins as the calcium ions combine with troponin, a reaction that overcomes the inhibitory function of the troponin-tropomyosin system. Myosin binds to actin, forming cross-bridges. The myosin heads attach to the exposed actin-binding sites, pulling actin (the thin filament) inward. The thin filament, actin, then
slides toward the thick filament, myosin. The two ends of the myofibril shorten after contraction when the myosin heads attach to the actin molecules, forming a cross-bridge that constitutes an actin-myosin complex. ATP, located on the actin-myosin complex, is released when the cross-bridges attach. The process of contraction was first described by A.F. Huxley in the 1950s. It is commonly known as the cross-bridge theory because the actin and myosin proteins form cross-bridges as they contract. The useful distance of contraction of a skeletal muscle is approximately 25% to 35% of the muscle's length.

The last step, relaxation, begins as calcium ions are actively transported back into the sarcoplasmic reticulum, removing ions from interaction with troponin. The cross-bridges detach, and the sarcomere lengthens. (The cross-bridge theory of muscle contraction is discussed in Chapter 23.)

**Muscle Metabolism**

Skeletal muscle requires a constant supply of ATP and phosphocreatine. These substances are necessary to fuel the complex processes of muscle contraction, driving the cross-bridges of actin and myosin together and transporting calcium from the sarcoplasmic reticulum to the myofibril. Other internal processes of the muscular system that require ATP include protein synthesis, which replenishes muscle constituents and accommodates growth and repair. The rate of protein synthesis is related to hormone levels (particularly insulin), the presence of amino acid substrates, and overall nutritional status. At rest, the rate of ATP formation by oxidation of glucose or acetoacetate is sufficient to maintain internal processes, given normal nutritional status. During activity, the need for ATP increases 100-fold. The metabolic pathways for muscle activity in Table 38-6 show reactions to the immediate need for increased ATP caused by contraction. Activity lasting longer than 5 seconds expends the available stored ATP and phosphocreatine.

Stored glycogen and blood glucose are converted anaerobically to sustain brief
activity without increasing the demand for oxygen. Anaerobic glycolysis is much less efficient than aerobic glycolysis, using six to eight times more glycogen to produce the same amount of ATP. With increased activity, such as intense exercise, or with ischemia, an increase in the amount of lactic acid occurs because of the breakdown of glycogen, thus causing a shift in muscle pH (see Table 38-6). This short-term mechanism buys time by allowing ATP formation in spite of inadequate energy stores or oxygen supply. When the anaerobic threshold is reached and more oxygen is required, physiologic changes occur, including an increase in lactic acid level and increases in oxygen consumption, heart rate, respiratory rate, and muscle blood flow.

Strenuous exercise requires oxygen, which activates the aerobic glycogen pathway for ATP formation. During maximal exercise, free fatty acid mobilization and the aerobic glycogen pathways provide ATP over an extended time. These pathways require oxygen both to maintain maximal activity and to return the muscle to the resting state. Maximal exercise increases oxygen uptake by 15 to 20 times over the resting state. When this system becomes exhausted or inadequate to respond to the need for ATP, fatigue and weakness finally force the muscle to reduce activity with a resultant buildup of lactic acid in muscle fibers. Creatine supplementation may provide some protective effects on muscle in older adult athletes as well as after strenuous physical activity.26

Sustaining maximal muscular activity accumulates an oxygen debt, which is the amount of oxygen needed to oxidize the residual lactic acid, convert it back to glycogen, and replenish ATP and phosphocreatine stores. For example, after running at maximal speed for 10 seconds, the average person has consumed 1 L of oxygen. At rest, oxygen consumption for the same period is approximately 40 ml. As the person recovers, the measured oxygen debt is 4 L greater than the amount used during activity.

Oxygen consumption is measured to calculate the metabolic cost of activity in normal and diseased muscle. It is an indirect measure of energy expenditure, along with timed tests of activity, heart rate, and respiratory quotient (ratio of carbon dioxide to expired oxygen consumed). Energy expenditure is measured directly by heat production because heat is released whenever work is accomplished.

Another factor that changes energy requirements is muscle fiber type. Type II fibers rely on anaerobic glycolytic metabolism and fatigue readily. Type I fibers can resist fatigue for longer periods because of their capacity for oxidative metabolism.

**Muscle Mechanics**

Muscle contraction cannot be viewed in isolation. Several factors determine how
force is transmitted from the cross-bridges on individual muscle fibers to accomplish whole-muscle contraction. First, when a motor unit responds to a single nerve stimulus, it develops a phasic contraction, also called a *twitch*. Because the motor unit contracts in an all-or-nothing manner, the contraction that is generated will be a maximal contraction. The central nervous system smoothly grades the force generated by recruiting additional motor units and varying the discharge frequency of each active motor unit. This adding of motor units within the muscle is called **repetitive discharge**.

Recruitment and repetitive discharge of motor units allow the muscle to activate the number of motor units needed to generate the desired force. The total force developed is the sum of the force generated by each motor unit. If the motor units are stimulated again and the muscle unit has not been able to relax between stimulation and the next contraction, the second contraction will fuse with the first, causing **physiologic tetanus** (not to be confused with the disease tetanus).

Other variables, such as fiber type, innervation ratio, muscle temperature, and muscle shape, influence the efficiency of muscular contraction. The two muscle fiber types differ in their responses to electrical activity. Tetanus and duration of phasic contractions, which take microseconds to accomplish, are achieved more rapidly in type II (white fast-twitch) than in type I (red slow-twitch) muscle fibers. Low innervation ratios promote control and coordination, whereas high ratios promote strength and endurance. Muscles work best at normal body temperature, 98.6° F (37° C). Finally, muscles with a large cross-sectional area, such as the fan-shaped pennate muscles, develop greater contractile forces than smaller-diameter muscles. The initial length of a muscle and the range of shortening that occur when the muscle contracts also determine the force it can generate. The long fusiform muscles have a greater range of shortening and can contract up to 57% of their resting length. A certain amount of elongation is necessary to generate sufficient tension and muscular force. The elongation that occurs during the swing of a golf club or tennis racket is an example of how stretch improves contractile force.

### Types of Muscle Contraction

During **isometric** (or **static**) contraction, the muscle maintains constant length as tension is increased (Figure 38-16). Isometric contraction occurs, for example, when the arm or leg is pushed against an immovable object. The muscle contracts, but the limb does not move. Isometric contraction is also called **static (holding)** contraction.
During **dynamic** (formerly known as **isotonic** contraction, the muscle maintains a constant tension as it moves. Isotonic contractions can be **eccentric** (**lengthening**) or **concentric** (**shortening**). Positive work is accomplished during concentric contraction, and energy is released to exert force or lift a weight. In contrast, during an eccentric contraction the muscle lengthens and absorbs energy (such as extending the elbow while lowering a weight). Eccentric contraction requires less energy to accomplish and has been said to result in the development of pain and stiffness after unaccustomed exercise.

**Movement of Muscle Groups**

Muscles do not act alone but in groups, often under automatic control. When a
muscle contracts and acts as a prime mover, or **agonist**, its reciprocal muscle, or **antagonist**, relaxes. To illustrate this, hold the right arm in the horizontal position in front of the body and bend the elbow; use the other hand to feel the biceps on the top and the triceps on the bottom of the arm. When the elbow is bent, the biceps are firm, and the triceps are soft. As the arm is extended, the muscles change. When the elbow is completely extended, the biceps is soft and the triceps firm. Completing this movement causes the agonist and antagonist to change automatically; only the movement is commanded, not the alternate contraction and relaxation of the specific muscle groups.

Other associated actions may be seen during walking; as the foot leaves the ground, the paravertebral and gluteal muscles on the opposite sides of the body contract to maintain balance. One notices the loss of the associated muscle's action when paralysis offsets this process and decreases balance. If a person is paralyzed, difficulty in maintaining balance is noticeable.

### Tendons and Ligaments

**Tendons** are important musculoskeletal structures that attach muscle to bone at a site called an **enthesis**. **Ligaments** attach bone to bone, helping to form joints as well as stabilizing them against excessive movement. Both tendons and ligaments are primarily composed of types III, IV, V, and VI collagen and fibroblasts (termed **tenocytes in tendons**). The fibroblasts in tendon are arranged in parallel rows; fibroblasts appear less organized in ligaments. Collagen fibers and fibroblasts form fascicles, with multiple fascicles then forming whole tendon or ligament. In the proteoglycan matrix of tendons, collagen oligomeric matrix protein (COMP) assists in providing gliding and viscoelastic properties. Compared with tendons, ligament fibers typically contain a greater proportion of elastin.

Two main functions of tendons are (1) transferring forces from muscle to bone and (2) acting as a type of biologic spring for muscles to allow additional stability during movement. Ligaments stabilize joints by restricting movement. Although both tendons and ligaments can withstand significant distraction (stretching) force, they tend to buckle when compressive force is applied.

Both tendons and ligaments have complex structures at the attachment site of two dissimilar tissues. **Figure 38-17** illustrates the transition of tissue between tendon/ligament and bone. These complex structures and differences in mechanical and structural characteristics (either tendon and bone or ligament and bone) make healing and repair of damaged tissue complicated (see **Health Alert: Tendon and Ligament Repair**).
Injury of tendons and ligaments constitutes one of the greatest challenges in musculoskeletal rehabilitation. When these types of structures are damaged, attempts to engineer suitable tissue replacements have proved disappointing. The structures and intricate protein composition of tendons and ligaments are the basis for their complex biomechanical properties. One reason for poor clinical outcome in synthetic tendon structures has been the inability to replicate any material that can bear the high mechanical stresses that occur at the interface between two dissimilar materials (i.e., either tendon and bone or ligament and bone). One promising area of investigation is finding or engineering a biodegradable material, or “scaffold,” implanted with specific cells that would regenerate into normal tendon or ligament. The scaffold must be strong enough to withstand the forces at the tissue/bone interface and then gradually break down as it is completely replaced by new cells. Currently, investigators are using synthetic polymers, silk, and collagen as scaffolds, with tendon or ligament fibroblasts and mesenchymal stem cells as the implanted cells. Once these biochemical hurdles are overcome, the repair of damaged tendons and ligaments will be revolutionized.

**Tendon/ligament**
- Aligned collagen fibrils (lines)
- Fibroblasts embedded throughout (blue oval cells)
- Collagen fibrils extend into uncalcified fibrocartilage

**Uncalcified fibrocartilage**
- Larger, less parallel collagen bundles (vertical blue lines)
- Collagen types I and II, aggrecan (irregular-shaped cells)
- Avascular (yellow background)
- Ovoid-shaped, aligned cells (smooth-edged cells)
- Wavy tidemark (marks beginning of calcification)

**Calcified fibrocartilage**
- Mineralized tissue
- Hypertrophic, more circular chondrocytes
- Consists of collagen types I, II, and X

**Bone**
- Interdigitation at surface (zig-zag line)
- Calcified tissue
Aging & the Musculoskeletal System

Aging of Bones
Aging is accompanied by the loss of bone tissue. Bones become less dense, less strong, and more brittle with aging. The bone remodeling cycle takes longer to complete, and the rate of mineralization also slows. With aging, women experience loss of bone density, accelerated with the rapid bone loss that occurs during early menopause from increased osteoclastic bone resorption, fewer osteocytes, and decreased numbers of osteoblasts. By age 70 years, susceptible women have, on average, lost 50% of their peripheral cortical bone mass (see Chapter 39). Bone mass losses to such an extent can lead to deformity, pain, stiffness, and high risk for fractures. Men experience bone loss also but at later ages and much slower rates than seen in women. Also, initial bone mass in men is approximately 30% higher than in women; therefore bone loss in men causes less risk of disability than that found in women. Men's peak bone mass is related to their race, heredity, hormonal factors, physical activity, and calcium intake during childhood. Bone loss in both genders is related to smoking, calcium deficiency, alcohol intake, and physical inactivity. Bone mass can be gained in healthy young women up to the third decade through participation in physical activity, intake of dietary calcium and other minerals, and use of oral contraceptives. Height is also lost with aging because of intervertebral disk degeneration and, sometimes, osteoporotic spinal fractures.

Stem cells in the bone marrow perform less efficiently with aging, predisposing older persons to acute and chronic illnesses. Such illnesses cause weakness and confusion in older persons and may increase the risk of injury or falling.

Aging of Joints
With aging, cartilage becomes more rigid, fragile, and susceptible to fraying because of increased cross-linking of collagen and elastin, decreased water content in the cartilage ground substance, and reduced concentrations of glycosaminoglycans. Decreased range of motion of the joint is related to the changes in ligaments and muscles. Bones in joints develop evidence of osteoporosis with fewer trabeculae and thinner, less dense bones, making them prone to fractures. Intervertebral disk spaces decrease in height. The rate of loss of height accelerates at age 70 years and beyond. Tendons shrink and harden.

Aging of Muscles
The function of skeletal muscle depends on many influences that are affected by cellular factors, such as reduced mitochondrial volume associated with aging. Other influences include the nervous, vascular, and endocrine systems. In the young child, the development of muscle tissue depends greatly on continuing neurodevelopmental maturation. Muscle loss begins at about age 50; however, muscle function remains trainable even into advanced age. Maintaining musculoskeletal fitness at any age can improve overall health. Age-related loss in skeletal muscle is referred to as sarcopenia and is a direct cause of the age-related decrease in muscle strength. As the body ages, muscle mass and strength decline slowly; thus, strength is maintained through the fifth decade, with a slow decline in dynamic and isometric strength evident after age 70. The amount of type II fibers also decreases. There is reduced synthesis of RNA, loss of mitochondrial function, and reduction in the size of motor units. The regenerative function of muscle tissue remains normal in aging persons. As much as 30% to 40% of skeletal muscle mass and strength may be lost from the third to ninth decades. Muscle fatigue also may contribute to loss of function with aging. Sarcopenia is thought to be secondary to progressive neuromuscular changes and diminishing levels of anabolic hormones. There is an age-related decline in the synthesis of mixed proteins, myosin heavy chains, and mitochondrial protein. Changes in these muscle proteins are related to reduced levels of insulin-like growth factor-1 (IGF-1), testosterone, and dehydroepiandrosterone (DHEA) sulfate.

Maximal oxygen intake declines with age. Basal metabolic rate is reduced and lean body mass decreases in the aged population.

Quick Check 38-3

1. Name three differences between slow-twitch and fast-twitch muscle fibers.

2. Why is adenosine triphosphate (ATP) used for muscle contraction?

3. Define the differences between tendons and ligaments.

4. Describe significant changes in the musculoskeletal system with aging.
Did You Understand?

Structure and Function of Bones

1. Bones provide support and protection for the body's tissues and organs and are important sources of minerals and blood cells.

2. Bone formation begins with the production of an inorganic matrix by bone cells. Bone minerals crystallize in and around collagen fibers in the matrix, giving bone its characteristic hardness and strength.

3. Bone tissue is continuously being resorbed and synthesized by basic multicellular units of osteoclasts and osteoblasts, respectively.

4. Bones in the body are made up of compact bone tissue and spongy bone tissue. Compact bone is highly organized into haversian systems that consist of concentric layers of crystallized matrix surrounding a central canal that contains blood vessels and nerves. Dispersed throughout the concentric layers of crystallized matrix are small spaces containing osteocytes. Smaller canals, called canaliculi, interconnect the osteocyte-containing spaces. The crystallized matrix in spongy bone is arranged in bars or plates. Spaces containing osteocytes are dispersed between the bars or plates and interconnected by canaliculi.

5. Osteoblasts are multifunctional mononuclear cells derived from osteogenic mesenchymal stromal cells; they are the primary bone-producing cells and are involved in many functions related to the skeletal system.

6. Osteocytes are the most numerous cells in bone and represent the final stage of an osteoblast's life. Though imbedded in the bone matrix, osteocytes have important functions in directing bone remodeling.

7. Osteoclasts are large (typically 20 to 100 µm in diameter), multinucleated cells that develop from the hematopoietic monocyte-macrophage lineage. Osteoclasts are the major resorptive cells of bone.

8. There are 206 bones in the body divided into the axial skeleton and the appendicular skeleton. Bones are classified by shape as long, short, flat, or irregular. Long bones have a broad end (epiphysis), broad neck (metaphysis), and narrow midportion (diaphysis) that contains the medullary cavity.
9. Bone injuries are repaired in stages. Hematoma formation provides the fibrin framework for formation and organization of granulation tissue. The granulation tissue provides a cartilage model for the formation and crystallization of bone matrix. Remodeling restores the original shape and size to the injured bone.

**Structure and Function of Joints**

1. A joint is the site where two or more bones attach. Joints provide stability and mobility to the skeleton.

2. Joints are classified as synarthroses, amphiarthroses, or diarthroses, depending on the degree of movement they allow. Joints are also classified by the type of connecting tissue holding them together. Fibrous joints are connected by dense fibrous tissue, ligaments, or membranes. Cartilaginous joints are connected by fibrocartilage or hyaline cartilage. Synovial joints are connected by a fibrous joint capsule. Within the capsule is a small fluid-filled space. The fluid in the space nourishes the articular cartilage that covers the ends of the bones meeting in the synovial joint.

3. Articular cartilage is a highly organized system of collagen fibers and proteoglycans. The fibers firmly anchor the cartilage to the bone, and the proteoglycans control the loss of fluid from the cartilage.

**Structure and Function of Skeletal Muscles**

1. Skeletal muscle is made up of millions of individual fibers.

2. Whole muscles vary in size (2 to 60 cm) and shape (fusiform, pennate). They are encased in a three-part connective tissue framework. The fundamental concept of muscle function is the motor unit, defined as those muscle fibers innervated by a single motor nerve, its axon, and anterior horn cell.

3. Satellite cells are dormant myoblasts; however, when activated, they can regenerate muscle.

4. Muscle fibers contain bundles of myofibrils arranged in parallel along the longitudinal axis and include the muscle membrane, myofibrils, sarcotubular
system, sarcoplasm, and mitochondria. There are two types of muscle fibers, type I and type II, determined by motor nerve innervation.

5. Myofibrils and myofilaments contain the major muscle proteins actin and myosin, which interact to form cross-bridges during muscle contraction. The nonprotein muscle constituents provide an energy source for contraction and regulate protein synthesis and enzyme systems as well as stabilize cell membranes.

6. Muscle contraction includes excitation, coupling, contraction, and relaxation.

7. Muscle strength is graded by the all-or-nothing phenomenon and recruitment. Speed of contraction is affected by several factors: muscle fiber type, temperature, stretch, and weight of the load.

8. There are two types of muscle contraction: static (isometric) and dynamic (isotonic). Muscle shortening occurs during contraction but can be seen also during pathologic and physiologic contracture.

9. Skeletal muscle requires a constant supply of adenosine triphosphate (ATP) and phosphocreatine to fuel muscle contraction and for growth and repair. ATP and phosphocreatine can be generated aerobically or anaerobically.

10. Tendon attachment sites of muscle to bone are called entheses.

11. Ligaments attach bone to bone, helping to form joints as well as stabilizing them against excessive movement. Both tendons and ligaments are mostly composed of types III, IV, V, and VI collagen and fibroblasts (termed tenocytes in tendons).

**Aging & the Musculoskeletal System**

1. Sarcopenia, or age-related loss in skeletal muscle, is a direct cause of decrease in muscle strength. A slow decline in dynamic and isometric strength is evident after age 70 years.

2. The regenerative function of muscle tissue remains normal in elderly persons.

3. On average, people lose about one third of a pound of muscle every year after age 40 years and gain at least as much body fat.

4. Reduced basal metabolic rate and decreased lean body mass are also noted in the
elderly population.

Muscleskeletal injuries include fractures, dislocations, sprains, and strains. Metabolic disorders, infections, inflammatory or noninflammatory diseases, or tumors may cause alterations in bones, joints, and muscles. The most common disease affecting bone is osteoporosis; much attention and debate has been focused on its risk factors and pathophysiology. Soft tissue disorders—including muscle, tendon, and ligament injuries; tumors; and metabolic derangements—also affect the musculoskeletal system.
Musculoskeletal Injuries

Trauma is referred to as the “neglected disease.” It is the leading cause of death in people ages 1 to 44 years of all races and socioeconomic levels. Each year, more than 120,000 persons in the United States die from unintentional injuries.¹ Musculoskeletal injuries have a major impact on the affected individuals, families, and society in general because of the physical and psychologic effects of limitation on mobility and daily activities, pain, and decreased quality of life. In addition, there are direct costs of diagnosis and treatments, and indirect economic costs related to loss of employment and decreased productivity.

Skeletal Trauma

Fractures

A fracture is a break in the continuity of a bone. A break occurs when force is applied that exceeds the tensile or compressive strength of the bone. The incidence of fractures varies for individual bones according to age and gender, with the highest incidence of fractures in young males (between the ages of 15 and 24 years) and older persons (65 years of age and older). Fractures of healthy bones, particularly the tibia, clavicle, and lower humerus, tend to occur in young persons as the result of trauma. Fractures of the hands and feet are often caused by accidents in the workplace. The incidence of fractures of the upper femur, upper humerus, vertebrae, and pelvis is highest in older adults and is often associated with osteoporosis (see p. 1000). Hip fractures, the most serious outcome of osteoporosis, have a wide variation in geographic occurrence.²

Classification of fractures.

There are numerous classification systems for various types of fractures, but the simplest systems describe the basic features of the broken bone. Fractures can be classified as complete or incomplete and as open or closed (Figure 39-1). In a complete fracture the bone is broken entirely, whereas in an incomplete fracture the bone is damaged but is still in one piece. Complete and incomplete fractures also can be called open (formerly referred to as compound) if the skin is open and closed (formerly called simple or incomplete) if it is not. A fracture in which a bone breaks into more than two fragments is termed a comminuted fracture. Fractures are also classified according to the direction of the fracture line. A linear fracture runs parallel to the long axis of the bone. An oblique fracture occurs at a slanted angle to the shaft of the bone. A spiral fracture encircles the bone, and a
transverse fracture occurs straight across the bone.

FIGURE 39-1 Examples of Types of Bone Fractures. A, Oblique: fracture at oblique angle across both cortices. Cause: Direct or indirect energy, with angulation and some compression. B, Occult: fracture that is hidden or not readily discernible. Cause: Minor force or energy. C, Open: skin broken over fracture; possible soft tissue trauma. Cause: Moderate to severe energy that is continuous and exceeds tissue tolerance. D, Pathologic: transverse, oblique, or spiral fracture of bone weakened by tumor pressure or presence. Cause: Minor energy or force, which may be direct or indirect. E, Segmented: fracture with two or more pieces or segments. Cause: Direct or indirect moderate to severe force. F, Spiral: fracture that curves around cortices and may become displaced by twist. Cause: Direct or indirect twisting energy or force with distal part held or unable to move. G, Transverse: horizontal break through bone. Cause:
Incomplete fractures tend to occur in the more flexible, growing bones of children. The three main types of incomplete fractures are greenstick, torus, and bowing fractures. A **greenstick fracture** perforates one cortex and splinters the spongy bone. The name is derived from the damage sustained by a young tree branch (a green stick) when it is bent sharply. The outer surface is disrupted, but the inner surface remains intact. Greenstick fractures typically occur in the metaphysis or diaphysis of the tibia, radius, and ulna. In a **torus fracture**, the cortex buckles but does not break. **Bowing fractures** usually occur when longitudinal force is applied to bone. This type of fracture is common in children and usually involves the paired radius-ulna or the fibula-tibia. A complete diaphyseal fracture occurs in one of the bones of the pair, which disperses the stress sufficiently to prevent a complete fracture of the second bone, which bows rather than breaks. A bowing fracture resists correction (**reduction**) because the force necessary to reduce it must be equal to the force that bowed it. Treatment of bowing fractures is also difficult because the bowed bone interferes with reduction of the fractured bone. Types of fractures are summarized in **Table 39-1**.

Fractures may be further classified by cause as pathologic, stress, or
transchondral fractures. A **pathologic** (also known as **insufficiency** or **fragility**) **fracture** is a break at the site of a preexisting abnormality, resulting from force that would not fracture a normal bone. In any bone that lacks normal ability to deform and recover, these fractures can occur with normal weightbearing or activity. Rheumatoid arthritis, osteoporosis, Paget disease, osteomalacia, rickets, hyperparathyroidism, and radiation therapy all cause bone to lose its normal ability to deform and recover. Pathologic fractures are generally a result of bone weakness caused by another disease such as cancer, metabolic bone disorders, or infection. Although usually considered insufficiency fractures, breaks in the bone attributable to osteoporosis can also be referred to as pathologic fractures. Any disease process that weakens a bone (especially the cortex) predisposes the bone to pathologic fracture.

During activities that subject a bone to repeated strain, such as certain athletics, a **stress fracture** can occur in normal or abnormal bone. The forces placed on the bone are cumulative, eventually causing a fracture. A **fatigue fracture** is caused by repetitive, sometimes abnormal stress or torque applied to a bone with normal ability to deform and recover. Fatigue fractures usually occur in individuals who engage in a new or different activity that is both strenuous and repetitive (e.g., joggers, skaters, dancers, military recruits). Because gains in muscle strength occur more rapidly than gains in bone strength, the newly developed muscles place exaggerated stress on the bones that are not yet ready for the additional stress. The imbalance between muscle and bone development causes microfractures to develop in the cortex. If the activity is controlled and increased gradually, new bone formation catches up to the increased demands and microfractures do not occur.

A **transchondral fracture** consists of fragmentation and separation of a portion of the articular cartilage. (Joint structures are defined in Chapter 38.) Single or multiple sites may be fractured, and the fragments may consist of cartilage alone or cartilage and bone. Typical sites of transchondral fracture are the distal femur, the ankle, the patella, the elbow, and the wrist. Transchondral fractures are most prevalent in adolescents.

**Pathophysiology**

Fracture healing is a complex process that occurs primarily in one of two ways: direct or indirect healing. Both types of healing require integration of cells, signaling pathways, and various molecules. In **direct** (or **primary**) **healing**, intramembranous bone formation occurs when adjacent bone cortices are in contact with one another. This most often occurs when surgical fixation is used to repair a broken bone. No callus formation occurs with direct bone healing. **Indirect** (or **secondary**) **healing** involves both intramembranous and endochondral bone
formation, development of callus, and eventual remodeling of solid bone. Bone formation that begins with an underlying cartilage scaffold is termed endochondral bone formation.

A hallmark of indirect fracture healing is the formation of callus. Indirect fracture healing is most often observed when a fracture is treated with a cast or other nonsurgical method. When a bone is broken, the periosteum and blood vessels in the cortex, marrow, and surrounding soft tissues are disrupted. Bleeding occurs from the damaged ends of the bone and from the neighboring soft tissue. A clot (hematoma) forms within the medullary canal, between the fractured ends of the bone, and beneath the periosteum (Figure 39-2). Bone tissue immediately adjacent to the fracture dies. This dead tissue (along with any debris in the fracture area) stimulates an intense inflammatory response characterized by vasodilation, exudation of plasma and leukocytes, and infiltration by inflammatory leukocytes, growth factors, and mast cells that simultaneously decalcify the fractured bone ends. Within 48 hours after injury, vascular tissue from surrounding soft tissue and the marrow cavity invades the fracture area, and blood flow to the entire bone increases. Bone-forming cells in the periosteum, endosteum, and marrow are activated to produce subperiosteal procallus along the outer surface of the shaft and over the broken ends of the bone (see Figure 39-2). Osteoblasts within the procallus synthesize collagen and matrix, which becomes mineralized to form callus. As the repair process continues, remodeling occurs, during which unnecessary callus is resorbed and trabeculae are formed along lines of stress as the repair tissues align with the tissue cells of the host (Figure 39-3). Except for the liver, bone is unique among all body tissues in that it will form new bone, not scar tissue, when it heals after a fracture.
FIGURE 39-2  Bone Healing (Schematic Representation). A, Bleeding at broken ends of the bone with subsequent hematoma formation. B, Organization of hematoma into fibrous network. C, Invasion of osteoblasts, lengthening of collagen strands, and deposition of calcium. D, Callus formation; new bone is built while osteoclasts destroy dead bone. E, Remodeling is accomplished while excess callus is reabsorbed and trabecular bone is deposited. (From Monahan FD et al: Phipps’ medical-surgical nursing: health and illness perspectives, ed 8, St Louis, 2007, Mosby)
**Clinical manifestations**

The signs and symptoms of a fracture include unnatural alignment (deformity), swelling, muscle spasm, tenderness, pain and impaired sensation, and decreased mobility. The position of the broken bone segments is determined by the pull of attached muscles, gravity, and the direction and magnitude of the force that caused the fracture.

Immediately after a bone is fractured, there often is numbness at the fracture site because of trauma to the nerve or nerves at the injury site. The numbness may last several minutes, during which time the injured person can continue to use the fractured bone. However, once the numbness dissipates, the subsequent pain is quite severe and may be incapacitating until relieved with medication and treatment of the fracture. Pain can be caused by muscle spasms at the fracture site, overriding of the fracture segments, or damage to adjacent soft tissues.

Pathologic fractures can cause angular deformity, painless swelling, or generalized bone pain. Stress fractures are painful because of accelerated remodeling; initially, pain occurs during activity and is usually relieved by rest. Stress fractures also cause local tenderness and soft tissue swelling. Transchondral fractures may be entirely asymptomatic or may be painful during movement. Range of motion in the joint is limited, and movement may evoke audible clicking sounds (crepitus).
Evaluation and treatment

Adequate immobilization with a splint or cast is often all that is required for healing of fractures that are not misaligned. Treatment of a displaced fracture involves realigning the bone fragments (reduction) close to their normal or anatomic position and holding the fragments in place (immobilization) so that bone union can occur. Several methods are available to reduce a fracture: closed manipulation, traction, and open reduction. Many displaced fractures can be reduced by closed manipulation and reduction. The bone is moved or manipulated into place without opening the skin. Closed reduction is used when the contour of the bone is in fair anatomic alignment and can be manually placed into normal alignment, and then maintained with immobilization. Splints and casts are used to immobilize and hold a closed reduction in place.

Traction may be used to accomplish or maintain reduction. When bone fragments are displaced (not in their anatomic position), weights may be used to apply firm, steady traction (pull) and countertraction to the long axis of the bone. Traction stretches and fatigues muscles that have pulled the bone fragments out of place, more readily allowing the distal fragment to align with the proximal fragment. Traction can be applied to the skin (skin traction) or directly to the involved bone (skeletal traction). Skin traction is used when only a few pounds of pulling force are needed to realign the fragments or when the traction will be used only for a brief time, such as before surgery or, for children with femoral fractures, for 3 to 7 days before applying a cast. In skeletal traction, a pin or wire is drilled through the bone distal to the fracture site, and a traction bow, rope, and weights are attached to the pin or wire to apply tension and to provide the pulling force required to overcome the muscle spasm and help realign the fracture fragments. More often, surgical repair (open reduction and internal fixation) or external fixation devices are used to realign displaced fractures.

Open reduction is a surgical procedure that exposes the fracture site; the fragments are then manipulated into alignment under direct visualization. Some form of hardware, such as a screw, plate, nail, or wire, is used to maintain the reduction (internal fixation). External fixation, a procedure in which pins or rods are surgically placed into uninjured bone near the fracture site and then stabilized with an external frame of bars, is another method used to treat fractures that would not be adequately stabilized with a cast. Bone grafts—using donor bone from the individual (autograft), a cadaver (allograft), or bone substitutes (ceramic composites, bioactive cement)—can fill voids in the bone.

Improper reduction or immobilization of a fractured bone may result in nonunion, delayed union, or malunion. Nonunion is failure of the bone ends to grow together. The gap between the broken ends of the bone fills with dense fibrous
and fibrocartilaginous tissue instead of new bone. Occasionally, the fibrous tissue contains a fluid-filled space that resembles a joint and is termed a *false joint*, or *pseudoarthrosis*. **Delayed union** is union that does not occur until approximately 8 to 9 months after a fracture. **Malunion** is the healing of a bone in an incorrect anatomic position.

**Dislocation and Subluxation**

Dislocation and subluxation are usually caused by trauma. **Dislocation** is the displacement of one or more bones in a joint in which the opposing joint surfaces entirely lose contact with one another. If contact between the opposing joint surfaces is only partially lost, the injury is called a **subluxation**.

Dislocation and subluxation are most common in persons younger than 20 years of age and are generally associated with fractures. However, they may be the result of congenital or acquired disorders that cause (1) muscular imbalance, as occurs with congenital dislocation of the hip or neurologic disorders; (2) incongruities in the articulating surfaces of the bones, as occur with rheumatoid arthritis (see p. 1012); or (3) joint instability.

The joints most often dislocated or subluxated are the joints of the shoulder, elbow, wrist, finger, hip, and knee. The shoulder joint most often injured is the glenohumeral joint. Finger dislocations are common injuries in contact sports such as basketball, football, and rugby.

Traumatic dislocation of the elbow joint is common in the immature skeleton. In adults, an elbow dislocation is usually associated with a fracture of the ulna or head of the radius. Traumatic dislocation of the wrist usually involves the distal ulna and carpal bones. Any one of the eight carpal bones can be dislocated after an injury. Dislocation in the hand usually involves the metacarpophalangeal and interphalangeal joints.

Considerable trauma is needed to dislocate the hip. Anterior hip dislocation is rare in healthy persons; it is caused by forced abduction—for example, when an individual lands on his or her feet after falling from an elevated height. Posterior dislocation of the hip can occur as a result of an automobile accident in which the flexed knee strikes the dashboard, causing the head of the femur to be pushed posteriorly from the hip joint.

The knee is an unstable weightbearing joint that depends heavily on the soft tissue structures around it for support. It is exposed to many different types of motion (flexion, extension, rotation) and is one of the most commonly injured joints. A knee dislocation can be anterior, posterior, lateral, medial, or rotary. It is often the result of an injury that occurs during contact sports activities, such as soccer,
lacrosse, or football.

**Pathophysiology**
Dislocations and subluxations are often accompanied by fracture because stress is placed on areas of bone not usually subjected to stress. In addition, as the joint loses its normal congruity, there may be bruising or tearing of adjacent nerves, blood vessels, ligaments, supporting structures, and soft tissue. Dislocations of the shoulder may damage the shoulder capsule and the axillary nerve. Damage to axillary nerves can cause anesthesia or dysesthesia in the sensory distribution of the nerve and paralysis of the deltoid muscle. Dislocations also may disrupt circulation, leading to ischemia and possibly even permanent disability of the affected extremity tissues.

**Clinical manifestations**
Signs and symptoms of dislocations or subluxations include pain, swelling, limitation of motion, and joint deformity. Pain may be caused by effusion of inflammatory exudate into the joint or by associated tendon and ligament injury. Joint deformity is typically caused by muscle contractions that exert pull on the dislocated or subluxated joint. Limitation of motion results from effusion into the joint or the displacement of bones.

**Evaluation and treatment**
Evaluation of dislocations and subluxations is based on clinical manifestations and radiographic evaluation. Treatment consists of reduction and immobilization for 2 to 6 weeks to allow healing of damaged structures, followed by exercises to restore normal range of motion in the joint. Depending on the joint and severity of injury, complete healing can take months to sometimes years.

**Support Structures**
**Sprains and Strains of Tendons and Ligaments**
Tendon and ligament injuries often accompany fractures and dislocations. A **tendon** is fibrous connective tissue (composed primarily of type I collagen) that attaches skeletal muscle to a bone or other structure; the area of attachment on a bone is called an **enthesis**. The enthesis serves to evenly distribute tension differences between the bone and tendon. The zone where muscle transitions into tendon is known as the myotendinous junction. Functionally, muscles and tendons work together as a single, integrated unit allowing motion. A **ligament** is a band of
fibrous connective tissue that connects bones where they meet in a joint. Ligaments are structurally quite similar to tendons, although ligaments have a higher proportion of small-diameter collagen fibrils. The primary difference between tendons and ligaments is their anatomic location.\textsuperscript{7} Tendons and ligaments support the bones and joints and either facilitate or limit motion, respectively. Either structure can be completely separated from bone at their points of attachment, torn, lacerated, or ruptured.

Tearing or stretching of a muscle or tendon is commonly known as a strain. Major trauma can tear or rupture a tendon at any site in the body. Most commonly injured are the tendons of the hands and feet, the knee (patellar), the upper arm (biceps and triceps), the thigh (hamstring), the ankle, and the heel (Achilles).

Ligament tears are commonly known as sprains. Ligament tears and ruptures can occur at any joint but are most common in the wrist, ankle, elbow, and knee joints. A complete separation of a tendon or ligament from its bony attachment site is known as an avulsion and is commonly seen in young athletes, especially sprinters, hurdlers, and distance runners.

Strains and sprains are classified as first degree (mild), second degree (moderate), and third degree (severe). In first-degree injuries, the fibers are stretched but the muscle (strain) or joint (sprain) remains stable. In second-degree strains or sprains, there is more tearing of the tendon or ligament fibers, with muscle weakness (strain) or some joint instability (sprain) but incomplete tearing of fibers. Third-degree strains and sprains result in an inability to contract the muscle normally (strain) and cause significant joint instability (sprain).

**Pathophysiology**

When a tendon or ligament is torn, an inflammatory exudate develops between the torn ends. Multiple growth factors that direct the repair process are released. Later, granulation tissue containing macrophages, fibroblasts, and capillary buds grows inward from the surrounding soft tissue and cartilage to begin the repair process. Within 4 to 5 days after the injury, collagen formation begins. At first, collagen formation is random and disorganized. As the collagen fibers interweave and connect with preexisting tendon fibers, they become organized parallel to the lines of the musculotendinous unit. Eventually vascular fibrous tissue fuses the new and surrounding tissues into a single mass. Collagen fibers reconnect the tendon and bone, forming a type of enthesis.\textsuperscript{7} Usually a healing tendon or ligament lacks sufficient strength to withstand some stress for 4 to 5 weeks after the injury; it may take more than 3 months to achieve mechanical stability of a joint.\textsuperscript{8} If powerful muscle pull does occur during healing, the tendon or ligament ends may separate again, which causes the tendon or ligament to heal in a lengthened shape or with an
excessive amount of scar tissue, resulting in poor tendon or ligament function.

Clinical manifestations

Tendon and ligament injuries are painful and are usually accompanied by soft tissue swelling, changes in tendon or ligament contour, and dislocation or subluxation of bones. Pain is generally sharp and localized, and tenderness persists over the distribution of the tendon or ligament. Movement or weightbearing increases pain. Even with prompt treatment, depending on the tendon or ligament involved, significant injuries may result in decreased mobility, instability, and weakness of the affected joints.

Evaluation and treatment

Evaluation is based on mechanism of injury, clinical manifestations, stress radiography, arthroscopy, or arthrography. Initial treatment consists of PRICE (Protection, Rest, Ice, Compression, and Elevation) for the first 48 to 72 hours. Once swelling and acute pain subside, in most cases, support of the affected tendon or ligament with a compression dressing or brace will provide appropriate reinforcement while the tissues heal. Rehabilitation is crucial to regaining good functional outcome. In severe (third-degree) injuries, treatment may include suturing the tendon or ligament ends in close approximation. If this is not feasible because of the extent of damage, tendon or ligament grafting may be necessary. Prolonged, functional rehabilitation programs help ensure return of near-normal functions, but recovery may be complicated by posttraumatic arthritis.

Tendinopathy, Epicondylopathy, and Bursitis

Trauma also can cause painful inflammation of tendons (tendinopathy [tendonitis]) and bursae (bursitis). Other causes of damage to tendons include reduced tissue perfusion, mechanical irritation, crystal deposits, postural misalignment, and hypermobility of a joint. Thus, tendinopathy is a more accurate term than tendonitis in most cases. Studies have shown that vascular ingrowth in tendinopathy (neovascularization) is accompanied with nerve ingrowth, facilitating pain transmission in Achilles and patellar tendinopathy.

The histopathology of common conditions, such as lateral epicondylopathy (“tennis elbow”) or medial epicondylopathy (“golfer’s elbow”), is a degenerative process (Figure 39-4). A bony prominence at the end of a bone where tendons or ligaments attach is termed an epicondyle. When force is sufficient to cause microscopic tears (microtears) in tissue, the result is known as tendinopathy or epicondylopathy. Microtears in the tendon, the presence of disorganized collagen
fibers, and neovascularization are indicative of incomplete tissue repair. Initial inflammatory changes cause thickening of the tendon sheath, limiting movements and causing pain. Microtears cause bleeding, edema, and pain (because of the presence of substance P) in the involved tendon or tendons. At times, after repeated microtears, calcium may be deposited in the tendon origin area.
**Lateral epicondylopathy (tennis elbow)** is caused by irritation and overstretching of the extensor carpi radialis brevis (ECRB) tendon and forearm extensor muscles, resulting in tissue degradation, loss of grip strength, and pain. Medial epicondylopathy (golfer’s elbow) is the result of similar forces affecting the forearm muscles responsible for forearm flexion and pronation (see Figure 39-
Repetitive load-bearing activities or acute injuries that involve flexion, extension, pronation, or supination of the elbow and forearm can lead to either lateral or medial elbow symptoms.

Clinical manifestations of epicondylopathy are usually localized to one side of the joint. In general, there is local tenderness and more pain with active motion than with passive motion. With tendinopathy or tendonitis, the pain is localized over the involved tendon. Stressing the tendon with simple activities, such as lifting even a few pounds of weight, can increase pain. Pain and sometimes weakness limit joint movement.

**Bursae** are small sacs lined with synovial membrane and filled with synovial fluid that are located between bony prominences and soft tissues such as tendons, muscles, and ligaments (Figure 39-5). Bursae can be either “constant” (those formed during embryologic development) or “adventitious” (bursae that develop as a result of chronic friction and degeneration of fibrous tissue between adjacent structures). The primary function of a bursa is to separate, lubricate, and cushion these structures. When irritated or injured, these sacs become inflamed and swell. Because most bursae lie outside joints, joint movement is rarely compromised with bursitis. Acute bursitis occurs primarily in middle age and is caused by trauma. Chronic bursitis can result from repeated trauma. Septic bursitis is caused by wound infection or bacterial infection of the skin overlying the bursae. Bursitis commonly occurs in the shoulder, hip, knee, and elbow but also can affect the spine, wrist, foot, and ankle.
Pathophysiology

Bursitis usually is an inflammation that is reactive to overuse or excessive pressure but also can be caused by infection, autoimmune diseases, crystal deposition, or acute trauma. The inflamed bursal sac becomes engorged, and the inflammation can spread to adjacent tissues. The inflammation may decrease with rest, ice, and aspiration of the fluid. (Inflammation is discussed in Chapter 6.)

Clinical manifestations

Joint motion is rarely limited in bursitis, except by pain. Shoulder pain may impair arm abduction. Bursitis in the knee produces pain when climbing stairs, and crossing the legs is painful in bursitis of the hip. Lying on the side of the inflamed trochanteric bursa is also very painful. Signs of infectious bursitis may include the presence of pain, a puncture site, warmth and erythema, prior corticosteroid injection, severe inflammation, or an adjacent source of infection, such as from total joint replacement surgery.

Evaluation and treatment

The diagnosis of tendinopathy, epicondylopathy, and bursitis is primarily based on clinical history and physical examination. Other imaging techniques, such as ultrasound or magnetic resonance imaging (MRI), may be used to evaluate the severity of the problem. Treatment may include temporary immobilization of the joint with a sling, splint, or cast; administration of systemic analgesics; application
of ice or heat; or local injection of an anesthetic, a corticosteroid, platelet-rich plasma (PRP), or a combination local anesthetic/corticosteroid. Physical therapy to prevent loss of function begins after acute inflammation subsides (see Health Alert: Managing Tendinopathy).

**Health Alert**

**Managing Tendinopathy**

Tennis and golfer’s elbow, Achilles tendinopathy, and other tendon problems account for a large percentage of sports-related overuse injuries. Successful treatment of these conditions is challenging because of the mechanisms of tendon healing as well as inconsistent results, with many interventions still not completely understood. Chronic pain is common and may be the result of ingrowth of nerves that accompanies ingrowth of new blood vessels during the healing process. Recent studies suggest that the traditional approach of corticosteroid injections is helpful only for the short term. Other therapies that show promise include the following:

**Prolotherapy:** An irritant such as glucose or lidocaine is injected into the affected tendon, inducing an inflammatory response, thereby stimulating growth of new tendon fibers.

**Eccentric exercises:** The tendon is “prestretched,” increasing its resting length and resulting in less strain during movement. The load on the tendon is gradually increased, causing the tendon, itself, to strengthen.

**Extracorporeal shockwave therapy (SWT):** External acoustic or sonic waves are focused on the affected area. The shockwaves stimulate soft tissue healing and inhibit pain receptors.

**Needling:** This treatment involves multiple insertions of a sterile needle into affected tissue. It is thought the pain sensation is reduced by stimulating A-nerve fibers. This technique is often referred to as “dry needling” since no fluid is introduced.

**Platelet-rich plasma (PRP):** This autologous source of concentrated platelets is obtained by centrifugation of plasma. The resulting solution contains high concentrations of cytokines and growth factors, such as platelet-derived growth factor (PDGF) and transforming growth factor-beta (TGF-β), which are thought
to promote the growth of new, healthy tissue.

**Autologous tenocyte injections:** Autologous injection of tenocytes at the site of tendinopathy is thought to provide necessary mediators of tissue healing.

### Muscle Strains

Muscle strain is a general term for local muscle damage. Mild injury such as muscle strain is usually seen after traumatic or sports injuries. It is often the result of sudden, forced motion causing the muscle to become stretched beyond normal capacity. Strains often involve the tendon as well. Penetrating injuries, such as knife and gunshot wounds, can cause traumatic rupture (see Chapter 4). Muscles are ruptured more often than tendons in young people; the opposite is true in the older population. Muscle strain may be chronic when the muscle is repeatedly stretched beyond its usual capacity. There is evidence of tissue disruption with subsequent signs of muscle regeneration and connective tissue repair when a biopsy is performed. Hemorrhage into the surrounding tissue and signs of inflammation also may be present.

Muscle healing occurs in three phases:

1. Destruction, in which the myofibers of the damaged muscle contract and necrose, beginning an inflammatory reaction. The gap between torn fibers is filled by a hematoma.

2. Repair, which begins with monocytes phagocytizing the dead tissue and activating satellite cells, which become myoblasts. The myoblasts infiltrate the scar tissue and new capillary formation begins at the site of injury. The first two phases occur within a week of injury.

3. Remodeling occurs as the myofibers mature, form contractile tissue, and attach to the ends of scar tissue. Regeneration may take up to 6 weeks, and the affected muscle should be protected during that time.

Degrees of acute muscle strain, together with their manifestations and treatment, are summarized in Table 39-2.
### TABLE 39-2
Muscle Strain

<table>
<thead>
<tr>
<th>Type</th>
<th>Manifestations</th>
<th>Treatment</th>
</tr>
</thead>
<tbody>
<tr>
<td>First degree (example: bench press in untrained athlete)</td>

<td>Caused by tearing of fascia, marked weakness, deformity</td>
<td>Surgery to approximate ruptured edges; immobilization and non-weightbearing status for 6 weeks</td>
</tr>
</tbody>
</table>

A late complication of some muscle injuries is **myositis ossificans**, also known as **heterotopic ossification (HO)**. Its exact pathophysiology remains unknown, but the basic problem seems to be the inability of mesenchymal cells to differentiate into osteoblastic stem cells and inappropriate differentiation of fibroblasts into bone-forming cells. Though uncommon, HO is associated with burns, joint surgery, and trauma to the musculoskeletal system or central nervous system. HO may involve the muscle or tendons, ligaments, or bones near the muscle, causing stiffness or deformity of an extremity. Soft tissue calcifications may be seen on plain radiographs.

### Rhabdomyolysis

Once used interchangeably with the term **myoglobinuria**, **rhabdomyolysis** is the rapid breakdown of muscle that causes the release of intracellular contents, including the protein pigment myoglobin, into the extracellular space and bloodstream. Physical interruptions in the sarcolemma membrane, called delta lesions, are the route by which muscle constituents are released. (The sarcolemma membrane, the plasma membrane of the muscle cell, is described in Chapter 38.)

**Myoglobinuria**, first described in victims of crush injuries in London during World War II, refers to the presence of the muscle protein myoglobin in the urine.

### Pathophysiology

Rhabdomyolysis is sometimes incorrectly used interchangeably with **crush injury** (a description of injuries resulting from crushing of a body part), **compartment syndrome** (the consequences of increased intracompartmental pressures of a muscle), or **crush syndrome** (the systemic pathophysiologic events caused by rhabdomyolysis, primarily involving the kidneys and coagulation syndrome). Although relatively rare, rhabdomyolysis has many causes (Box 39-1) and can result in serious complications, including hyperkalemia (because of the release of intracellular potassium into the circulation) and cardiac dysrhythmias. The most clinically significant complication is acute renal failure (myoglobin precipitates in
the tubules, obstructing flow through the nephron and producing injury.\textsuperscript{18} Other complications include metabolic acidosis (from liberation of intracellular phosphorus and sulfate) and even disseminated intravascular coagulation (DIC) (likely caused by activation of the clotting cascade by sarcolemma damage and release of intracellular components from the damaged muscles).

### Box 39-1

**Selected Causes of Rhabdomyolysis**

#### Direct Trauma

- Blunt trauma or crush injury (motor vehicle crashes, collapsed buildings)
- Burns (thermal)
- Electrical injury
- Excessive compression (from immobility attributable to stroke, alcohol or drug intoxication)

#### Drugs

- Alcohol
- Amphetamines
- Anesthetic and paralytic agents (halothane, propofol, succinylcholine—malignant hyperthermia syndrome)
- Antihistamines (diphenhydramine, doxylamine)
- Anti-hyperlipidemic agents (statins, clofibrate, bezafibrate)
- Antipsychotics and antidepressants (amitriptyline, doxepin, fluoxetine, haloperidol, lithium, protriptyline, perphenazine, promethazine, chlorpromazine, trifluoperazine, venlafaxine)
- Caffeine
- Cocaine
Corticosteroids

Fibrinates (antilipid agents: bezafibrate, ciprofibrate, clofibrate, clofibrate, ezetimibe, gemfibrozil)

Heroin

HIV integrase inhibitor (raltegravir)

Hypnotics and sedatives (benzodiazepines, barbiturates)

LSD (lysergic acid diethylamide)

Methadone

Methamphetamine

Methylenedioxymethamphetamine (MDMA; “ecstasy”)

Miscellaneous medications (amphotericin B, azathioprine, ε-aminocaproic acid, quinidine, penicillamine, salicylates, theophylline, terbutaline, thiazides, vasopressin)

Phencyclidine

Protease inhibitors

Statins (atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, simvastatin)

Miscellaneous drugs (amphotericin B, arsenic, azathioprine, halothane, naltrexone, quinidine, penicillamine, propofol, salicylates, succinylcholine, theophylline, terbutaline, thiazides, vasopressin)

**Excessive Muscular Contraction**

Status epilepticus

Delirium tremens

Acute psychosis

Severe dystonia
Sporadic strenuous exercise (e.g., marathons, squats)

Tetanus

**Infectious Agents**

Bacteria (group B streptococci, *Streptococcus pneumoniae*, *Staphylococcus epidermidis*, *Borrelia burgdorferi*, *Escherichia coli*, *Clostridium perfringens*, *Clostridium tetani*, *Streptococcus viridans*; *Bacillus*, *Brucella*, *Legionella*, *Listeria*, *Leptospira*, *Mycoplasma*, *Plasmodium*, *Rickettsia*, *Salmonella*, and *Vibrio* species)

Fungal organisms (*Aspergillus*, *Candida* species)

Viruses (influenza types A and B, coxsackievirus, dengue, Epstein-Barr, HIV, cytomegalovirus, parainfluenza, varicella-zoster, West Nile)

**Toxins**

Carbon monoxide

Envenomation (black widow spider, Africanized honey bees, vipers)

Hemlock

Methanol

Toluene

**Hereditary Enzyme Disorders (Rare)**

McArdle disease (myophosphorylase deficiency)

Tarui disease (type VII glycogen storage disease)

Phosphoglycerate mutase deficiency (glycogen storage disease type X)

Carnitine palmitoyltransferase deficiency (CPT1 deficiency)

**Miscellaneous Causes**
Clinical manifestations

A classic triad of muscle pain, weakness, and dark urine is considered typical of rhabdomyolysis, but those affected may have no complaint of pain or muscle weakness.\textsuperscript{16} Abnormally dark urine caused by myoglobinuria may be the first and only symptom; however, the presence of myoglobin in urine is not a reliable test for rhabdomyolysis.\textsuperscript{19} The renal threshold for myoglobin in urine is low (approximately 0.5 mg/dl of urine); therefore only 200 g of muscle need to be damaged to cause visible changes in the urine. Myoglobin is rapidly cleared and levels may return to normal within 24 hours of injury. Along with the release of myoglobin, creatine kinase (CK) and other serum enzymes are released in massive quantities (normal CK levels are 5 to 25 international units/L for women and 5 to 35 international units/L for men). The efflux of intracellular proteins and enzymes includes loss of potassium, phosphate, nucleotides, creatinine, and creatine. Serum hypocalcemia is seen early in the course of myoglobinuria and is followed by late hypercalcemia. The risk of renal failure increases proportionately to the increase in the levels of serum CK, potassium, and phosphorus.

Evaluation and treatment

The most important and clinically useful measurement in rhabdomyolysis is serum creatine kinase (CK) level. A level 5 to 10 times the upper limit of normal (about...
1000 units/L) is used to identify rhabdomyolysis. Once CK levels exceed 15,000 units/L, acute renal failure is likely. Other laboratory tests may include electrolytes (elevated serum potassium level [hyperkalemia] can cause life-threatening cardiac abnormalities) and BUN/creatinine ratio (decreased ratio because of creatine released from damaged muscle being converted to creatinine). Additional laboratory tests—such as measurement of hemoglobin, hematocrit, and platelet levels and determination of activated partial thromboplastin time—may be indicated in the presence of other trauma or suspected bleeding. A recent study evaluated the ultrasonographic appearance of rhabdomyolysis in damaged muscle from earthquake victims and found abnormalities in muscle texture and subcutaneous tissue, as well as liquid areas in the damaged tissue.

Maintaining adequate urinary flow and prevention of kidney failure are goals of treatment. Rapid intravenous hydration maintains adequate kidney flow. Other issues, such as hyperkalemia, may require temporary hemodialysis. Treatments such as using mannitol to cause an osmotic diuresis or bicarbonate to alkalinize the urine have not been shown to consistently improve outcomes, though in most instances these types of therapy are unlikely to cause additional complications.

**Compartment Syndrome**

**Compartment syndrome** is the result of increased pressure within a muscle compartment. Several layers of fibrous fascia (that do not expand) surround skeletal muscles. Increased pressure on the muscle tissue causes diminished capillary blood flow, resulting in local tissue hypoxia and necrosis. Causes of compartment syndrome include conditions that increase the contents of the compartment (such as bleeding after a fracture), decrease the compartment volume (such as a tight bandage or cast), or a combination of both conditions that result in disturbing the muscle's microvasculature (Box 39-2).

Any condition that disrupts the vascular supply to an extremity (such as severe burns, bleeding disorders, crush injury, snake or insect bites, extremely tight bandages, or casts) can cause increased pressure within the muscle compartments.

**Box 39-2**

**Factors Affecting Development of Compartment Syndrome**

**Increased Intracompartamental Pressure**
Fracture (open or closed)

Traction

Crush syndrome

Vigorous exercise or nonroutine activity/overuse in nonathletes

High-energy soft tissue injury (blast injuries, blunt force trauma)

Fluid infusion

Arterial puncture

Ruptured abdominal aortic aneurysm

Ruptured ganglion/other cyst

Envenomation (venomous snakes, black widow spiders)

Nephrotic syndrome

Viral myositis

Acute hematogenous osteomyelitis

Orthopedic procedures (e.g., osteotomy, joint replacement)

Seizures

Tetany

**Reduced Compartment Volume**

Burns

Repair of muscle herniation

Circumferential dressings

Casts that are too tight
Conditions That Disturb Microcirculation

Diabetes

Hypothyroidism

Bleeding disorders (hemophilia, von Willebrand disease, leukemia, vitamin K deficiency, viral hemorrhagic fevers [dengue])

Excessive anticoagulation

Malignancies

Pathophysiology

The weight of a limb extremity can generate enough pressure to produce muscle ischemia (Figures 39-6 and 39-7). This causes edema, rising compartment pressure, and tamponade that lead to muscle infarction and neural injury and eventually result in cell loss.
FIGURE 39-6  Pathogenesis of Compartment Syndrome and Crush Syndrome Caused by Prolonged Muscle Compression. ECF, Extracellular fluid.
Clinical manifestations

Compartments often affected are the anterior and deep posterior tibial compartments in the leg, the forearm, the gluteal compartments in the buttocks, and the abdominal wall. Diagnosis is initiated by clinical examination. The “6 Ps” of compartment syndrome are Pain (out of proportion to the injury), Pressure (swelling, tenseness of the affected area), Pallor, Paresthesia, Paresis (of the involved extremity), and Pulselessness. None of these signs is truly dependable, although pain with passive extension of the fingers or toes in the affected extremity and paresthesia tend to be most suggestive of compartment syndrome.\(^{21,24}\)

A condition known as Volkmann ischemic contracture can develop when compartment syndrome is unrecognized or is not adequately treated. Irreversible neurovascular damage can occur. Contracture deformities of the fingers, hand, and wrist can lead to partial or complete disability of the affected limb.

Evaluation and treatment

Direct measurement of intracompartmental pressure, using a manometer or an
electronic transducer, is essential to confirm the diagnosis. Laboratory tests, ultrasonography, and imaging studies may help exclude other conditions but generally are not helpful in diagnosing compartment syndrome. Once intracompartmental pressures reach 30 mm Hg, surgical intervention is warranted to relieve pressure within the compartment.

Surgical intervention consists of performing a fasciotomy of the affected area to decompress the compartment and allow return of normal blood supply. Skin grafts are often required to close the resultant opening, but vacuum-assisted wound closure devices also have been used successfully in accelerating wound closure.

**Malignant Hyperthermia**

**Malignant hyperthermia (MH)** is an autosomal dominant inherited muscle disorder characterized by a hypermetabolic reaction to certain volatile anesthetics or certain depolarizing muscle relaxants (such as succinylcholine) that activate a prolonged release of intracellular calcium from the sarcoplasmic reticulum. Recently, advances in molecular genetics have shown that a mutation in the ryanodine receptor of skeletal muscle (RyR1) is responsible for the majority of cases, though other genetic mutations also may be involved. The normal excitation-coupling process of muscle contraction is altered in MH. Mutations of RyR1 receptors release uncontrolled amounts of calcium from the sarcoplasmic reticulum into the cytoplasm, causing continuous muscle contraction. This process also causes hypermetabolism with extremely high body temperature, muscle rigidity, rhabdomyolysis, and death if not quickly treated with dantrolene infusion.

Though reported in all countries, ages, and both genders, young males tend to be more susceptible to MH. Common signs and symptoms are respiratory acidosis (with elevated end tidal CO₂), tachycardia, masseter and skeletal muscle spasm, and elevated body temperature.

**Evaluation and treatment**

Careful and thorough preoperative assessment should alert the anesthesiologist to the possibility of an individual being susceptible to malignant hyperthermia. A family history of anesthetic problems and previous untoward anesthetic experiences (muscle cramping, unexplained fevers, dark urine) are criteria that require further clarification before administration of a volatile anesthetic, such as halothane, or of the muscle relaxant succinylcholine. Currently, the muscle contracture test is considered the best predictor of developing MH. A muscle biopsy is obtained from the individual and then separately exposed to standardized amounts halothane and caffeine. If the muscle bundles exhibit a contracture at specified limits, the
individual is considered susceptible to MH. Molecular and DNA testing are promising future means of identifying at-risk individuals.

Priorities in treatment of MH include identifying and treating the underlying disorder and preventing life-threatening renal failure. Malignant hyperthermia and myoglobinuria can be treated by infusing dantrolene sodium (Dantrium). Secondary problems include electrolyte imbalance, volume depletion, acidosis, hyperuricemia, hyperkalemia, and calcium imbalance; these need specific treatment. Short-term dialysis also may be necessary.

Quick Check 39-1

1. How are fractures classified?

2. What is the primary pathology of epicondylopathy?

3. What are some causes of compartment syndrome?

4. Why is myoglobinuria a dangerous complication of rhabdomyolysis?
Disorders of Bones

**Metabolic Bone Diseases**

Metabolic bone disease is characterized by abnormal bone structure that is caused by altered or inadequate biochemical reactions, which may be attributable to genetics, diet, or hormones.

**Osteoporosis**

**Osteoporosis**, or porous bone, is generally described as decreased bone mineral density (BMD) and an increased risk of fractures because of alterations in bone microarchitecture. It is a complex, multifactorial, chronic disease that often progresses silently for decades until fractures occur. It is the most common disease that affects bone but is not necessarily a consequence of the aging process because some elderly people retain strong, relatively dense bones. In osteoporosis, old bone is being resorbed faster than new bone is being made, causing the bones to lose density, becoming thinner and more porous. A progressive loss of bone mass may continue until the skeleton is no longer strong enough to support itself. Eventually, bones can fracture spontaneously. As bone becomes more fragile, falls or bumps that would not have caused a fracture previously now cause bone to break (a fragility fracture). The most common sites for osteoporosis-related fractures are the spine, femoral neck, and wrist.  

Bone tissue can be normally mineralized in osteoporosis but the mass (density) of bone is decreased and the structural integrity of trabecular bone is impaired. Cortical bone becomes more porous and thinner, making bone weaker and prone to fractures (Figures 39-8 and 39-9). The World Health Organization (WHO) has defined osteoporosis as “a systematic skeletal disease characterized by low bone density and microarchitectural deterioration of bone tissue with a consequent increase in bone fragility.”
Bone density is based on the number of standard deviations that differ from the mean bone mineral density of a young-adult reference population (a T-score). Table 39-3 lists these categories. Bone density between 1.5 and 2.5 standard deviations below normal is considered osteopenia. A T-score of 2.5 or more standard deviations below normal bone density is considered osteoporotic. Severe or established osteoporosis is identified when there has been a fragility fracture associated with low bone density. The disease can be (1) generalized, involving major portions of the axial skeleton, or (2) regional, involving one segment of the appendicular skeleton.

*BMD, Bone mineral density; SD, standard deviation.*

Skeletal homeostasis depends on a narrow range of plasma calcium and phosphate concentrations, which are maintained by the endocrine system. Therefore, endocrine dysfunction ultimately can cause metabolic bone disease. In addition to declining levels of sex steroids, the hormones most commonly associated with osteoporosis are parathyroid hormone, cortisol, thyroid hormone, and growth hormone. (Endocrine function is discussed in Chapters 18 and 19.)

Other factors that can adversely affect normal bone homeostasis include multiple medications (such as glucocorticoids, proton pump inhibitors, thiazolidinediones, antiseizure medications, aromatase inhibitors, selective serotonin reuptake inhibitors [SSRIs], and anticoagulants), vitamin D deficiency, underlying diseases (rheumatoid disease, Paget disease, cancer, diabetes), low physical activity, and abnormal body mass index.\(^{34-38}\)

Throughout a lifetime, old bone is removed (resorption) and new bone is added (formation) to the skeleton. During childhood and teenage years, new bone is added faster than old bone is removed. Consequently, bones become larger, heavier, and denser. Bone formation continues at a pace faster than resorption until peak bone mass or maximum bone density and strength is reached, around age 30. Up to 90% of peak bone mass is obtained by age 20. After age 30, bone resorption slowly exceeds bone formation. In women, bone loss is most rapid in the first years after menopause but persists throughout the postmenopausal years. In 2011, the U.S. Preventive Services Task Force (USPSTF) issued a new recommendation that women age 65 and older be routinely screened for osteoporosis.\(^{39}\) Fractures are the major complication of osteoporosis and it has been estimated that nearly one in two white American women older than age 50 will sustain at least one fragility fracture in her lifetime.\(^ {40}\) Hospitalization admissions and costs for osteoporosis-related fractures in the United States are more than those from myocardial infarction, stroke, or breast cancer.\(^ {41}\) Osteoporosis is a worldwide problem with significant economic and health implications.\(^ {42-44}\) Hip fractures, in particular, can have devastating effects on an individual’s life. In addition to direct medical costs, studies have shown decreased quality of life as well as excess loss of life-years for those experiencing hip or osteoporotic fractures.\(^ {45-47}\) The major complications for
persons with osteoporosis are fractures (see *Health Alert: Osteoporosis Facts and Figures at a Glance*). Bone structure in men allows for improved torque strength and although men lose bone density with aging, it is at a slower, steadier rate than that of women.\(^{48}\) Nevertheless, men are more likely to die after a hip fracture than are women.\(^{49,50}\)

### Health Alert

#### Osteoporosis Facts and Figures at a Glance

- Osteoporosis is the most common bone disease of adults and the foremost cause of fractures in the elderly.

- Nearly 10 million Americans have osteoporosis (T-score ≥ 2.5 SD below normal peak bone mass) and nearly 43.1 million have low bone density (T-score 1.5 to 2.5 SD below normal peak bone mass).

- The National Osteoporosis Foundation (NOF) estimates that only about 40% of individuals with a hip fracture return to their prefracture level of functioning.

- Hip fractures account for only 14% of fractures in osteoporosis, but are responsible for 72% of fracture costs.

- Osteoporosis-related fractures result in approximately 180,000 nursing home admissions, more than 432,000 hospital admissions, and nearly 2.5 million medical office visits annually.

- By 2025, fractures are estimated to increase to 3 million annually, with medical costs escalated to $25.3 billion.

- It is estimated that one in two white women and one in five white men will experience a hip, spine, or wrist fracture sometime in their lives.

- By 2025, Hispanics are predicted to account for 20% of fractures in Arizona and California, with Asians and other non-white ethnic groups sustaining 27% of fractures in New York.

Vertebral fractures tend to occur in the later years of life; however, they are more difficult to ascertain because people may be unaware of the fracture. The degree of compression necessary to define a vertebral fracture is not standardized, although attempts have been made to standardize the definition and diagnosis of vertebral fractures. Thus, the true prevalence is unknown but fractures do increase in frequency by the sixth and seventh decades. Approximately 1 in 6 women and 1 in 12 men will sustain a vertebral fracture.\textsuperscript{51}

Age-related loss of bone density and osteoporosis is most common in white women but affects all races. Asian and black women have only about half the fracture rate of whites, but that percentage is expected to increase with improved life expectancy.\textsuperscript{52} In spite of lower incidence, mortality in black women after a hip fracture is higher than among white women. Other factors may include lower calcium intake, a high percentage of lactose intolerance, and increased prevalence of diseases such as sickle cell disease and lupus that increase the risk of developing osteoporosis.\textsuperscript{53} Both black women and black men have generally been undertreated for osteoporosis.

Fracture prevention is a primary goal of osteoporosis treatment. Measuring bone mineral density (BMD) by using dual x-ray absorptiometry (DXA) to calculate an individual's T-score continues to be the most common method of evaluating bone health and predicting fracture risk. Unfortunately, the technology to perform DXA scans is not available in all areas of the world. As a result, several tools that do not require BMD testing have been developed and validated to predict future fracture risk. These tools are summarized in Table 39-4. Interestingly, when BMD measurement is not available, there is little difference in fracture prediction between the Internet-based FRAX\textsuperscript{®} and the other tools, including the simplest screening tool—the Osteoporosis Self-assessment Tool, or OST.\textsuperscript{54}

*FRAX, World Health Organization's “Fracture Risk Assessment Tool”; ORAI, osteoporosis risk assessment instrument; OSIRIS, osteoporosis index of risk; OST, osteoporosis self-assessment tool; SCORE, simple calculated osteoporosis risk estimation.*

Bone quality is not defined by bone mass alone (as measured by BMD) but also by the microarchitecture of the bone. Thus, other variables include crystal size and shape, brittleness, vitality of bone cells, structure of the bone proteins, integrity of the trabecular network, and the ability to repair tiny cracks. Because bone density relates to *quantity* of bone, *quality* of bone is not accurately identified by bone density testing alone. As a result, bone density testing may not accurately identify those who will eventually be susceptible to fractures.

**Postmenopausal osteoporosis** is bone loss that occurs in middle-aged and older women. It can occur because of estrogen deficiency as well as from estrogen-independent age-related mechanisms (e.g., secondary causes such as hyperparathyroidism and decreased mechanical stimulation). Estrogen deficiency can also increase with stress, excessive exercise, and low body weight. Postmenopausal changes include alterations in the RANKL/OPG/RANK system resulting in a substantial increase in bone turnover—that is, a remodeling imbalance between the activity of osteoclasts (bone destroyers) and osteoblasts (bone formers). Increased formation and activity of osteoclasts causes removal or resorption of bone and results in a cascade of proinflammatory cytokines. Increased cytokine activation, especially tumor necrosis factor (TNF), can occur with declining estrogen levels.\(^5\) In addition, estrogen helps osteoclast apoptosis (programmed cell death) so a decrease in estrogen levels is associated with *survival* of the bone-removing osteoclasts. Biologically, these processes involve the receptor activator nuclear factor κB ligand (RANKL), osteoprotegerin (OPG) signaling pathways, and
insulin-like growth factor (IGF) (see Chapter 38, p. 975, and Figures 38-5 and 39-10). Other causes may include a combination of inadequate dietary calcium intake and lack of vitamin D (and possibly decreased magnesium), lack of exercise, low body mass, and family history. IGF is known to help in fracture healing and collagen synthesis and improves conditions for bone mineralization. IGF levels significantly decline by age 60. Excessive phosphorus intake, chiefly through the intake of highly processed foods, hampers the calcium/phosphorus balance by interfering with parathyroid hormone and fibroblast growth factor 23 (FGF-23).56,57

---

**FIGURE 39-10** OPG/RANKL/RANK System. Expression of RANKL, a cytokine and part of the TNF family, and OPG, a glycoprotein receptor antagonist, is modulated by various cytokines, hormones, drugs, and mechanical strains (see inserts). In bone RANKL is expressed by both stromal cells and osteoblasts. RANKL stimulates the receptor RANK on osteoclast precursor cells and mature osteoclasts and activates intracellular signaling pathways to promote osteoclast differentiation and activation as well as cytoskeletal reorganization and survival (PKB/Akt pathway), which increase resorption and bone loss. OPG, secreted by stromal cells and osteoblasts, acts as a “decoy” receptor and blocks RANKL binding to and activation of RANK. BMP, Bone morphogenic protein; IL, interleukin; OPG, osteoprotegerin; PTH, parathyroid hormone; RANK, receptor activator nuclear factor kB; RANKL, receptor activator nuclear factor kB ligand; TGF-β, transforming growth factor-beta; TNF-α, tumor necrosis factor-alpha. (Adapted from Hofbauer LC, Schoppet M: JAMA 292[4]:490-495, 2004.)

---

Sex hormones, particularly estradiol (estrogen), are major determinants of bone density in both females and males.58,59 Androgens (i.e., testosterone and dihydrotestosterone) have long been recognized as stimulants of bone formation. Increasing age in both men and women is associated with declining levels of estradiol and androgen, leading to losses in BMD. Other factors, such as inadequate dietary calcium intake, decreases in weightbearing exercise, and sarcopenia, also
are associated with osteoporosis. Other risk factors are identified in *Risk Factors: Osteoporosis.*

### Risk Factors

#### Osteoporosis

**Genetic**

- Family history of osteoporosis
- White race
- Increased age
- Female gender

**Anthropometric**

- Small stature
- Fair or pale skinned
- Thin build
- Low bone mineral density

**Hormonal and Metabolic**

- Early menopause (natural or surgical)
- Late menarche
- Nulliparity
- Obesity
- Hypogonadism
- Gaucher disease
Cushing syndrome

Weight below healthy range

Acidosis

**Dietary**

Low dietary calcium and vitamin D

Low endogenous magnesium

Excessive protein*

Excessive sodium intake

Anorexia

Malabsorption

**Lifestyle**

Sedentary

Smoker

Alcohol consumption (excessive)

Low-impact fractures as an adult

Inability to rise from a chair without using one's arms

**Concurrent**

Hyperparathyroidism

**Illness and Trauma**

Renal insufficiency, hypocaliuria

Rheumatoid arthritis
Spinal cord injury
Systemic lupus erythematosus

Liver Disease

Marrow disease (myeloma, mastocytosis, thalassemia)

Drugs

Corticosteroids
Dilantin
Gonadotropin-releasing hormone agonists
Loop diuretics
Methotrexate
Thyroid medications
Heparin
Cyclosporin
Medroxyprogesterone acetate (Depo-Provera)
Retinoids

*Low levels of protein intake also have been reported.

Insufficient intake or malabsorption of dietary minerals is a factor in the development of osteoporosis. Calcium absorption from the intestine decreases with age, and studies of individuals with osteoporosis show that their calcium intake is lower than that of age-matched controls. Other mineral deficiencies, including magnesium, also may be important. Vitamin deficiencies, particularly vitamin D, as well as either deficiencies or excesses of protein also contribute to bone loss. Decreased serum levels of trace elements (zinc, copper, iron, magnesium, and
manganese) have been associated not only with lower peak bone mass in developing bone but also with later development of osteoporosis.\(^{60-62}\) Excessive intake of caffeine, phosphorus, alcohol, and nicotine along with low body fat (weight less than 125 pounds) has been shown to lower bone mineral density.\(^{63-65}\) Secondary osteoporosis is osteoporosis caused by other conditions, including hormonal imbalances (endocrine disease, diabetes, hyperparathyroidism, hyperthyroidism), medications (e.g., heparin, corticosteroids, phenytoin, barbiturates, lithium), and other substances (e.g., tobacco, ethanol). Other conditions, including rheumatoid disease, human immunodeficiency virus (HIV), malignancies, malabsorption syndrome, and liver or kidney disease, also increase the risk for developing osteoporosis (see Risk Factors: Osteoporosis).

Secondary osteoporosis sometimes develops temporarily in individuals receiving large doses of heparin by decreasing osteoblast formation and increasing bone resorption by reducing OPG and, thus, increasing osteoclast formation.\(^{66}\) Osteoporosis caused by heparin therapy usually resolves when therapy ceases. Other medications increasing risk of osteoporosis include glucocorticoids, proton pump inhibitors, aromatase inhibitors, lithium, methotrexate, anticonvulsants, cyclophosphamide, thiazolidinediones, and cyclosporine.

Regional osteoporosis—osteoporosis confined to a segment of the appendicular skeleton—often has no known cause. Classic regional osteoporosis is associated with disuse or immobilization of a limb because of fractures or bone or joint inflammation. A negative calcium balance develops early and continues throughout the period of immobilization. After 8 weeks of immobilization, significant osteoporosis is present. One result of weightlessness has been a uniform distribution of osteoporosis observed in astronauts and in individuals treated with air suspension therapy.

Transient regional osteoporosis has no known etiology and is characterized by bone marrow edema and, sometimes, severe pain. Transient regional osteoporosis is usually self-limiting, and tends to occur in middle-aged men and in women during their late second or third trimester of pregnancy.\(^{67,68}\) Bone marrow edema can be seen on magnetic resonance imaging (MRI) and areas of localized bone demineralization are seen in plain radiographs.\(^{69}\) The lower extremity is most often affected but other areas also can be involved. Treatment is primarily symptomatic and the condition usually resolves spontaneously over 3 to 6 months, with no long-term adverse effects.

**Pathophysiology**

Osteoporosis develops when the remodeling cycle (coupling)—bone resorption and bone formation—is disrupted, leading to an imbalance in the coupling process.
Osteoclasts are differentiated cells that function to resorb bone. The explosion of new information in the field of bone biology has led to new understandings of osteoclast biology and bone pathophysiology. Of primary importance is the osteoclast differentiation pathway that is dependent on various processes including proliferation, maturation, fusion, and activation. These processes, in turn, are dependent on the availability of stem cells to allow differentiation to occur and are controlled by hormones, cytokines, and paracrine stromal cell interactions. Thus, proper intracellular communication within bone among its molecular regulators is necessary for normal bone homeostasis. Numerous interleukins, tumor necrosis factor (TNF), transforming growth factor-beta (TGF-β), prostaglandin E₂, and hormones interact to control osteoclasts (Figure 39-10). Staggering in its importance to understanding osteoclast biology is the cytokine receptor activator of nuclear factor κB ligand (RANKL); its receptor activator nuclear factor κB (RANK); and its decoy receptor osteoprotegerin (OPG), a glycoprotein (see Chapter 36 and Figure 36-5).

Glucocorticoid-induced osteoporosis (e.g., prednisone, cortisone) is the most common type of secondary osteoporosis. Glucocorticoids have a direct impact on bone quality by improving osteoclast survival, inhibiting osteoblast formation and function, and increasing osteocyte apoptosis.⁷⁰-⁷² Glucocorticoids increase RANKL expression and inhibit OPG production by osteoblasts. Overall, these alterations result in decreased thickness of the bone cortex and fewer, thinner, and more widely spaced trabeculae in the marrow.⁷³

Age-related bone loss begins in the third to fourth decade.⁷⁴ The cause remains unclear, but it is known that decreased serum growth hormone (GH) and insulin-like growth factor 1 (IGF-1) levels, along with increased binding of RANKL and decreased OPG production, affect osteoblast and osteoclast function.⁷⁵ Loss of trabecular bone in men proceeds in a linear fashion with thinning of trabecular bone rather than complete loss, as is noted in women (Figure 39-11).⁷⁶ Men have approximately 30% greater bone mass than women, which may be a factor in their later involvement with osteoporosis (Figure 39-12). In addition, men have a more gradual decrease in the levels of testosterone and estradiol (and possibly progesterone), thereby maintaining their bone mass longer than women. Reduced physical activity in older persons is also a likely factor.
Clinical manifestations

The specific clinical manifestations of osteoporosis depend on the bones involved. The most common manifestations, however, are pain and bone deformity because of fracture. Unfortunately, these manifestations occur only in an advanced disease state. Fractures are likely to occur because the trabeculae of spongy bone become thin and sparse, and compact bone becomes porous. As the bones lose volume, they become brittle and weak and may collapse or become misshapen. Vertebral collapse
causes **kyphosis** (hunchback) and diminishes height (Figure 39-13). Fractures of the long bones (particularly the femur),\(^77\) distal radius, ribs, and vertebrae are most common. Fracture of the neck of the femur—the so-called broken hip—tends to occur in older or elderly women with osteoporosis. Fatal complications of fractures include fat or pulmonary embolism, pneumonia, hemorrhage, and shock. Approximately 20% of persons may die as a result of surgical complications. Osteoporosis in men, as in women, also may be related to hypogonadism, with estradiol levels being more clinically important than testosterone levels in both genders. Adequate dietary intake of calcium, vitamin D, magnesium, and other trace minerals (see *Health Alert: Calcium, Vitamin D, and Bone Health*); adherence to a regular regimen of weightbearing exercise; and avoidance of alcoholism, tobacco, and glucocorticoids seem to help prevent primary osteoporosis.

### Health Alert

**Calcium, Vitamin D, and Bone Health**

Adequate calcium intake is essential for developing and maintaining normal bone structure, but the following question remains a topic of discussion and research: “What is adequate calcium intake?” Calcium is the most abundant mineral in the body and plays a role in maintaining muscle function, hormonal secretion, neurotransmission, and vascular health. Recent conflicting evidence about the effect of calcium on heart disease, for example, has been hotly debated in the medical literature. The conflicting reports about extraskeletal health benefits of vitamin D also were reviewed by the Institute of Medicine (IOM) and were found to lack enough evidence to be considered reliable.

The role of vitamin D in bone health is unquestioned; the clinical effects of inadequate vitamin D (osteomalacia, rickets) have been well known for many years. Vitamin D is essential for absorbing and maintaining calcium homeostasis in the body. Recently, vitamin D has been postulated to be involved in many extraskeletal functions, such as reducing cancer risk, improving cognitive function in the elderly, preventing autoimmune diseases, improving resistance to infection, providing cardiovascular support, stabilizing posture, and inhibiting metabolic syndrome. Some of these potentially beneficial effects are from data gleaned from the National Health and Nutrition Examination Survey III (NHANES III), whereas other descriptions are based on observational or small studies. Vitamin D levels are evaluated by measuring serum 1,25-dihydroxy-vitamin D levels. There is still disagreement about what constitutes an “optimal” vitamin D level, but many
sources indicate it should be at least 30 to 32 ng/ml. Based on these levels, it has been estimated that nearly 75% of the adult population in the United States have low vitamin D levels.

The IOM recently evaluated and summarized clinical evidence and literature reviews regarding the roles of calcium and vitamin D in disease reduction and other health outcomes in North America. Review of these findings resulted in updates of the recommended daily intake of both nutrients. In general, daily calcium intakes of 500 mg for ages 1 through 3, 800 mg for ages 4 through 8, 1100 to 1300 mg for ages 9 to 13, and 800 to 1000 mg for ages 14 through adulthood are adequate for maintaining proper bone health. Recommended dietary allowances for vitamin D vary from 400 to 600 international units (IU) a day for all ages. Additionally, the IOM found that once calcium intake exceeds more than 2000 mg a day or vitamin D intake is more than 4000 IU per day, there is increased risk for harm.

Evaluation and treatment

In general, osteoporosis is detected radiographically as increased radiolucency of bone. By the time abnormalities are detected by radiologic examination, up to 25% to 30% of bone tissue may have been lost.

**Dual x-ray absorptionometry (DXA)** is the current gold standard for detecting and monitoring osteoporosis; however, bone density is not necessarily indicative of bone quality. The utility of DXA in predicting fracture risk has recently been enhanced by development of a trabecular bone score (TBS). TBS evaluates pixel variations in the gray-level areas of lumbar spine images from DXA scans and has been shown to correlate with high-resolution peripheral quantitative computed tomography (HRpQCT) and be a reliable predictor of fractures. High-resolution imaging techniques, such as quantitative computed tomography (QCT) scans and HRpQCT imaging, show changes of trabecular and cortical microarchitecture in osteopenic women. Newer magnetic resonance imaging techniques also show promise for providing more detailed information about cortical and trabecular bone and have the added safety of no radiation exposure. Other evaluation procedures include measurement of serum and urinary biochemical markers to monitor bone turnover *(Box 39-3)*.
Biochemical Markers of Bone Turnover

Biochemical markers of bone turnover are useful in monitoring osteoporosis treatment. Markers of resorption include urinary N-telopeptide (NTx), C-telopeptide (CTx), and deoxypyridinoline. Markers of bone formation include bone-specific alkaline phosphatase (BSAP) and osteocalcin. However, these tests have diurnal variability within the same individual, so there must be significant changes in levels to indicate a difference in bone turnover.

The goals of osteoporosis treatment are risk reduction and the prevention of fractures. Bisphosphonates are first-line medications for treating osteoporosis; they primarily work by inhibiting hydroxyapatite breakdown, reducing bone resorption. New medications formulated to prevent or treat osteoporosis are currently being prescribed and evaluated. There are new treatments that help rebuild the skeleton (see Health Alert: New Treatments for Osteoporosis). Selective steroid agents—for example, raloxifene—also may be prescribed (see Chapter 33). Regular, moderate weightbearing exercise can slow the rate of bone loss and, in some cases, reverse demineralization because the mechanical stress of exercise stimulates bone formation. An exercise program to enhance strength and balance has the added benefits of reducing the risk of falls and promoting bone quality.

Health Alert

New Treatments for Osteoporosis

Although bisphosphonates remain the first line of osteoporosis therapy, not all individuals are able to tolerate them and side effects can include bisphosphonate-related osteonecrosis of the jaw (BRONJ), atrial fibrillation, and fractures. Zoledronic acid, a third-generation bisphosphonate, is given as an annual intravenous infusion and has demonstrated efficacy in treating glucocorticoid-associated osteoporosis, in addition to reducing vertebral and nonvertebral fractures in women and men. However, it can cause an acute phase response in recipients and still carries some risk of BRONJ. Several new treatment options promise progress in treating osteoporosis and may be better tolerated than bisphosphonates.

Denosumab is the first commercially available human monoclonal antibody for treatment of osteoporosis. It binds to the receptor activator nuclear factor κB ligand
(RANKL) (see Chapter 38), preventing activation of osteoclasts. By reducing osteoclast activity, bone density is increased and bone resorption is reduced, thus lessening the incidence of fractures. Because denosumab is not cleared by the kidneys (as are bisphosphonates), it has the potential to be useful in those with chronic kidney disease. It is given every 6 months as a 60-mg subcutaneous injection.

Raloxifene, a selective estrogen receptor modulator (SERM), has been in use for several years to treat postmenopausal osteoporosis. It has been effective in reducing vertebral fractures but not hip or other nonspinal fractures. Newer SERMs, including lasofoxifene (which is approved for use in Europe, but not the United States), have been shown to reduce both vertebral and nonvertebral fractures. Bazedoxifene, in combination with estrogen, has been designated as a tissue-selective estrogen complex (TSEC), and is approved for use in Japan and Europe. It has been shown to reduce both vertebral and nonvertebral fractures in postmenopausal women. Neither of these agents, given as daily oral doses, stimulates endometrial or breast tissue.

Other biologic agents for treating osteoporosis include odanacatib, a cathepsin K inhibitor. By affecting this enzyme (produced by osteoclasts), bone density is increased. It is given as a once weekly oral agent. Agents directed at signaling pathways of bone formation and homeostasis are another target of osteoporosis intervention. One of the main signaling targets is the Wnt pathway (see Chapter 38). Wnt stimulates osteoblast function and bone formation but is blocked by sclerostin (which is produced by the osteocyte gene SOST). Parathyroid hormone (PTH) inhibits sclerostin expression, which may result in increased numbers of osteoblasts. The development of monoclonal antibodies to sclerostin may provide another means to increase bone formation and density.

The anabolic or bone-building drug parathyroid hormone (PTH) has been widely studied and is a major regulator of calcium homeostasis. PTH acts directly on osteocytes, stimulates bone formation, and promotes migration of progenitor bone cells from the marrow into the bloodstream, increasing the production of osteoblasts when intermittently administered (see Health Alert: New Treatments for Osteoporosis).

Osteomalacia
Osteomalacia is a metabolic disease characterized by inadequate and delayed mineralization of osteoid in mature compact and spongy bone. In osteomalacia, the remodeling cycle proceeds normally through osteoid formation, but mineral calcification and deposition do not occur. Bone volume remains unchanged, but the replaced bone consists of soft osteoid instead of rigid bone. Rickets is similar to osteomalacia in pathogenesis, but it occurs in the growing bones of children, whereas osteomalacia occurs in adult bone. (Rickets is described in Chapter 40.)

Both osteomalacia and rickets are relatively rare in the United States and Western Europe but are significant health problems in Great Britain, Ethiopia, Pakistan, Iran, and India. Concomitant diseases, such as HIV, chronic kidney or liver disease, certain cancers, and impaired nutrient absorption from bariatric surgery, can result in vitamin D deficiency and secondary osteomalacia. In the United States, other causes include prematurity with very low birth weight and adhering to a rigid macrobiotic vegetarian diet. Breast-fed black infants who do not receive vitamin D supplementation have been shown to be at risk for developing nutritional rickets.

Many factors contribute to the development of osteomalacia, but the most important is a deficiency of vitamin D. The major risk factors in vitamin D deficiency are diets deficient in vitamin D, decreased endogenous production of vitamin D, intestinal malabsorption of vitamin D, renal tubular diseases, certain types of tumors (particularly of mesenchymal origin), and anticonvulsant therapy. Classic vitamin D deficiency is rare in the United States because of the addition of synthetic vitamin D to dairy products and bread.

Disorders of the small bowel, hepatobiliary system, and pancreas are causes of vitamin D deficiency in the United States. In malabsorptive disease of the small bowel, both vitamin D and calcium absorption are decreased, so vitamin D is lost in feces. Liver disease interferes with the metabolism of vitamin D to its more active form, and diseases of the pancreas and biliary system cause a deficiency of bile salts, which are necessary for normal intestinal absorption of vitamin D.

The mechanism by which anticonvulsant drug therapy results in vitamin D deficiency is not completely understood, but researchers think that the anticonvulsants phenobarbital and phenytoin interfere with calcium absorption and increase degradation of vitamin D metabolism in the liver. Renal osteodystrophy is another cause of osteomalacia.

Pathophysiology

Crystallization of minerals in osteoid requires adequate concentrations of calcium and phosphate. When the concentrations are too low, crystallization (and hence ossification) does not proceed normally.

Vitamin D deficiency disrupts mineralization because vitamin D normally
regulates and enhances the absorption of calcium ions from the intestine. A lack of vitamin D causes the plasma calcium concentrations to fall. Low plasma calcium levels stimulate increased synthesis and secretion of PTH. Although the increase in circulating PTH level raises the plasma calcium concentration, it also stimulates increased renal clearance of phosphate. When the concentration of phosphate in the bone decreases below a critical level, mineralization cannot proceed normally. Newer research has identified a complex interplay of matrix proteins, hormones, metallopeptidases, and certain proteins as also being involved in the development of osteomalacia.

Abnormalities occur in both spongy and compact bone. Trabeculae in spongy bone become thinner and fewer, whereas haversian systems in compact bone develop large channels and become irregular. Because osteoid continues to be produced but not mineralized, abnormal quantities of osteoid accumulate, coating the trabeculae and the linings of the haversian canals. Excessive osteoid also can accumulate in areas beneath the periosteum. The excess of osteoid leads to gross deformities of the long bones, spine, pelvis, and skull.

**Clinical manifestations**

Osteomalacia causes varying degrees of diffuse muscular and skeletal pain and tenderness. Pain is noted particularly in the hips, and the individual may be hesitant to walk. Muscular weakness is common and may contribute to a waddling gait. Facial deformities and bowed legs or “knock-knees” may be present. Bone fractures and vertebral collapse occur with minimal trauma. Low back pain may be an early complaint, but pain may also involve ribs, feet, other areas of the vertebral column, and other sites. Fragility fractures may occur. Uremia may be present in renal osteodystrophy.

**Evaluation and treatment**

Laboratory data may include elevated blood urea nitrogen (BUN) and creatinine levels, normal or low serum calcium levels, and a serum inorganic phosphate level that is usually more than 5.5 mg. Alkaline phosphatase and PTH levels are usually elevated. Radiographic findings may show symmetric bowing deformities and fractures with callus formation, particularly in the lower extremities. These types of fractures, known as pseudofractures, along with radiolucent bands perpendicular to the surface of involved bones can help differentiate osteomalacia from fragility fractures that are seen in osteoporosis. A bone biopsy is used to obtain information on bone structure and remodeling and evaluate the presence of subclinical renal osteodystrophy to determine bone architecture, turnover, and even aluminum deposits. 
Treatment of osteomalacia may vary, depending on its etiology, but the following general principles are included:

1. Adjustment of serum calcium and phosphorus levels to normal

2. Suppression of secondary hyperthyroidism

3. Chelation of bone aluminum if needed

4. Administration of calcium carbonate to decrease hyperphosphatemia

5. Administration of vitamin D supplements (oral or infusion)

6. Administration of bisphosphonate

7. Implementation of renal dialysis, if indicated

**Paget Disease**

**Paget disease of bone (PDB, or osteitis deformans),** the second most common bone disease after osteoporosis, is a state of increased metabolic activity in bone characterized by localized abnormal and excessive bone remodeling. Chronic accelerated remodeling eventually enlarges and softens the affected bones, causing bowing deformity, fracture, or neurologic problems.

Paget disease can occur in any bone but most often affects the vertebrae, skull, sacrum, sternum, pelvis, and femur. The disease process may occur in one or more bones without causing significant clinical manifestations.

Paget disease occurs with equal frequency in men more than 55 years of age and women older than 40 years of age. It is often symptomless and diagnosis is often suspected when an elevated serum alkaline phosphatase level or abnormal x-ray is noted. Radioisotope bone scan, x-rays, and CT are used to confirm the diagnosis. Serum plasma procollagen-1 N-peptide (PINP) is another serum marker that may provide a more accurate diagnosis. Autopsy data from England and Germany indicate that approximately 3% to 4% of the population older than 40 years of age has Paget disease. It is most prevalent in Australia, Great Britain, New Zealand, and the United States. Paget disease affects several members of the same family in 5% to 25% of individuals.

The cause of PDB is not yet fully known, but studies have implicated both genetic and environmental factors. Environmental factors that seem to be implicated are primarily viruses, particularly the paramyxovirus family (that includes mumps, parainfluenza, and measles viruses), but no definitive microorganism has yet been
Of individuals diagnosed with PDB, 10% to 30% have mutations of a specific gene, \textit{sequestosome-1 (SQSTM1)}. Interaction between genetic and environmental factors appears to increase osteoclast activity in PDB.

\textbf{Pathophysiology}

Certain chromosomes on \textit{SQSTM1} are known to affect osteoclast differentiation and function, although the exact locus of the genetic abnormality has yet to be identified. Paget disease begins with excessive resorption of spongy bone and deposition of disorganized bone. The trabeculae diminish, and bone marrow is replaced by extremely vascular fibrous tissue.

The resorption phase of Paget disease is followed by the formation of abnormal new bone at an accelerated rate. The collagen fibers are disorganized, and glycoprotein levels in the matrix decrease. Mineralization may extend into the bone marrow. Bone formation is excessive around partially resorbed trabeculae, causing them to thicken and enlarge. The net result of this accelerated remodeling process is increased bone fragility and an increased risk for bone tumors.

\textbf{Clinical manifestations}

In the skull, abnormal remodeling is first evident in the frontal or occipital regions; then it encroaches on the outer and inner surfaces of the entire skull. The skull thickens and assumes an asymmetric shape. Thickened segments of the skull may compress areas of the brain, producing altered mentality and dementia. Impingement of new bone on cranial nerves causes sensory abnormalities, impaired motor function, deafness (because of involvement of the middle ear ossicles or compression of the auditory nerve), atrophy of the optic nerve, and obstruction of the lacrimal duct. Headache is commonly noted.

Extensive alterations of the facial bones are rare except in the jaw, where sclerosis and thickening of the maxilla and mandible displace teeth and produce malocclusion. In long bones, resorption begins in the subchondral regions of the epiphysis and extends into the metaphysis and diaphysis. Occasionally, Paget disease affects both ends of a tubular bone. In the femur, Paget disease produces an exaggerated lateral curvature. In the tibia, anterior curvature is also exaggerated. Stress fractures are common in the lower extremities.

Clinical manifestations of Paget disease in the vertebral column depend on the level of involvement and are caused by compression of adjacent structures. In the cervical spine, cord compression can lead to spastic quadriplegia. Approximately 1% of persons with Paget disease develop osteogenic sarcoma.

\textbf{Evaluation and treatment}
Evaluation of Paget disease is made on the basis of radiographic findings of irregular bone trabeculae with a thickened and disorganized pattern. Early disease is detected by bone scanning that shows increased uptake of bone radionuclides. Plasma alkaline phosphatase and urinary hydroxyproline levels are elevated. Many individuals require no treatment if the disease is localized and does not cause symptoms. Treatment during active disease is for relief of pain and prevention of deformity or fracture. Bisphosphonates are the treatment of choice; a one-time infusion of zoledronic acid can provide long-term reduction of biochemical markers and even remission.\textsuperscript{99-102} Newer agents, including monoclonal antibodies (denosumab), interleukin-6 receptor inhibitors (tocilizumab), cathepsin K inhibitors (odanacatib), and Dickkopf-1 inhibitors, are under study for treatment of PDB.\textsuperscript{91,98}

**Infectious Bone Disease: Osteomyelitis**

*Osteomyelitis* is a bone infection most often caused by bacteria; however, fungi, parasites, and viruses also can cause bone infection (Figure 39-14). Multiple classification systems have been used to describe osteomyelitis; the simplest refers to the mode of infection. A bone infection caused by pathogens carried through the bloodstream is termed *hematogenous osteomyelitis*. Acute hematogenous osteomyelitis is more often seen in children and is characterized by fever, pain, and voluntary immobility of the affected limb. (Osteomyelitis in children is discussed in Chapter 40.) *Contiguous osteomyelitis* occurs when infection spreads to an adjacent bone and is often caused by open fractures, penetrating wounds, or surgical procedures. Other causes of osteomyelitis include metabolic and vascular diseases (diabetes, peripheral vascular disease), lifestyle risks (smoking, alcohol or drug abuse), and advanced age.\textsuperscript{103} In infants, incidence rates among males and females are approximately equal. In children and older adults, however, males are most commonly affected. A new category of autoimmune, noninfectious osteomyelitis, known as chronic nonbacterial osteomyelitis (CNO), has recently been identified as a cause of chronic bone pain in children.\textsuperscript{104}
Staphylococcus aureus remains the primary microorganism responsible for osteomyelitis. Other microorganisms include group B streptococcus, Haemophilus influenzae, Salmonella, and gram-negative bacteria. Group B streptococcus and H. influenzae tend to infect young children; Salmonella infection is associated with sickle cell anemia; and gram-negative infections are most common in older adults and immunocompromised individuals with impaired immunity. Mycobacterial, viral, and fungal infections occur in immunocompromised individuals.

Cutaneous, sinus, ear, and dental infections are the primary sources of bacteria in hematogenous bone infections. Soft tissue infections, disorders of the gastrointestinal tract, infections of the genitourinary system, and respiratory tract infections are also sources of bacterial contamination. In addition, infections that occur after total joint replacement procedures are sometimes the cause. The vulnerability of specific bone depends on the anatomy of its vascular supply.

In adults, hematogenous osteomyelitis is more common in the spine, pelvis, and small bones. Microorganisms reach the vertebrae through arteries, veins, or lymphatic vessels. The spread of infection from pelvic organs to the vertebrae is well documented. Vaginal, uterine, ovarian, bladder, and intestinal infections can lead to iliac or sacral osteomyelitis.

Superficial animal or human bites inoculate local soft tissue with bacteria that later spread to underlying bone. Deep bites can introduce microorganisms directly onto bone. The most common infecting organism in human bites is Staphylococcus aureus. In animal bites, the most common infecting organism is Pasteurella multocida, which is part of the normal mouth flora of cats and dogs.

Direct contamination of bones with bacteria can also occur in open fractures or dislocations with an overlying skin wound. Intervertebral disk surgery and operative procedures involving implantation of large foreign objects, such as
metallic plates or artificial joints, are associated with contiguous osteomyelitis. Osteomyelitis of the arm and hand bones tends to occur in persons who abuse drugs. In general, persons who are chronically ill, have diabetes or alcoholism, or are receiving large doses of steroids or immunosuppressive drugs are particularly susceptible to chronic osteomyelitis or recurring episodes of this disease.

Pathophysiology

Regardless of the source of the pathogen, the pathologic features of bone infection are similar to those in any other body tissue (see Chapter 6). First, the invading pathogen provokes an intense inflammatory response. S. aureus, in addition to producing toxins that destroy neutrophils, also forms colonies of microorganisms, called biofilms, that adhere to surfaces (such as implants) and increase antibiotic resistance. Biofilms also can reduce the duration of osteoblast activity while enhancing osteoclast activity and promoting inflammation\(^ {108-110}\) (also see Chapter 8). Primarily through activation of the cytokine pathway, the biofilm and inflammation alter the normal balance between osteoblast and osteoclast activity.\(^ {107,111}\)

Inflammation in bone is characterized by vascular engorgement, edema, leukocyte activity, and abscess formation. Once inflammation is initiated, the small terminal vessels thrombose and exudate seals the bone's canaliculi. Inflammatory exudate extends into the metaphysis and the marrow cavity and through small metaphyseal openings into the cortex. In children, exudate that reaches the outer surface of the cortex forms abscesses that lift the periosteum of underlying bone. Lifting of the periosteum disrupts blood vessels that enter bone through the periosteum, which deprives underlying bone of its blood supply. This leads to necrosis and death of the area of bone infected, producing sequestrum, an area of devitalized bone. Lifting of the periosteum also stimulates an intense osteoblastic response. Osteoblasts lay down new bone that can partially or completely surround the infected bone. This layer of new bone surrounding the infected bone is called an involucrum (Figure 39-15). Openings in the involucrum allow the exudate to escape into surrounding soft tissue and ultimately through the skin by way of sinus tracts.
In adults, this complication is rare because the periosteum is firmly attached to the cortex and resists displacement. Instead, infection disrupts and weakens the cortex, which predisposes the bone to pathologic fracture.

Clinical manifestations

Clinical manifestations of osteomyelitis vary with the age of the individual, the site of involvement, the initiating event, the infecting organism, and the type of infection—acute, subacute, or chronic. Osteomyelitis is generally considered acute if diagnosed within 2 weeks after symptom onset and is associated with abrupt onset of inflammation (see Figure 39-15). Subacute osteomyelitis is disease that has been present for 1 to several months, and chronic disease is that which has been present for many months to even years.103,112

If an acute infection is not completely eliminated, the disease may become subacute or chronic. In subacute osteomyelitis, signs and symptoms are usually vague. In the chronic stage, infection is indolent or silent between exacerbations. The microorganisms persist in small abscesses or fragments of necrotic bone and produce occasional exacerbations of acute osteomyelitis. The progression from acute to subacute osteomyelitis may be the result of inadequate or inappropriate therapy, or the development of drug-resistant microorganisms.

In the adult, hematogenous osteomyelitis has an insidious onset. The symptoms are usually vague and include fever, malaise, anorexia, weight loss, and pain in and around the infected areas. Edema may or may not be evident. Recent infection (urinary, respiratory, cutaneous) or instrumentation (catheterization, cystoscopy,
myelography, diskography) usually precedes onset of symptoms.

Single or multiple abscesses (Brodie abscesses) characterize subacute or chronic osteomyelitis. Brodie abscesses are circumscribed lesions 1 to 4 cm in diameter that are found usually in the ends of long bones and surrounded by dense ossified bone matrix. The abscesses are thought to develop when the infectious microorganism has become less virulent or the individual's immune system is resisting the infection somewhat successfully.

In contiguous osteomyelitis, signs and symptoms of soft tissue infection predominate. Inflammatory exudate in the soft tissues disrupts muscles and supporting structures and forms abscesses. Low-grade fever, lymphadenopathy, local pain, and swelling usually occur within days of contamination by a puncture wound.

**Evaluation and treatment**

Laboratory data show an elevated white cell count and an elevated level of noncardiac C-reactive protein (CRP). Radiographic studies include radionuclide bone scanning, CT, functional imaging using a combination of radionuclide scanning (using fluorodeoxyglucose [FDG]) and single photon emission computed tomography (SPECT), positron emission tomography (PET), and MRI. MRI scanning with gadolinium contrast shows both bone and soft tissue, providing more accurate assessment of infection. MRI also shows early changes of bone marrow edema. FDG-SPECT imaging is highly sensitive for evaluating osteomyelitis of the extremities.113

Treatment of osteomyelitis includes bone biopsy to identify the causative organism, use of antimicrobial agents, and débridement of infected bone.106,114 Biodegradable antibiotic-impregnated bioabsorbable beads have also benefited many individuals; newer therapies include the promise of injectable scaffolds impregnated with antibiotics and other antimicrobial substances.115 Chronic conditions may require surgical removal of the inflammatory exudate followed by continuous wound irrigation with antibiotic solutions in addition to systemic treatment with antibiotics. The ideal antibiotic regimen for treating osteomyelitis has not yet been developed. **Hyperbaric oxygen therapy** of 100% oxygen may stimulate healing by suppressing proinflammatory cytokines and prostaglandins. Implants for total joint replacements may be removed to treat the infected joint more thoroughly.

Quick Check 39-2
1. What are the causes associated with osteoporosis in women and men?

2. How does osteoporosis differ from osteomalacia? Name three differences.

3. What are the risk factors for osteomyelitis?
Disorders of Joints

The American College of Rheumatology (ACR) recognizes several groups of joint disease (arthropathies). Most of these disorders can be placed into two major categories: noninflammatory joint disease and inflammatory joint disease. With the improvement in detection methods, however, inflammatory pathways are now being identified in conditions previously classified as noninflammatory, such as osteoarthritis.

Osteoarthritis

**Osteoarthritis (OA)** is the most common, age-related disorder of synovial joints. Affecting the entire joint, OA is characterized by local areas of loss and damage of articular cartilage, inflammation, new bone formation of joint margins (osteophytosis), subchondral bone changes, variable degrees of mild synovitis, and thickening of the joint capsule (Figure 39-16). Pathology centers on load-bearing areas. Advancing disease shows narrowing of the joint space attributable to cartilage loss, bone spurs (osteophytes), and sometimes changes in the subchondral bone. OA can arise in any synovial joint but is commonly found in the knees, hips, hands, and spine. It is less common in people younger than 40 years of age and its prevalence increases with age. Although the exact causes of OA are unclear, obesity and trauma are well-known risk factors. Recent research has identified specific microRNAs that affect gene expression in chondrocytes, and that may play a role in developing OA. OA involves a complex interaction of transcription factors, cytokines, growth factors, matrix molecules, the immune system, mechanical stresses on joints, and enzymes (see the following Pathophysiology section). Emerging understanding of synovitis and inflammation in OA has led to the recognition of the role played by the body's immune system in OA.
Although incidence rates are quite similar in men and women, after age 50, women typically are more severely affected. OA usually occurs in those persons who put exceptional stress (or joint loading) on joints (e.g., obese persons, gymnasts, long-distance runners or marathoners); persons participating in such sports as basketball, soccer, or football have been shown to develop osteoarthritis at earlier ages than usual. Obesity itself seems to be an independent risk factor for developing OA of the knee.\textsuperscript{123-126} Chondrocyte death because of mitochondrial release of reactive oxygen species (ROS) is thought to be caused by increased stress
A previously torn anterior cruciate ligament or meniscectomy increases the risk for accelerated osteoarthritis of the knee.\textsuperscript{127,128}

**Types of Osteoarthritis**

**Pathophysiology**

The primary defect in OA is loss of articular cartilage.\textsuperscript{129} Early in the disease, the articular cartilage loses its glistening appearance, becoming yellow-gray or brownish gray. As the disease progresses, surface areas of the articular cartilage flake off and deeper layers develop longitudinal fissures (fibrillation). The cartilage becomes thin and may be absent over some areas, leaving the underlying bone (subchondral bone) unprotected. Consequently, the unprotected subchondral bone becomes sclerotic (dense and hard). Cysts sometimes develop within the subchondral bone and communicate with the longitudinal fissures in the cartilage. Pressure builds in the cysts until the cystic contents are forced into the synovial cavity, breaking through the articular cartilage on the way. As the articular cartilage erodes, cartilage-coated osteophytes may grow outward from the underlying bone and alter the bone contours and joint anatomy. These spurlike bony projections enlarge until small pieces, called *joint mice*, break off into the synovial cavity. If osteophyte fragments irritate the synovial membrane, synovitis and joint effusion result. Interestingly, joint pain may be more related to inflammation of the synovium than subsequent cartilage damage or the radiographic extent of arthritis.\textsuperscript{130,131} The joint capsule also becomes thickened and at times adheres to the deformed underlying bone, which may contribute to the limited range of motion of the joint (see Figure 39-16).

Articular cartilage is lost through a cascade of signaling, cytokine, and anabolic growth factor pathways.\textsuperscript{132,133} Enzymatic processes (including matrix metalloproteinases) assist in breaking the macromolecules of proteoglycans, glycosaminoglycans, and collagen into large, diffusible fragments. Then the fragments are taken up by the cartilage cells (chondrocytes) and digested by the cell's own lysosomal enzymes. (Processes of cellular uptake and lysosomal digestion are described in Chapter 1.) The loss of proteoglycans from articular cartilage is a hallmark of the osteoarthritic process.

Enzymatic destruction of articular cartilage begins in the matrix, with destruction of proteoglycans and collagen fibers. Enzymes, particularly stromelysin and acid metalloproteinases, affect proteoglycans by interfering with assembly of the proteoglycan subunit or the proteoglycan aggregate (see Chapter 38); levels of these enzymes are markedly elevated in OA. Changes in the conformation of proteoglycans disrupt the pumping action that regulates movement of water and
synovial fluid into and out of the cartilage. Without the regulatory action of the proteoglycan pump, cartilage imbibes too much fluid and becomes less able to withstand the stresses of weightbearing. With aging, the proteoglycan content is decreased, and water content in cartilage can be increased by as much as 8%, affecting the strength of the cartilage. Persons with OA, even those with fairly extensive cartilage destruction, have elevated levels of proteoglycans/fragments in their synovial fluid, perhaps indicative of the degree of disease activity. MicroRNAs, small nucleic acids that do not code for proteins (but appear to regulate the RNAs that do), may have a direct effect on developing OA by targeting specific genes involved in cartilage development and homeostasis.\textsuperscript{118,134,135}

Disruptions in cellular signaling pathways, particularly the transforming growth factor-beta (TGF-\(\beta\)) superfamily, play a significant role in developing OA.\textsuperscript{136} Other studies indicate that cytokines, such as interleukin-1 and tumor necrosis factor (TNF) (see Chapter 7 for discussion of cytokines), play a major role in cartilage degradation\textsuperscript{132} as a result of release and activation of proteolytic and collagenolytic enzymes associated with an imbalance of cell responses to growth factor activity.\textsuperscript{137,138}

Cell-signaling proteins, particularly adipokines such as adiponectin and collagensases (enzymes that degrade collagen), contribute to collagen breakdown in cartilage.\textsuperscript{139} Collagen breakdown destroys the fibrils that give articular cartilage its tensile strength and exposes the chondrocytes to mechanical stress and enzyme attack. The osteochondral junction formed by cartilage and its underlying subchondral bone allows alterations in one tissue to affect the adjacent one (biomechanical coupling). When articular cartilage is damaged, abnormal subchondral bone remodeling occurs.\textsuperscript{140,141} Thus, a cycle of destruction begins that involves all the components of a joint: cartilage, bone, and the synovium.

**Clinical manifestations**

Clinical manifestations of OA typically appear during the fifth or sixth decade of life; although often asymptomatic, articular surface changes are common after the age of 40 years. Pain in one or more joints—usually with weightbearing, use of the joint, or load bearing—is the first and most predominant symptom of the disease. Resting the joint often relieves pain. If present, nocturnal pain is usually not relieved by rest and may be accompanied by paresthesias (numbness, tingling, or prickling sensations). Sometimes pain is referred to another part of the body. For example, osteoarthritis of the lumbosacral spine may mimic sciatica, causing severe pain in the back of the thigh along the course of the sciatic nerve. OA in the lower cervical spine may cause brachial neuralgia (pain in the arm) and is aggravated by movement of the neck. Osteoarthritic conditions in the hip cause pain that may be
referred to the lower thigh and knee area. Sleep deprivation adds to the stress of the chronic pain of OA. Physical examination of the person with OA usually shows general involvement of both peripheral and central joints. Peripheral joints most often involved are in the hands, wrists, knees, and feet. Central joints most often afflicted are in the lower cervical spine, lumbosacral spine, shoulders, and hips.

Joint structures are capable of generating a limited number of signs and symptoms. The primary signs and symptoms of osteoarthritic joint disease are pain, stiffness, enlargement or swelling, tenderness, limited range of motion, muscle wasting, partial dislocation, and deformity (see Risk Factors: Osteoarthritis).

### Risk Factors

**Osteoarthritis**

- Trauma, sprains, strains, joint dislocations, and fractures
- Long-term mechanical stress—athletics, ballet dancing, repetitive physical tasks, and obesity
- Inflammation in joint structures
- Joint instability from damage to supporting structures
- Neurologic disorders (e.g., diabetic neuropathy, Charcot neuropathic joint) in which pain and proprioceptive reflexes are diminished or lost
- Congenital or acquired skeletal deformities
- Hematologic or endocrine disorders, such as hemophilia, which causes chronic bleeding into the joints, or hyperparathyroidism, which causes bone to lose calcium
- Drugs (e.g., colchicine, indomethacin, steroids) that stimulate the collagen-digesting enzymes in the synovial membrane

The origin of joint stiffness is unknown. **Joint stiffness** is generally defined as difficulty initiating joint movement, immobility, or a loss of range of motion. The stiffness usually occurs as joint movement begins, and it dissipates rapidly after a few minutes. Stiffness lasting longer than 30 minutes is uncommon in OA.
Enlargement and bulging of bone contour, commonly described as swelling, may be caused by bone enlargement or the proliferation of osteophytes around the margins of the joint. In the hands, these areas are called Heberden and Bouchard nodes, where they are typical features of OA (see Figure 39-16). Inflammation of the joint lining, known as synovitis, is thought to be initiated by the release of cartilage extracellular matrix into the joint, which then activates the body's complement system.\textsuperscript{142} Swelling also occurs if inflammatory exudate or blood enters the joint cavity, thereby increasing the volume of synovial fluid. This condition, termed joint effusion, is caused by (1) the presence of osteophyte fragments in the synovial cavity, (2) drainage of cysts from diseased subchondral bone, or (3) acute trauma to joint structures, resulting in hemorrhage and inflammatory exudation into the synovial cavity (see Figure 39-16, C).

Range of motion is limited to some degree, depending on the extent of cartilage degeneration. Frequently, joint motion is accompanied by sounds of crepitus, creaking, or grating. Hypermobility and subluxation of joints occur in OA secondary to a neurologic disorder. Abnormal knee alignment (either varus or valgus) has been shown to be a risk factor for and can increase progression of the disease.\textsuperscript{143,144}

As OA of the lower extremity progresses, the person may begin to noticeably limp (Figure 39-17). Having a limp is distressing because it affects the person's independence and ability to perform usual activities of daily living. The affected joint is also more symptomatic after use, such as at the end of a period of strenuous activity.
Evaluation and treatment

Evaluation consists primarily of clinical assessment and radiologic studies. More expensive studies, including CT scan, arthroscopy, and MRI, are rarely needed. Newer imaging technologies, such as compositional MRI, are showing promise in identifying structural changes in cartilage; improvements in technology may also allow better monitoring of OA treatment.

Treatment is either conservative or surgical. Conservative treatment includes both pharmacologic and nonpharmacologic therapies; surgery is a last resort. Both exercise and weight loss have been shown to be two of the most important nonpharmacologic treatments in improving knee OA symptoms. Exercise can reduce pain and improve physical function in people with knee OA.\textsuperscript{145-149} Exercises to improve muscle tone, range of motion, and balance; stretch the joint capsule; and decrease fear of falling also have shown promise in reducing OA symptoms.\textsuperscript{150,151} Braces and foot orthoses may help correct biomechanical abnormalities, thereby reducing pain and improving mobility.\textsuperscript{152} Dietary and nutritional supplements can sometimes also improve symptoms. Nutraceuticals, such as chondroitin and glucosamine, have shown success in relieving OA pain in some individuals.\textsuperscript{153} Other nonsurgical therapies include analgesic and anti-inflammatory drug therapy to
reduce swelling and pain. Acetaminophen was once considered first-line treatment, but it has been shown to be less effective than nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen. However, prolonged use significantly increases the risk of serious associated side effects that are common. Intra-articular injection of corticosteroids and high-molecular-weight viscose supplements, such as hyaluronic acid, also decreases knee pain with OA. Recently, because of its high concentration of growth factors, platelet-rich plasma (PRP) also has been injected into osteoarthritic knee joints with some success in reducing pain and markers of inflammation. Current evidence does not support low-level laser therapy for knee osteoarthritis. Newer agents, including inhibitors of cytokines, matrix metalloproteinases (MMPs), and leptin, are under investigation and may prove more effective in treating OA. Surgery is used to improve joint movement, correct deformity or malalignment, or create a new joint with artificial implants. It has been estimated by some researchers that one in four individuals has a lifetime risk of developing symptomatic OA of the hip. More than 280,000 total hip and more than 600,000 total knee replacement surgeries are performed yearly in the United States, most of which are related to OA.

### Classic Inflammatory Joint Disease

**Inflammatory joint disease** is commonly called arthritis. Inflammatory joint disease is characterized by inflammatory damage or destruction in the synovial membrane or articular cartilage and by systemic signs of inflammation (fever, leukocytosis, malaise, anorexia, hyperfibrinogenemia).

Inflammatory joint disease can be infectious or noninfectious. Infectious inflammatory joint disease is caused by invasion of the joint by bacteria, mycoplasmas, viruses, fungi, or protozoa. These agents can invade the joint through a traumatic wound, surgical incision, or contaminated needle, or they can be delivered by the bloodstream from sites of infection elsewhere in the body—typically bones, heart valves, or blood vessels. Noninfectious inflammatory joint disease, the most common form, is caused by immune reactions or the deposition of crystals of monosodium urate in and around the joint. Rheumatoid arthritis, psoriatic arthritis, and ankylosing spondylitis are noninfectious inflammatory diseases caused by immune reactions and possibly hypersensitivity reactions; gouty arthritis is a noninfectious inflammatory disease caused by crystal deposition.

### Rheumatoid Arthritis

*Rheumatoid arthritis* (RA) is a chronic, systemic, inflammatory autoimmune disease distinguished by joint swelling and tenderness and destruction of synovial
joints leading to disability and premature death.\textsuperscript{161} (Autoimmune disease is described in \textit{Chapter 8}.) The first joint tissue to be affected is the synovial membrane, which lines the joint cavity (see \textit{Chapter 36, Figure 36-9}). The two primary types of synovial cells are fibroblast-like synovial cells and macrophage-like synovial cells. Though the initiating mechanism of RA is still unknown, its pathology is fairly well understood. Some factor activates the synovial fibroblasts (SFs) that line the joint cavity.\textsuperscript{162-164} The SFs undergo significant changes and develop an exaggerated immune response. Once activated, both types of SF abnormally proliferate and produce proinflammatory cytokines, enzymes, and prostaglandins that perpetuate the inflammatory process,\textsuperscript{165} including increasing their lining depth from the normal 1 to 2 cells deep up to 10 to 20 cells thick. This thickened synovial tissue, called “pannus,” invades the bone and acts like a localized tumor, where other factors (including increased osteoclast activity) cause bone destruction.\textsuperscript{166} Some of the most significant synovial changes involve altered signaling pathways for immune reactions, where SFs attach to articular cartilage and attack it, causing more inflammation; the release of enzymes, such as metalloproteinases, inflammatory chemokines, and cytokines (interleukins and tumor necrosis factor); and ingrowth of blood vessels. Increased blood vessel formation improves the opportunity for activated SFs to enter the bloodstream and affect other joints.\textsuperscript{1,167,168} Eventually, inflammation spreads to the fibrous joint capsule and surrounding ligaments and tendons, causing pain, joint deformity, and loss of function (\textit{Figure 39-18}). The joints most commonly affected are in the fingers, feet, wrists, elbows, ankles, and knees, but the shoulders, hips, and cervical spine also may be involved, as well as the tissues of the lungs, heart, kidneys, and skin.
The incidence and prevalence of RA have decreased over the past five decades; RA now affects about 1% of the adult population in developed countries. The frequency of RA increases with age. Besides inflammation and destruction of the joints, RA can cause fever, malaise, rash, lymph node or spleen enlargement, and Raynaud phenomenon (transient lack of circulation to the fingertips and toes).

Despite intensive research, the exact cause of RA remains obscure. It is likely a combination of genetic factors interacting with inflammatory mediators. There is a strong genetic predisposition to developing RA. The chronic inflammation characteristics of RA result from an intricate interplay of chemokines that are powerful mediators of inflammation. Ligand/receptor chemokines attract T cells
and produce inflammatory changes.\textsuperscript{1} A key genetic element has been localized to the human leukocyte antigen (HLA) areas of the major histocompatibility complex in all ethnic groups. Recent research reveals the possibility of specific amino acid malpositions in the (HLA) molecule as a major factor in developing rheumatic diseases.\textsuperscript{170} A surprising new discovery is the presence of T-cell abnormalities in individuals with RA, indicating a defect in telomere repair that may result in faster aging of telomeres and consequent less efficient immune function. With long-term or intensive exposure to the antigen, normal antibodies (immunoglobulins [Igs]) become autoantibodies—antibodies that attack host tissues (self-antigens). Because they are usually present in individuals with RA, the altered antibodies are termed \textbf{rheumatoid factors (RFs)}. The RFs usually consist of two classes of immunoglobulin antibodies (antibodies for IgM and IgG) but occasionally involve antibodies for IgA. Their main antigenic targets are portions of the immunoglobulin molecules. RFs bind with their target self-antigens in blood and synovial membrane, forming immune complexes (antigen-antibody complexes). (See Chapter 7 for a discussion about antigen-antibody binding in the immune response.)

Environmental factors, including geographic area of birth, diet, socioeconomic status, and especially smoking, have been identified as risk factors for developing and having higher disease activity of RA.\textsuperscript{171,172} RA and other autoimmune diseases have a higher prevalence among women. Additionally, because disease symptoms lessen during pregnancy and are increased again in the postpartal period, researchers are including hormonal involvement in their studies.

\textbf{Pathophysiology}

Although no specific events (such as trauma, illness, or environmental conditions) have been identified that would cause immune abnormalities to develop into localized tissue and joint inflammation, the pathology of RA is fairly well understood. During inflammation, arginine (an $\alpha$-amino acid) can be enzymatically modified into another $\alpha$-amino acid, citrulline. This process (citrullination) changes the structure and function of the protein. Other proteins, like fibrin and vimentin, become citrullinated during cell death and tissue inflammation.\textsuperscript{173} In turn, the citrullinated proteins can be seen as antigens by the body's immune system.\textsuperscript{174} Thus both T and B cells play a role in the autoimmune response. T cells express receptor activator of nuclear factor $\kappa$B ligand (RANKL), which promotes osteoclast formation and causes bony erosion.

Basically, cartilage damage in RA is the result of at least three processes: (1) neutrophils and other cells in the synovial fluid become activated, degrading the surface layer of articular cartilage; (2) inflammatory cytokines, particularly tumor
necrosis factor-alpha (TNF-α), interleukin-1beta (IL-1β), interleukin-6 (IL-6), interleukin-7 (IL-7), and interleukin-21 (IL-21), induce enzymatic (metalloproteinase) breakdown of cartilage and bone; and (3) T cells also interact with synovial fibroblasts through TNF-α, converting synovium into a thick, abnormal layer of granulation tissue known as pannus (see Chapter 7). Macrophages, components of pannus (Figure 39-19), stimulate the release of IL-1, platelet-derived growth factor (PDGF), and fibronectin. The B lymphocytes are stimulated to produce more RFs. The newly targeted self-antigens (immunoglobulins) are in relatively constant supply and can thus perpetuate inflammation and the formation of immune complexes indefinitely (Figure 39-20).

FIGURE 39-19 Synovitis. Inflamed synovium showing typical arrangements of macrophages and fibroblastic cells.
Rheumatoid arthritis is an autoimmune disease of a genetically susceptible host triggered by an unknown antigenic agent. Chronic autoimmune reaction with activation of CD4+ helper T cells and possibly other lymphocytes and the local release of inflammatory cytokines and mediators eventually destroy the joint. T cells stimulate cells in the joint to produce cytokines that are key mediators of synovial damage. Apparently, immune complex deposition also plays a role. Tumor necrosis factor (TNF) and interleukin-1 (IL-1), as well as some other cytokines, stimulate synovial cells to proliferate and produce other mediators of inflammation, such as prostaglandin E2 (PGE$_2$), matrix metalloproteinases, and enzymes that all contribute to destruction of cartilage. Activated T cells and synovial fibroblasts also produce receptor activator of nuclear factor-κB ligand (RANKL), which activates the osteoclasts and promotes bone destruction. Pannus is a mass of synovium and synovial stroma with inflammatory cells, granulation tissue, and fibroblasts that grows over the articular surface and causes its destruction.
Inflammatory and immune processes have several damaging effects on the synovial membrane. Along with the swelling caused by leukocyte infiltration, the synovial membrane undergoes hyperplastic thickening as its cells proliferate and abnormally enlarge. As synovial inflammation progresses to involve its blood vessels, small venules become occluded by hypertrophied endothelial cells, fibrin, platelets, and inflammatory cells, which decrease vascular flow to the synovial tissue. Compromised circulation, coupled with increased metabolic needs as a result of hypertrophy and hyperplasia, causes hypoxia and metabolic acidosis. Acidosis stimulates the release of hydrolytic enzymes from synovial cells into the surrounding tissue, initiating erosion of the articular cartilage and inflammation in the supporting ligaments and tendons. Pannus formation does not lead to synovial or articular regeneration but rather to formation of scar tissue that immobilizes the joint.

**Clinical manifestations**

The onset of RA is usually insidious, although as many as 15% of cases have an acute onset. RA begins with general systemic manifestations of inflammation, including fever, fatigue, weakness, anorexia, weight loss, and generalized aching and stiffness. Local manifestations also appear gradually over a period of weeks or months. Typically, the joints become painful, tender, and stiff. Pain early in the disease is caused by pressure from swelling. Later in the disease, pain is caused by sclerosis of subchondral bone and new bone formation. Pain and inability to perform normal functions are the main reasons people seek medical help. Stiffness usually lasts for about 1 hour after rising in the morning and is thought to be related to synovitis. Initially the joints most commonly involved are the metacarpophalangeal (MCP) joints, proximal interphalangeal (PIP) joints, and wrists, with later involvement of larger weightbearing joints.

Widespread, symmetric joint swelling is caused by increasing amounts of inflammatory exudate (leukocytes, plasma, plasma proteins) in the synovial membrane, hyperplasia of inflamed tissues, and formation of new bone. On palpation, the swollen joint feels warm and the synovial membrane feels boggy. The skin over the joint may have a ruddy, cyanotic hue and may look thin and shiny.

An inflamed joint may lose some of its mobility. Even mild synovitis can lead to reduced range of motion, which becomes evident after inflammation subsides. Extension becomes limited and is eventually lost if flexion contractures develop. Limited range of motion can progress to permanent deformities of the fingers, toes, and limbs, including ulnar deviation of the hands, boutonnière and swan neck deformities of the finger joints, plantar subluxation of the metatarsal heads of the foot, and hallux valgus (angulation of the great toe toward the other toes). Flexion
contractures of the knees and hips are also common.

Joint deformities cause the physical limitations experienced by persons with RA (see Figure 39-18). Loss of joint motion is quickly followed by secondary atrophy of the surrounding muscles. With secondary muscle atrophy, the joint becomes unstable, which further aggravates joint pathology.

Two complications of chronic RA are caused by excessive amounts of inflammatory exudate in the synovial cavity. One complication is the formation of cysts in the articular cartilage or subchondral bone. Occasionally, these cysts communicate with the skin surface (such as in the sole of the foot) and can drain through passages called fistulae. The second complication is rupture of a cyst or of the synovial joint itself, usually caused by strenuous physical activity that places excessive pressure on the joint. Rupture releases inflammatory exudate into adjacent tissues, thereby spreading inflammation.

Extrasynovial rheumatoid nodules, seen in up to 30% of individuals with RA, are the most common extra-articular manifestations. Each nodule is a collection of inflammatory cells surrounding a central core of fibrinoid and cellular debris. T lymphocytes are the predominant leukocytes in the nodule. B lymphocytes, plasma cells, and phagocytes are found around the periphery. Nodules are most often found in subcutaneous tissue over the extensor surfaces of elbows and fingers. Less common sites are the scalp, back, feet, hands, buttocks, and knees.

Rheumatoid nodules also may invade the skin, cardiac valves, pericardium, pleura, lung parenchyma, and spleen. These nodules are identical to those encountered in some individuals with rheumatic fever and are characterized by central tissue necrosis surrounded by proliferating connective tissue. Also noted are large numbers of lymphocytes and occasional plasma cells. Acute glaucoma may result with nodules forming on the sclera. Pulmonary involvement may result in diffuse pleuritis or multiple intraparenchymal nodules. Together, the occurrence of pulmonary nodules and pneumoconiosis (chronic inflammation of the lungs from inhalation of dust) creates the syndrome called Caplan syndrome. Diffuse pulmonary fibrosis may occur because of immunologically mediated immune complex deposition.

Rheumatoid nodules within the heart may cause valvular deformities, particularly of the aortic valve leaflets, and pericarditis. Lymphadenopathy of the nodes close to the affected joints may develop. Rheumatoid nodules within the spleen result in splenomegaly. Involvement of blood vessels results in an acute necrotizing vasculitis, characteristic of that noted in other immunologic/inflammatory states. Thromboses of such involved vessels may lead to myocardial infarctions, cerebrovascular occlusions, mesenteric infarction, kidney damage, and vascular insufficiency in the hands and fingers (Raynaud phenomenon). Fortunately, the
development of vascular changes (particularly systemic vasculitis) is decreasing in frequency as more effective RA treatments are becoming available. Changes in skeletal muscle are often noted in the form of nonspecific atrophy secondary to joint dysfunction.

**Evaluation and treatment**

The diagnosis of RA relies on clinical evaluation of joint swelling; however, limitation of movement and control of pain often prevent identification of individuals who would benefit from treatment in early stages of the disease. Early treatment can be effective in preventing the systemic and joint abnormalities of chronic disease. Research has shown that the autoantibodies rheumatoid factor (RF) and anti-citrullinated protein antibody (ACPA) can be present for years to decades before synovial or radiographic involvement becomes apparent. Compared with RF, ACPA is a much more specific serum marker for RA. The American College of Rheumatology (ACR) and the European League Against Rheumatism (EULAR) revised their RA classification criteria in 2010 in order to better identify the early stage of RA. These new criteria are shown in Table 39-5. Clinical examination and history are the mainstays of RA diagnosis, but new imaging techniques show promise for earlier diagnosis, leading to earlier treatment with a better chance for avoiding disability and joint destruction (see Health Alert: Musculoskeletal Molecular Imaging).

**Health Alert**

**Musculoskeletal Molecular Imaging**

With improved understanding of the molecular and cellular mechanisms responsible for the effects of rheumatoid arthritis (RA), new imaging techniques promise benefits in earlier and more accurate diagnosis and monitoring of cartilage and bone involvement. Imaging on that same molecular level can provide a “biological read-out” of disease progression and response to treatment. Nuclear medicine imaging, positron emission tomography (PET), and magnetic resonance imaging (MRI) all incorporate some element of molecular imaging.

New modalities of molecular imaging use various probes and contrast agents that have an affinity for specific targets, such as cells, hormones, antigens, and enzymes. Certain monoclonal antibodies have already been successfully labeled with various nuclides and could be used to identify disease progression. Bioluminescent and fluorescent imaging techniques have the advantage of being
radiation-free tests and are being used to view in vivo activity, osteoblast activity, osteocalcin expression in bone damage, and osteoclast activity and gene expression during inflammation. A significant area of promise for molecular imaging in RA is recognition of the initial molecular events that occur before cartilage and joint damage becomes apparent. Better monitoring of response to medications also may allow more accurate dosing with the potential for fewer side effects. Because certain bioluminescent and fluorescent agents have specific affinities for particular cells, more efficient bone regeneration may be possible by targeted delivery of appropriate growth factors or stem cells to damaged bone and cartilage.

*The criteria are aimed at classification of newly presenting persons. In addition, persons with erosive disease typical of rheumatoid arthritis (RA) with a history compatible of prior fulfillment of the 2010 criteria should be classified as having RA. Persons with longstanding disease—including those whose disease is inactive (with or without treatment) and who, based on retrospectively available data, have previously fulfilled the 2010 criteria—should be classified as having RA.*

*D Differential diagnoses vary among persons with different presentations, but may include conditions such as systemic lupus erythematosus, psoriatic arthritis, and gout. If it is unclear about the relevant differential diagnoses to consider, an expert rheumatologist should be consulted.*

*Although persons with a score <6/10 are not classifiable as having RA, their status can be reassessed and the criteria might be fulfilled cumulatively over time.*
Joint involvement refers to any swollen or tender joint on examination, which may be confirmed by imaging evidence of synovitis. Distal interphalangeal joints, first metacarpophalangeal joints, and first metatarsophalangeal joints are excluded from assessment. Categories of joint distribution are classified according to the location and number of involved joints, with placement into the highest category possible based on the pattern of joint involvement.

“Large joints” refer to shoulders, elbows, hips, knees, and ankles.

“Small joints” refer to the metacarpophalangeal joints, proximal interphalangeal joints, thumb interphalangeal joints, and wrists.

In this category, at least one of the involved joints must be a small joint; the others can include any combination of large and additional small joints, as well as other joints not specifically listed elsewhere (e.g., temporomandibular, acromioclavicular, sternoclavicular).

Negative refers to international unit (IU) values that are less than or equal to the upper limit of normal (ULN) for the laboratory and assay; low-positive refers to values that are higher than the ULN but ≤3 times the ULN for the laboratory and assay; high-positive refers to IU values that are >3 times the ULN for the laboratory and assay. Where rheumatoid factor (RF) information is only available as positive or negative, a positive result should be scored as low-positive for RF. ACPA, Anti-citrullinated protein antibody.

Normal/abnormal is determined by local laboratory standards. CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.

Duration of symptoms refers to individual's self-report of the duration of signs and symptoms of synovitis (e.g., pain, swelling, tenderness) of joints that are clinically involved at the time of assessment, regardless of treatment status.

Early treatment of RA begins with disease-modifying antirheumatic drugs (DMARDs), such as methotrexate (MTX), azathioprine, sulfasalazine, hydroxychloroquine, leflunomide, and cyclosporine. These agents have been shown to slow the progression of RA and may prevent complications such as joint deformities and extra-articular complications. MTX remains the first line of treatment. More recently, targeted treatment for RA has involved use of agents aimed at interrupting the pathogenesis of the disease. Known as biologic DMARDs (bDMARDs), these medications affect specific processes in the development of RA and include tumor necrosis factor inhibitors, such as etanercept, adalimumab, and infliximab. They have recently been augmented by the monoclonal antibodies golimumab and certolizumab. Other agents interfere with cytokine function (anakinra inhibits IL-1 function and tocilizumab targets IL-6), inhibit T-cell activation (abatacept), or deplete B cells (rituximab).

Education for individuals with RA is fundamental to treatment. Other treatments and therapies include nonsteroidal anti-inflammatory drugs (NSAIDs), glucocorticoids, intra-articular steroid injections, physical and occupational therapy with therapeutic exercise, and use of assistive devices. Surgery is used to treat deformities or mechanical deficiencies of joints and can include synovectomy or joint replacement surgery.
Ankylosing Spondylitis

Ankylosing spondylitis (AS) is the most common of a group of inflammatory arthropathies known as spondyloarthropathies (SpAs). The Assessment of SpondyloArthritis International Society (ASAS) has recommended classifying spondyloarthropathies to include individuals who do not have visible radiographic changes of the skeleton, as well as those who do. There would then be two subgroups: (1) mainly axial disease, including AS; and (2) peripheral SpA. AS is a chronic, inflammatory joint disease characterized by stiffening and fusion (ankylosis) of the spine and sacroiliac joints. Like RA, ankylosing spondylitis is a systemic, autoimmune inflammatory disease. Although inflammation is the primary pathologic process in both RA and ankylosing spondylitis, the two diseases differ in the primary site of inflammation and the end result. In RA, the primary site of inflammation is the synovial membrane, resulting in the destruction and instability of synovial joints. In ankylosing spondylitis, excessive bone formation occurs. The primary pathologic site is the enthesis (the point at which ligaments, tendons, and the joint capsule are inserted into bone), and the end result is fibrosis, ossification, and fusion of the joint, primarily the sacroiliac joints and the vertebral column (axial skeleton).

AS occurs worldwide, with the lowest prevalence in South Asian countries and highest in North America and Europe; it affects men more often than women. In women, AS may affect the peripheral joints of the appendicular skeleton rather than the axial skeleton, progress less rapidly, and cause less dramatic spinal changes. Primary AS usually develops in late adolescence and young adulthood, with peak incidence at about 20 years of age. Secondary AS affects older age groups and is often associated with other inflammatory diseases (e.g., psoriatic arthropathy, inflammatory bowel disease, Reiter syndrome).

The exact cause of AS is unknown, but its high association with histocompatibility antigen human leukocyte antigen (HLA-B27) has been known for decades. Misfolding of HLA-B27 in the endoplasmic reticulum (ER) may play a key role in developing AS. As misfolded proteins accumulate, they may cause an unfolded protein response (UPR) that disrupts normal cellular functions and causes a stress response of the ER (also see Chapter 4). That stress response increases production of interleukins-17 and -23 (IL-17, IL-23), potent cytokines that also may act on T-helper 17 (Th17) cells, promoting their survival. Th17 cells are important mediators in human immune diseases. Additional studies have revealed that HLA-B27, itself, has many forms; to date more than 100 subtypes have been identified. Certain variations in the endoplasmic reticulum aminopeptidase 1 (ERAP1) protein appear to increase the likelihood of developing AS in people who
are HLA-B27 positive.

**Pathophysiology**

Ankylosing spondylitis begins with inflammation of fibrocartilage in cartilaginous joints. In men, the sacroiliac joint is often affected first, usually before any damage can be radiographically detected.\(^{181}\) Knee pain may be the initial symptom in women.\(^{184}\) Inflammatory cells infiltrate the fibrous tissue of the joint capsule, the cartilage that surrounds intervertebral disks, the entheses, and the periosteum. As inflammatory cells (chiefly macrophages) and lymphocytes infiltrate and erode bone and fibrocartilage in joint structures, repair begins. Repair of cartilaginous structures begins with the proliferation of fibroblasts. Fibroblasts synthesize and secrete collagen. The collagen becomes organized into fibrous scar tissue that eventually undergoes calcification and ossification. With time, all the cartilaginous structures of the joint are replaced by ossified scar tissue, causing the joint to fuse, or lose flexibility.

Repair of eroded bone begins with osteoblast activation and proliferation. Osteoblasts lay down new bone (callus), which is remodeled and replaced by compact, lamellar bone. Bone repair changes the contour of the bone's surface because the new bone grows outward (outside the normal border of unaffected bone) to form a new enthesis with the end of the eroded ligament. The new enthesis, which forms on top of the old one, is called a **syndesmophyte**. As calcification of the spinal ligaments progresses, the vertebral bodies lose their concave anterior contour and appear square. The spine assumes the classic bamboo spine appearance of ankylosing spondylitis.

**Clinical manifestations**

The most common signs and symptoms of early AS are low back pain and stiffness. Typically, the individual with primary disease develops low back pain during the early twenties. The pain is at first insidious but progressively becomes persistent. It is often worse after prolonged rest and is alleviated by physical activity. Early morning stiffness usually accompanies the low back pain, and the individual typically has difficulty sitting up or twisting the spine. Forward flexion, rotation, and lateral flexion of the spine are restricted and painful. Early pain and resultant loss of motion are caused by the underlying inflammation and reflex muscle spasm rather than by soft tissue or bony fusion.

As the disease progresses, the normal convex curve of the lower spine (lumbar lordosis) diminishes and concavity of the upper spine (kyphosis) increases. The individual becomes increasingly stooped. The thoracic spine becomes rounded, the head and neck are held forward on the shoulders, and the hips are flexed (Figure 39-
Inflammation in the tendon insertions of the many costosternal and costovertebral muscles can cause pleuritic chest pain and restricted chest movement. The pain is usually worse on inspiration. Movement of the diaphragm is normal and full. Pressure on the anterior chest wall over the sternum, ribs, and costal cartilages may cause tenderness. Tenderness over the pelvic brim may cause discomfort at night and interfere with sleep because turning onto the iliac crests causes pain. Tenderness over the ischial tuberosities may make sitting on hard seats unbearable. Tenderness in the heels may contribute to a limp or cautious placement of the feet during walking.

Along with low back pain and sacroiliac pain, inflammation of the bowels, anterior uveitis, aortic regurgitation, fibrosis of the upper lobes of the lung, Achilles tendonitis, and immune-related (IgA) kidney disease frequently accompany AS. Elevated sedimentation rate (ESR) and elevated level of C-reactive protein (CRP) also are common.

**Evaluation and treatment**
Diagnosis of AS is based on specific criteria. One of the previous problems with diagnosing AS has been a requirement for radiographic (x-ray) evidence of sacroiliitis; MRI can discover sacroiliitis an average of 7.7 years before there is evidence on x-rays. Both MRI and plain radiographic findings are important in detecting early disease and for evaluating individuals younger than 45 years of age with back pain of at least 3 months' duration.

In addition to sacroiliitis being present on imaging, one or more of the following features allow a diagnosis of spondyloarthritis (SpA): inflammatory back pain, arthritis, anterior uveitis, heel pain, dactylitis, psoriasis, Crohn disease or ulcerative colitis, good response to NSAIDs, family history of SpA, positive HLA-B27, or elevated CRP. If the individual has a positive HLA-B27, at least two of the previously mentioned items must be present along with sacroiliitis on MRI or radiographic imaging in order to make a diagnosis.

Treatment of individuals with AS consists of education about the disease, as well as physical therapy to maintain skeletal mobility and prevent the natural progression of contractures. Prevention of deformity and maintenance of mobility require a continuous program of physical therapy. Supervised group exercises have been shown to reduce pain and to maintain and improve chest expansion and respiratory function, spine mobility, and complete range of motion in the proximal joints.

Nonsteroidal anti-inflammatory drugs (NSAIDs) will often provide temporary symptom relief within 48 hours. Analgesic medications are prescribed to suppress some of the pain and stiffness and to facilitate exercise. The medications do not prevent disease progression, but they do provide relief from symptoms. Biologic response modifying agents, such as tumor necrosis factor inhibitors (certolizumab, golimumab) or B-cell depleting agents (rituximab), are increasingly being used to treat AS. Newer agents that target cytokines of Th17 and small nano particles that alter certain inflammatory pathways are showing promise in treating AS. Surgical procedures, such as osteotomy, total hip replacement, and cervical spinal fusion, and radiation therapy are sometimes used to provide relief for individuals with end-stage disease or intolerable deformity. Individuals should stop smoking to lessen pulmonary problems.

Gout

The prevalence of gout has steadily increased over the past several decades and is now considered the most common inflammatory arthritis worldwide. Gout is a syndrome caused by either overproduction or underexcretion of uric acid and is characterized by inflammation and pain of the joints. Incomplete purine metabolism results in excess serum uric acid levels (hyperuricemia). Either excessive uric acid
production or underexcretion of uric acid by the kidneys will cause hyperuricemia. Underexcretion of uric acid is responsible for about 90% of the cases of elevated uric acid level and appears to have a strong genetic basis.\textsuperscript{194,195}

When uric acid reaches a certain concentration in fluids, it crystallizes, forming insoluble precipitates that are deposited in connective tissues throughout the body. Crystallization in synovial fluid triggers the TNF-\(\alpha\) inflammatory pathway, causing the release of various chemokines and interleukins, resulting in painful inflammation of the joint, a condition known as \textit{gouty arthritis}. Urate crystal deposits cause oxidative stress reactions in other tissues as well. With time, crystal deposition in subcutaneous tissues causes the formation of small, white nodules, or \textit{tophi}, that are visible through the skin. Tophi are associated with joint damage and an increased death rate, primarily because of cardiovascular events.\textsuperscript{196} Hyperuricemia is associated with hypertension, heart disease, type 2 diabetes, kidney disease, and metabolic syndrome.\textsuperscript{197}

In classic gouty arthritis, monosodium urate crystals form and are deposited in joints and their surrounding tissues, initiating a powerful inflammatory response.\textsuperscript{198} Pseudogout is caused by the formation of calcium pyrophosphate-dihydrate crystals. The effect of either crystal is the same—the onset of an acute inflammatory response (see Chapter 6).

Gout is rare in children and premenopausal women and is uncommon in males younger than 30 years. Male gender, increasing age, and high intake of alcohol, red meat, and fructose are all risk factors for gout.\textsuperscript{193} The peak age of onset in males is between 40 and 50 years. The risk of developing gouty arthritis is similar in males and females for a particular urate concentration. Females tend to have onset at a later age and have greater use of diuretics, more coexisting diseases (hypertension, renal insufficiency), more frequent involvement of other joints, and fewer recurrent episodes.\textsuperscript{199} Plasma urate concentration is the single most important determinant of the risk of developing gout (Table 39-6).

\begin{table}[h]
\centering
\begin{tabular}{|l|l|}
\hline
\textbf{Characteristic} & \textbf{Mean Urate Levels (mg/dl)} \\
\hline
Prepuberty & 3.5 \\
Males (at puberty) & Steep rise to 5.2 \\
Females (puberty to after premenopause) & Slow rise to \(\approx\)4.0 \\
Females (after menopause) & 4.7 \\
Hyperuricemia & \\
Males & 7.0 \\
Females & 6.0 \\
\hline
\end{tabular}
\caption{Mean Urate Concentrations by Age and Gender}
\end{table}

Uric acid is a weak acid that is ionized at normal body pH and thus occurs in the
blood or tissues in the form of urate ion. When ionized, uric acid can form salts with various cations, but 98% of extracellular uric acid is in the form of monosodium urate (urate acid salt). At any time the proportion of uric acid or urate is pH dependent, so the ratio of these two forms varies considerably in urine.

The solubility of urate and uric acid is critical to the development of crystals. Urate is more soluble in plasma, synovial fluid, and urine than in aqueous solutions. The solubility of uric acid in urine rises dramatically as the pH increases. There is little change, however, in the solubility of urate within the normal pH range that exists in the plasma, synovial fluid, and other tissues. The pH can be 5.0 in the collecting tubules of the kidney, thus favoring formation of uric acid. Decreasing temperatures cause both urate and uric acid solubility to fall. The pathways of production of uric acid are shown in Figure 39-22.

**Pathophysiology**

The pathophysiology of gout is closely linked to purine metabolism (or cellular metabolism of purines) and kidney function. Most mammals, except humans, have the enzyme uricase, which catalyzes the conversion of uric acid to allantoin, thus
preventing overproduction of uric acid. Environmental and genetic factors also play a role in an individual's urate concentration. At the cellular level, purines are synthesized to purine nucleotides, which are used in the synthesis of nucleic acids, adenosine triphosphate (ATP), cyclic adenosine monophosphate (cAMP), and cyclic guanosine monophosphate (cGMP). Uric acid is a breakdown product of purine nucleotides (urate synthesis and elimination are illustrated in Figure 39-23).
Most uric acid is eliminated from the body through the kidneys. Urate is filtered at the glomerulus and undergoes both reabsorption and excretion within the renal tubules. In primary gout, urate excretion by the kidneys is sluggish. The sluggish excretion may be the result of a decrease in glomerular filtration of urate or acceleration in urate reabsorption. In addition, monosodium urate (MSU) crystals are deposited in renal interstitial tissues, causing impaired urine flow. (Kidney function is described in Chapter 29.)

The exact process by which crystals of monosodium urate are deposited in joints and induce gouty arthritis is unknown, but several mechanisms may be involved, including the following:

1. Monosodium urate precipitates at the periphery of the body, where lower body temperatures may reduce the solubility of monosodium urate.

2. Albumin or glycosaminoglycan levels decrease, which causes decreased urate solubility.

3. Changes in ion concentration and decreases of pH enhance urate deposition.

4. Trauma promotes urate crystal precipitation.

The monosodium urate crystals may form in the synovial fluid or in the synovial
membrane, cartilage, or other connective tissues in joints and elsewhere, such as in the heart, earlobes, and kidneys. Evidence suggests that an acute attack of gout is the result of the formation of crystals rather than the release of crystals from connective tissues into the synovial fluid.

Monosodium urate crystals can stimulate and perpetuate the inflammatory response (see Figure 39-23, A, B). The presence of the crystals triggers the acute inflammatory response, releasing proinflammatory cytokines and tumor necrosis factors, during which neutrophils are attracted out of the circulation and begin to phagocytose (ingest) the crystals.

Importantly, deposits of MSU in joints and other tissues can be present years before an acute gout attack occurs. Early identification and intervention in treating gout can reduce morbidity and mortality associated with the disease. Traditionally, plain radiographs (x-rays) have been used to assess joints affected by gout, but only damaged joints can be seen. Newer technologies, including high-resolution ultrasound, dual-energy computed tomography (DECT), and MRI, can assess the presence of MSU crystals before joint, tendon, or ligament damage occurs. Imaging modalities also can be used when joints cannot be aspirated to look for MSU crystals microscopically. Earlier identification allows timely as well as ongoing evaluation of treatment.

**Clinical manifestations**

Gout is manifested by (1) an increase in serum urate concentration (hyperuricemia); (2) recurrent attacks of monoarticular arthritis (inflammation of a single joint); (3) deposits of monosodium urate monohydrate (tophi) in and around the joints; (4) renal disease involving glomerular, tubular, and interstitial tissues and blood vessels; and (5) the formation of renal stones. These manifestations appear in three clinical stages:

1. **Asymptomatic hyperuricemia.** The serum urate level is elevated but arthritic symptoms, tophi, and renal stones are not present; this stage may persist throughout life.

2. **Acute gouty arthritis.** Attacks develop with increased serum urate concentrations; tends to occur with sudden or sustained increases of hyperuricemia but also can be triggered by trauma, drugs, and alcohol.

3. **Tophaceous gout.** The third and chronic stage of the disease; can begin as early as 3 years or as late as 40 years after the initial attack of gouty arthritis. Progressive inability to excrete uric acid expands the urate pool until monosodium urate crystal
deposits (tophi) appear in cartilage, synovial membranes, tendons, and soft tissue.

Trauma is the most common aggravating factor of an acute gouty exacerbation. Attacks of gouty arthritis occur abruptly, usually in a peripheral joint (see Figure 39-23, C). The primary symptom is severe pain. Approximately 50% of the initial attacks occur in the metatarsophalangeal joint of the great toe (a condition known as podagra). The other 50% can occur in almost any joint, but most often involve the heel, ankle, instep of the foot, knee, wrist, or elbow. The pain is usually noted at night. Within a few hours the affected joint becomes hot, red, and extremely tender and may be slightly swollen. Lymphangitis and systemic signs of inflammation (leukocytosis, fever, elevated sedimentation rate) are occasionally present. Untreated, mild attacks usually subside in several hours but may persist for 1 or 2 days. Severe attacks may persist for several days or weeks. When the individual recovers, the symptoms resolve completely.

Tophaceous deposits produce irregular swellings of the fingers, hands, knees, and feet. The helix of the ear is the most common site of tophi, which are the characteristic diagnostic lesions of chronic gout. Tophi also may develop along the ulnar surface of the forearm, the tibial surface of the leg, the Achilles tendon, olecranon bursa, or other areas. Tophi may produce marked limitation of joint movement and can eventually cause grotesque deformities of the hands and feet (see Figure 39-23, C). Although the tophi themselves are painless, they often cause progressive stiffness and persistent aching of the affected joint. Tophi in the extremities can cause nerve compression—carpal tunnel syndrome in the wrists, tarsal tunnel syndrome in the ankles. Tophi also may erode and drain through the skin.

Renal stones are 1000 times more prevalent in individuals with primary gout than in the general population. The stones can be the size of a grain of sand or a piece of gravel, or they can accumulate in massive deposits called staghorn calculi. They range in color from pale yellow to brown to reddish black, depending on their composition. Some stones consist of pure monosodium urate; others consist of calcium oxalate or calcium phosphate. Renal stones can form in the collecting tubules, pelvis, or ureters, causing obstruction, dilation, and atrophy of the more proximal tubules and leading eventually to acute renal failure. Stones deposited directly in renal interstitial tissue initiate an inflammatory reaction that leads to chronic renal disease and progressive renal failure.

**Evaluation and treatment**

Evaluation of gout may include history and physical examination, blood tests, joint fluid test, ultrasound, and other imaging. The goals of treatment are to terminate the
acute gouty attack as promptly as possible, decrease serum uric acid levels (to dissolve monosodium urate crystals), prevent acute attacks of gout by removing tophi, and, finally, cure gout. \(^{202}\) Acute gouty arthritis should be treated with anti-inflammatory drugs within 24 hours after the attack. The drugs of choice are nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, and colchicine. \(^{203}\) Newer medications include interleukin inhibitors. \(^{204}\) In persons unable to tolerate NSAIDs, colchicine is useful but can be poorly tolerated because of a number of side effects. Once infection has been ruled out, steroids may be injected into the joint to relieve pain. Local application of ice reduces pain during an acute attack. \(^{205}\) Weightbearing on the involved joint is avoided until the acute attack subsides. A diet that includes mostly vegetables and fruit with little meat, avoidance of alcohol, and weight loss can help lower serum uric acid concentration. \(^{206}\) Current recommendations are to decrease serum urate levels to less than 6 mg/dl (or less than 5 mg/dl if the individual has marked monosodium urate crystal deposits on clinical examination or imaging studies). \(^{200}\) High fluid intake, particularly water, can increase urinary output. Long-term use of anti-hyperuricemic drugs, including newer agents such as pegloticase, helps reduce serum urate concentrations. Allopurinol and febuxostat are both used to lower serum urate levels by inhibiting the activity of xanthine oxidase.

Quick Check 39-3

1. How does noninflammatory joint disease differ from inflammatory joint disease? Describe two principal features of each.

2. How does rheumatoid arthritis affect the skin, heart, lungs, and kidneys?

3. How do monosodium urate crystals cause gout to develop?
**Disorders of Skeletal Muscle**

Muscle diseases (myopathies) encompass many entities. Muscle weakness and muscle fatigue are common symptoms. In many cases, neural, traumatic, and psychogenic causes provide an adequate explanation for the failure to generate force (weakness) or sustain force (fatigue) seen in myopathies. The pathophysiologic mechanisms in some of the metabolic and inflammatory muscle diseases have been explored, but the cause of many of the myopathies remains obscure. The complex interaction between muscles and nerves affects muscular function as well. Only inherited and acquired disorders of skeletal muscles are discussed here.

**Secondary Muscular Dysfunction**

Muscular symptoms arise from a variety of causes unrelated to the muscle itself. Secondary muscular phenomena (contracture, stress-related muscle tension, immobility) are common disorders that influence muscular function.

**Contractures**

Contractures are described as the loss of full passive range of motion secondary to joint, muscle, or other soft tissue limitations and can be pathologic or physiologic. A physiologic muscle contracture occurs in the absence of a muscle action potential in the sarcolemma. Muscle shortening is explained on the basis of failure of the calcium pump in the presence of plentiful adenosine triphosphate (ATP). A physiologic contracture is seen in McArdle disease (muscle myophosphorylase deficiency) and malignant hyperthermia. The contracture is usually temporary if the underlying pathology is reversed.

A pathologic contracture is a permanent muscle shortening caused by muscle spasm or weakness. Heel cord (Achilles tendon) contractures are examples of pathologic contractures. They are associated with plentiful ATP and occur in spite of a normal action potential. The most common contractures are seen in stroke, neuromuscular diseases (such as muscular dystrophy), Charcot-Marie-Tooth disease, amyotrophic lateral sclerosis, and central nervous system (CNS) injury. Lower extremity contractures are more common than those in the upper extremity. Prolonged splinting in a single position or an imbalance between agonist-antagonist muscles also can cause joint stiffness and contractures. Contractures also may develop secondary to scar tissue contraction in the flexor tissues of a joint, as in scarring of burned tissues in the antecubital area of the forearm, leading to a flexion contracture.
Stress-Induced Muscle Tension

Abnormally increased muscle tension has been associated with chronic anxiety as well as a variety of stress-related muscular symptoms including neck stiffness, back pain, and headache. Abnormalities in the CNS, reticular activating system, and autonomic nervous system (ANS) have been implicated. For example, as an individual progressively relaxes, the amplitude of the knee jerk reflex diminishes. Conversely, individuals with absent reflexes increase tension by such maneuvers as clenching the teeth or strengthening the handgrip. The underlying pathophysiology may be related to the fact that as a muscle contracts, the muscle spindle is activated. This gamma-feedback system produces a series of impulses that are transmitted to the brain by the sensitive 1A afferent fibers. Unconscious tension is thought to increase the activity of the reticular activating system as well, which stimulates firing of the efferent loop of the gamma fibers, produces further muscle contraction, and increases muscle tension. ANS function that regulates increased blood flow to the muscle during sympathetic activity may be related to increased muscle contraction tension.

Various forms of treatment have been used to reduce the muscle tension associated with stress. Progressive relaxation training, yoga, meditation, and biofeedback are examples of stress reduction therapies. Biofeedback uses integrated electromyography (EMG) to make recordings from the skin surface. The goal is to teach the individual to control maladaptive tension. It is particularly useful in individuals who have a connection between skeletal muscle tension and pain.

Progressive relaxation training emphasizes the individual's ability to perceive the difference between tension and relaxation. This technique involves sequential tensing and a relaxing environment. The individual is taught to practice this routine daily, often with the use of audiotaped instructions. By teaching the individual to recognize excessive contraction of skeletal muscle, one hopes to enhance the person's ability to relax specific muscle groups to relieve tension and thus reduce CNS arousal as well as ANS arousal.

Disuse Atrophy

The term disuse atrophy describes the pathologic reduction in normal size of muscle fibers after prolonged inactivity from bed rest, trauma (casting), or local nerve damage as can be seen with spinal cord trauma or poliomyelitis. Decreased muscle activity reduces muscle mass through both decreased muscle protein synthesis and increased muscle protein breakdown. Reduced protein synthesis is primarily responsible for muscle atrophy. The effects of muscular deconditioning associated with lack of physical activity may be apparent in a matter of days. A
normal individual prescribed bed rest loses muscle strength from baseline levels at a rate of 3% per day. Bed rest also is associated with cardiovascular, skeletal, and other organ system changes. Likewise, as people age, their muscles atrophy and become weaker (sarcopenia).

Measures to prevent atrophy include frequent forceful isometric muscle contractions and passive lengthening exercises. Artificial gravity (through the use of a “human centrifuge”) has shown benefit in maintaining muscle strength. One of the simplest ways to improve disuse atrophy is to restore a load to the muscle, such as returning to walking, starting active motion to a limb, and adding resistance to movements.\(^{210}\) If reuse is not restored within 1 year, regeneration of muscle fibers becomes impaired.

**Fibromyalgia**

**Fibromyalgia (FM)** is a chronic musculoskeletal syndrome characterized by diffuse pain, fatigue, increased sensitivity to touch (i.e., tender points), the absence of systemic or localized inflammation, and the presence of fatigue and nonrestorative sleep; anxiety and depression also are frequently present. FM has often been misdiagnosed or completely dismissed by clinicians because there are few objective clinical findings on examination. A common misdiagnosis has been chronic fatigue syndrome. Of affected individuals, 80% to 90% are women, and the peak age is 30 to 50 years. New research supports the possible role of inflammation in FM.\(^{211-213}\) FM and its symptoms are viewed as the result of central nervous system dysfunction, where pain transmission and interpretation are amplified, a condition called central sensitization. Although the incidence is unknown, the prevalence is reported to be 2% to 8% and increases with age.\(^{214}\) Certain autoimmune diseases, especially systemic lupus erythematosus (SLE) and irritable bowel syndrome (IBS), are often seen in association with FM and may coexist if not initially present with fibromyalgia.

**Pathophysiology**

Genetic factors are increasingly being suggested as important in developing FM. Relatives of individuals with FM have an increased risk of developing FM. Studies of genetic factors have implicated alterations in genes affecting serotonin, catecholamines, and dopamine—all of these substances are involved in the stress response and sensory processing.\(^{215-217}\) In spite of these studies, the role of genetic factors has not yet been fully identified in FM. External stressors, such as infection, psychosocial stress, and physical or emotional trauma, have been proposed as mechanisms precipitating FM; however, as yet, there is no definitive scientific
Functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) scans of the brains of individuals with FM have shown activity in different areas of the brain than normally seen in healthy individuals exposed to painful stimuli. These functional abnormalities within the central nervous system (CNS) are shown in Figure 39-24. Other pathophysiologic evidence includes hypothalamic-pituitary axis alterations that show abnormal response to stress.

Clinical manifestations
The prominent symptom of fibromyalgia is diffuse, chronic pain. Chronic pain is defined as being present more than 3 months. Traditionally, to be classified as FM, tenderness in 11 of 18 specific points was required along with widespread pain. In 2010 the classification of FM was simplified and expanded to include other important non–pain symptoms. The pain often begins in one location, especially the neck and shoulders, but then becomes more generalized. People describe the pain as burning or gnawing. Fatigue is profound. The effect on everyday life is considerable. Fatigue is most notable when arising from sleep and in midafternoon. Headaches and memory loss are common complaints. There is a strong association between fibromyalgia, Raynaud phenomenon, and irritable bowel syndrome. Individuals with fibromyalgia are light sleepers and awake frequently, which may explain why individuals feel nonrefreshed upon waking.
Almost 25% of individuals seek psychologic support for depression. Anxiety, particularly with regard to their diagnosis and future, is almost universal.

**Evaluation and treatment**

Because the manifestations of chronic, generalized pain and fatigue are present in many musculoskeletal (e.g., rheumatic) disorders, these disorders should be considered in the differential diagnosis of FM. In an effort to simplify and more accurately diagnose FM, the American College of Rheumatology (ACR) recently expanded the diagnostic criteria to include a widespread pain index (WPI) definition as “axial pain, left- and right-sided pain, and upper and lower segment pain” and a symptom severity (SS) score. The SS score includes symptoms such as fatigue, waking unrefreshed, and cognitive difficulty. The WPI and SS scores are then tabulated to identify or exclude the diagnosis of FM in individuals who also meet the following criteria:

1. Symptoms have been present at a similar level for at least 3 months.

2. The individual does not have a disorder that would otherwise explain the pain.

The 2010 FM classification criteria were further updated in 2011 so that FM can be classified solely by patient-report using a questionnaire and scale. Treatment should be highly individualized and can include mind-body interventions (such as biofeedback), movement therapies, and relaxation techniques as well as medication. No one regimen of medication has proved successful for FM. Exercise regimens are beneficial in reducing symptoms. Recommended exercises for individuals with FM include aerobic activities (including kickboxing and weightlifting), stretching, and gentle strengthening programs. Medications also are helpful. The FDA has currently approved three medications specifically to treat FM: pregabalin, duloxetine, and milnacipran. Pregabalin reduces the release of several neurochemicals, decreasing pain. Duloxetine and milnacipran are norepinephrine and serotonin reuptake inhibitor antidepressants that also improve pain and depression. Milnacipran also improves fatigue, cognition, and other FM symptoms. Two of the most important aspects of treatment are physical activity and patient education (Box 39-4).

---

**Box 39-4**

**Educating and Providing Reassurance for Individuals with Fibromyalgia**
Stress that the illness is real, not imagined.

Explain that fibromyalgia is presumably not caused by infection.

Explain that fibromyalgia is not a deforming or deteriorating condition.

Explain that fibromyalgia is neither life-threatening nor markedly debilitating, although it is an irritating presence.

Discuss the role of sleep disturbances and the relationship of neurohormones to pain, fatigue, abnormal sleep, and mood.

Reassure that although the cause is unknown, some information is known about the physiologic changes responsible for the symptoms.

Use muscle “spasms” and, perhaps, “low muscle blood flow” to lay the groundwork for exercise recommendations.

Assist the individual to use aerobic exercise to reduce stress and increase rapid eye movement (REM) sleep.

**Chronic Fatigue Syndrome**

**Chronic fatigue syndrome (CFS)** is a chronic debilitating disease that is likely best described as neuroimmunoendocrine disease that is characterized by cognitive impairment, severe postexertional fatigue (including physical, emotional, or cognitive activity), unrefreshing sleep, and decreased physical activity that affects daily functioning. Other frequent symptoms include sore throat, tender lymph nodes, pain, and psychiatric complaints. CFS has often been a diagnosis of exclusion because it cannot be objectively identified by any laboratory or specific clinical tests. Because of the difficulty finding objective data to diagnose CFS, the disease also has been termed myalgic encephalomyelitis (ME) and has been considered a psychiatric disorder. CFS/ME has remained a controversial diagnosis until recently.

Though there seems to be some psychologic involvement in CFS/ME, there is emerging evidence for a physiologic basis. New research has revealed a number of physiologic abnormalities associated with CFS/ME. Some of these processes include skeletal muscle abnormalities, mitochondrial dysfunction, diminished activity of several types of immune cells, abnormal cytokine regulation, and dysfunction of the hypothalamic-pituitary-adrenal (HPA) axis. Because of the
continued controversy surrounding CFS/ME and the difficulties diagnosing and treating it, the U.S. Institute of Medicine recommended a new term for the condition in 2015, systemic exertional intolerance disease (SEID).\textsuperscript{234} Treatment for SEID remains challenging and must be individualized, because there both physical and psychologic components to the disease. Learning how to adapt to stressors and improving physical activity may assist in improving symptoms.\textsuperscript{235, 236}

**Muscle Membrane Abnormalities**

Two defects of the muscle membrane (plasma membrane of the muscle fiber) have been linked to clinical syndromes: the hyperexcitable membrane seen in myotonic disorders and the intermittently unresponsive membrane seen in periodic paralyses. Although these are rare disorders, research into their pathologic processes has led to an improved understanding of cell membrane channelopathies (ion channels are described in Chapter 13).

**Myotonia**

*Myotonias* are genetically inherited diseases caused by alterations in skeletal muscle sodium and calcium ion channels that result in delayed relaxation after voluntary muscle contraction, such as handgrip, eye closure, or muscle percussion.\textsuperscript{237, 238} Definitive diagnosis is made by genetic testing. Needle electromyography (EMG) is useful in determining likelihood of disease; the distinctive “dive bomber” noise, audible on needle EMG, is caused by the prolonged depolarization of the muscle membrane.

Myotonia comprises various disorders: myotonia congenita, paramyotonia congenita, myotonic muscular dystrophy, and some forms of periodic paralysis. With the exception of myotonic muscular dystrophy, most are mild in symptomatology. Treatment includes sodium channel blocking agents, such as mexiletine, but no pharmacologic agents have yet received FDA approval for treating myotonia.\textsuperscript{239, 240} Other treatment modalities include genetic counseling as well as lifestyle and dietary modifications.\textsuperscript{241}

**Periodic Paralysis**

*Periodic paralysis* encompasses a rare group of muscle diseases characterized by episodes of flaccid weakness. Most are hereditary (autosomal dominant) and caused by calcium or sodium channel abnormalities (pore gating anomalies) because of specific genetic mutations. In normal skeletal muscle, the cellular inflow and outflow of potassium are balanced to maintain the cell’s resting potential. Sodium
channels, in response to nerve stimulation, create the action potentials that initiate muscle contraction. Calcium channels interact with ryanodine receptors to initiate fast muscle contraction. In susceptible individuals, some instigating factor (such as hyperthyroidism, strenuous exercise, or intake of a high carbohydrate meal) allows increased muscle uptake of potassium from the plasma. This results in slightly decreased plasma potassium levels but it triggers depolarization of the sarcolemma and allows more potassium to enter the cell, causing hypokalemia. Hypokalemic periodic paralysis also can be triggered by exposure to cold or by rest after strenuous exercise. During an attack of hypokalemic periodic paralysis, the resting muscle membrane potential both is unresponsive to neural stimuli and is reduced from −90 to −45 mV. This condition can last hours to days.

Thyrotoxic hypokalemic periodic paralysis (TPP) is caused by a potassium channelopathy that causes increased flow of potassium into the cell; it does not indicate a potassium deficiency. Most common in Asian males, TPP is increasingly being seen in all ethnic groups. Thyrotoxic hypokalemic periodic paralysis (TPP) is caused by a potassium channelopathy that causes increased flow of potassium into the cell; it does not indicate a potassium deficiency. Hypokalemic periodic paralysis also can be triggered by exposure to cold or by rest after strenuous exercise. During an attack of hypokalemic periodic paralysis, the resting muscle membrane potential both is unresponsive to neural stimuli and is reduced from −90 to −45 mV. This condition can last hours to days.

Thyrotoxic hypokalemic periodic paralysis (TPP) is caused by a potassium channelopathy that causes increased flow of potassium into the cell; it does not indicate a potassium deficiency. Most common in Asian males, TPP is increasingly being seen in all ethnic groups. The main consequence of increased concentration of intracellular potassium is depolarization of the muscle and resulting weakness. Prevention is aimed at correcting the hyperthyroidism. β-Adrenergic blockers, such as propranolol, are sometimes given until thyroid function is normal. Oral and intravenous administration of potassium can relieve acute hypokalemic attacks.

Hyperkalemic periodic paralysis is another genetic disorder and is characterized by episodes of flaccid paralysis. It can be activated by several factors, including pregnancy, alcohol, illness, certain medications, eating potassium-rich foods, exposure to cold, and rest after exercising. Although the most striking feature of the condition is flaccid paralysis, many individuals have myotonia present on examination. The sodium channel fails to completely inactivate, causing more sodium to enter the cell and forcing potassium into the extracellular space, thus blocking sodium channels from depolarizing. Though hyperkalemic PP episodes are typically of shorter duration than those in hypokalemic PP, there is often a lifelong trend to have increasing frequency of attacks. In addition, hyperkalemic PP can cause permanent muscle weakness. Respiratory insufficiency can be a life-threatening situation.

Preventive measures include avoiding alcohol and diet soda, potassium-rich foods, or activities that provoke symptoms. Maintaining adequate water intake, eating carbohydrate-rich foods, and keeping warm seem to help some individuals. In acute hyperkalemic periodic paralysis, inhaled albuterol or glucose/insulin therapy can reduce symptoms. Preventive medications include potassium-lowering agents, such as hydrochlorothiazide or mexiletine.
Metabolic Muscle Diseases

Disorders in muscle metabolism can be caused by endocrine abnormalities or diseases of energy metabolism, such as glycogen storage disease, enzyme deficiencies, and abnormalities in lipid metabolism and mitochondrial function. The term *metabolic myopathies* refers to a group of hereditary muscle disorders caused by defective genes.

Endocrine Disorders

Often the systemic effects of hormonal imbalance overshadow the individual's muscular symptoms. For example, individuals with thyrotoxicosis may have signs of proximal weakness, paresis of the extraocular muscles (exophthalmic ophthalmoplegia), and, rarely, hypokalemic periodic paralysis. Hypothyroidism is often associated with a decrease in muscle mass and strength, with weak, flabby skeletal muscles and sluggish movements.

Thyroid hormone is believed to regulate muscle protein synthesis and electrolyte balance. Alterations in muscle protein synthesis and electrolyte balance may therefore explain the changes in muscle mass and contractility seen in endocrine disorders. The muscular symptoms subside with appropriate treatment of the primary hormonal disorder.

Diseases of Energy Metabolism

Muscles rely on carbohydrates (such as glycogen) and lipids (free fatty acids) for energy. When stored glycogen or lipids cannot be metabolized because of lack of enzymes necessary to generate ATP for muscle contraction, the individual experiences cramps, fatigue, and exercise intolerance. Disorders of muscle metabolism can be self-limiting, such as McArdle disease and some lipid disorders, or they can cause widespread irreversible muscle destruction, as in acid maltase deficiency.

McArdle disease.

**McArdle disease (MD),** or myophosphorylase deficiency, is also known as glycogen storage disease type V. It was the first myopathy in which a single enzyme defect was identified. It is now one of nine diseases identified to date that have in common an underlying defect in glycogen synthesis, glycogenolysis, or glycolysis. These diseases are often referred to as *glycogen storage diseases (GSDs)* because each defect results in the abnormal deposition and accumulation of glycogen in skeletal muscle. Individuals with McArdle disease lack muscle phosphorylase, an
enzyme responsible for the breakdown of glycogen in muscle. Normally, after the body uses the short-term ATP and phosphocreatine stores, intramuscular lactic acid accumulated as glycogen is used (see Chapter 18). The individual with McArdle disease is not able to metabolize glycogen or produce lactic acid.

The altered energy production manifests itself in exercise intolerance, fatigue, and painful muscle cramps. When exercise is carried to an extreme, painful muscle contracture and myoglobinuria can develop. Some individuals describe a “second wind” phenomenon, in which exercise tolerance increases if they slow their pace once the initial sensation of fatigue commences. The muscles of persons with McArdle disease are able to readily utilize glucose and lactate from the bloodstream. After it is converted to pyruvate, lactate has been shown to be an energy substrate that is oxidized more quickly than either fructose or glucose. Higher levels of lactate found in skeletal muscles of those with MD may account for this “second wind.” As the disease progresses, some individuals have pronounced muscle weakness and wasting. Other organs are not involved, because the absence of phosphorylase is limited to muscle. In general, individuals with McArdle disease learn to adapt their daily routine to avoid muscle symptoms.

**Acid maltase deficiency.**

Acid maltase deficiency (glycogen storage disease type II or Pompe disease) is an autosomal recessive neuromuscular disease because of mutations of the acidic α-glucosidase (GAA) gene. This results in an accumulation of glycogen in the lysosomes of muscle cells and other tissues because of the lack of the enzyme acid maltase (also known as acid α-glucosidase). The exact mechanism of disease progression is still unknown, but mitochondrial dysfunction and abnormal autophagy of cells appear to play a major role in the disease’s clinical manifestations.

The infantile form, which is more severe, is called Pompe disease (PD) and is recognized shortly after birth by hypotonia, dysreflexia, and an enlarged heart, tongue, and liver. Hypertrophy of these tissues is thought to be the result of glycogen deposition. Muscle biopsy is an important diagnostic tool in identifying PD. In the past, children died of cardiac or respiratory failure within 1 year of diagnosis, but new treatments have improved survival. Late-onset Pompe disease (LOPD) occurs from childhood into adulthood. Muscular symptoms of LOPD are highly variable and can range from muscle cramping and weakness to varying degrees of respiratory insufficiency. The mainstay of treatment is enzyme replacement therapy with recombinant GAA but dietary modifications also may improve the course of the disease.
Myoadenylate deaminase deficiency.

An enzyme deficiency that produces changes in skeletal muscle and is associated with exercise intolerance is **myoadenylate deaminase deficiency (MDD)**. More often referred to as adenosine monophosphate deaminase deficiency (AMDD), this autosomal recessive condition has a wide variation in symptoms. Because these individuals lack myoadenylate deaminase, they have a poor capacity for sustained energy production, yet some with the condition have been able to perform as high-level athletes. The most common symptoms appear to be postexercise muscle cramping or pain, or both, and easy fatigability. Myoadenylate deaminase is the catalytic enzyme that forms phosphocreatine and ATP during exercise through a metabolic pathway that binds the purine and phosphate molecules that constitute ATP. Persons with MDD differ from those with McArdle disease in that, during the ischemic exercise test, lactate production is normal in MDD when ATP and phosphocreatine are synthesized. The enzyme defect has been reported to be quite common, but in practice it may be rarely recognized as a cause of exercise intolerance.

Lipid deficiencies.

Disorders of lipid metabolism are uncommon but account for severe changes in muscle metabolism. These disorders are caused by abnormalities in the transport and processing of fatty acids for energy. The lipid content of muscle cells consists of free fatty acids, which are oxidized in the mitochondria. These acids require carnitine and the enzyme carnitine palmitoyltransferase (CPT) to transport long-chain fatty acids to the mitochondria. There are two types of CPT: CPT1 is found in liver, muscle, and brain tissue; only deficiencies of the liver type have been found in humans. Children younger than 18 months are most often affected. CPT2 deficiency, most often seen in adolescents or young adults, is an autosomal recessive disorder that invariably causes attacks of severe myalgia and may cause myoglobinuria. Carnitine deficiency causes abnormal lipid deposition in skeletal muscles.

Measuring the CPT and carnitine content in muscle is essential to diagnosis. Cells in the muscle biopsy show vacuoles and lipid deposits. Treatments with riboflavin, medium-chain triglycerides, oral carnitine, prednisone, and propranolol have been beneficial to some individuals. Bezafibrate, a drug to lower lipid levels, also has shown promise in treating CPT2 deficiency.

Inflammatory Muscle Diseases: Myositis

Viral, Bacterial, and Parasitic Myositis
Viral, bacterial, and parasitic infections of varying severity are known to produce inflammatory changes in skeletal muscle, a group of conditions collectively described by the term myositis. In tuberculosis and sarcoidosis, chronic inflammatory changes and granulomata are found in muscle as well as in other affected tissues. In the parasitic infection trichinellosis, *Trichinella* larvae reside in infected meat (primarily pork, but wildlife and even horses can carry the microorganism), migrate to the intestinal mucosa after ingestion, and then travel through the circulatory system to various tissues. The larvae that penetrate into skeletal muscle are able to survive and grow, causing symptoms such as severe pain, rash, and muscle stiffness. Treatment includes the administration of corticosteroids, immunotherapeutic agents, and the antiparasitic agent thiabendazole. Toxoplasmosis, a common parasitic infection, is also associated with a generalized polymyositis that responds rapidly to therapy.

In the tropics, more prevalent disorders include bacterial infections with *Staphylococcus aureus* and parasites such as cysticercus, the larva of the tapeworm *Taenia solium*. Viral infections can be associated with an acute myositis. Muscle pain, tenderness, signs of inflammation, and creatine kinase (CK) elevation are common manifestations of viral myositis. The self-limiting symptoms of muscle aches and pains during a bout of influenza may actually be a subacute form of viral myopathy.

**Polymyositis, Dermatomyositis, and Inclusion Body Myositis**

*Idiopathic inflammatory myopathies (IIMs)* are a group of autoimmune diseases that target skeletal muscle in both children and adults. There are generally four diseases included in this group: dermatomyositis (DM), polymyositis (PM), necrotizing myopathy (NM), and sporadic inclusion body myositis (IBM). The most common form, DM, has been further subclassified into additional subgroups, including the juvenile form—juvenile dermatomyositis (JDM). The exact cause of IIM is unknown, but recent investigations have uncovered strong links between genetic, environmental, and immunologic factors.\(^{258,259}\) Though still relatively rare, IIMs seem to have a geographic distribution, with greater incidence in Northern latitudes, further supporting the hypotheses of genetic and environmental influences in their development.\(^{260,261}\) The pathophysiology of IIMs remains fully unknown, but it involves interplay between specific autoantibodies, cytokine-mediated inflammation of muscle, and genetic factors.\(^{262,263}\)

Several characteristics differentiate IBM from the other IIMs in that IBM affects men more often than women and can cause asymmetric weakness. Compared with DM and PM, IBM does not respond as well to anti-inflammatory and
immunosuppressive medications.

**Clinical manifestations**

IIMs are characterized by progressive, symmetric proximal (shoulder girdle and quadriceps) muscle weakness and myalgia that develops over weeks to months. Because of their progressive nature, these illnesses can be initially confused with other myopathies. A thorough evaluation is required to exclude other disorders. Clinical features common in both PM and DM are joint pain, dysphagia, reduced esophageal motility, vasculitis, Raynaud phenomenon, cardiomyopathy, and interstitial pulmonary fibrosis. Reduced mobility with frequent falls is a common symptom in IBM because both proximal and distal muscles are affected. Some individuals have other coexisting collagen vascular disorders, such as rheumatoid arthritis, systemic lupus erythematosus, and progressive systemic sclerosis (formerly called *scleroderma*).

Although PM and DM have similar histories of onset, DM includes cutaneous manifestations. The presence of skin involvement is significant in that it can precede muscle involvement by months or even years. The two most classic signs of skin involvement are (1) rashes—a typical heliotrope (reddish purple) rash that generally covers the eyelids and periorbital tissue (*Figure 39-25*); and (2) erythematous, scaly lesions that cover joints such as the knees and elbows, known as Gottron lesions. Other differences between PM and DM include their suspected pathology. PM may be caused by T-cell invasion of the muscle fibers. DM, PM, and NM are associated with an increased risk of malignancy. Both PM and DM seem to respond to prednisone, with or without the addition of immunosuppressives as well as intravenous immunoglobulin administration.
Inclusion body myositis (IBM) is the most common acquired muscle disease affecting individuals older than age 50. IBM differs from both PM and DM in several important ways. Muscle biopsy and histopathologic studies of IBM show degenerative changes of muscle, accumulation of multiple proteins within muscle fibers, and evidence of endoplasmic reticular stress with misfolding of proteins. Clinical presentation may show earlier onset of asymmetric atrophy and weakness of the quadriceps as well as the wrists and finger flexors. Additionally, IBM generally does not improve with standard immunosuppressants or immune-modifying drugs.

**Evaluation and treatment**

Muscle biopsy results are striking in DM, with most individuals showing inflammatory cells grouped around blood vessels and atrophy of cells in muscle fascicles. This change, perifascicular atrophy, is absent in PM. Creatinine kinase (CK) level is often extremely elevated in both disorders and is a helpful indicator of disease activity. Levels of other muscle enzymes, including aldolase, aspartate aminotransferase (AST), alanine aminotransferase (AST), and lactate dehydrogenase (LDH), are also found to be elevated in most individuals. The presence of serum antinuclear antibodies (ANAs) also may be helpful in diagnosis. Muscle biopsy is indispensable for a diagnosis of PM or DM as opposed to other myotonic disease. MRI reveals inflammation and edema of the muscles, as well as changes in muscles that may not show clinical evidence of disease. Contrast-
Enhanced ultrasound can differentiate between IBM and myositis. Electromyography (EMG) is useful in guiding the site for muscle biopsy. Treatment primarily includes immunosuppressive drugs, although they are not always successful, particularly in the case of IBM. Most clinicians choose corticosteroids initially, usually prednisone on a daily or alternating day schedule, tapering the dosage as the symptoms subside. Successful treatment with azathioprine, methotrexate, creatine, and cyclosporine also has been reported. High-dose intravenous immunoglobulin administration is sometimes used during active disease. Individuals with muscle weakness require careful physiotherapy to design a regular exercise program that prevents contractures and maximizes functional ability.

**Toxic Myopathies**

Muscle damage caused by drugs or toxins is also called toxic myopathy. Alcohol, lipid-lowering agents (fibrates and statins), antimalarial drugs, steroids, thiol derivatives, and narcotics (particularly heroin) can all cause symptoms. Many drugs, diseases, and infectious and environmental agents can cause myopathy. The combination of certain medications can also cause muscle injury. Box 39-5 lists some of the causes of toxic myopathy.

**Box 39-5**

**Agents That Can Cause Toxic Myopathy**

**Drug-Induced**

- Alcohol
- Amiodarone (and others that inhibit CYP3A4 when combined with a statin)
- Amphotericin B
- Azathioprine
- Chloroquine
- Clofibrate
- Cocaine
Colchicine
Diuretics
Ethanol
Finasteride
Illicit drugs and drugs of abuse (heroin, cocaine, amphetamine, meperidine, pentazocine)
Ipecac (withdrawn from U.S. markets)
Isotretinoin
Labetalol
3,4-Methylenedioxymethamphetamine (MDMA, “ecstasy”)
Omeprazole
Pentachlorophenol (PCP)
Propofol
Retrovirals (AZT [zidovudine])
Statins
Steroids (especially with prolonged high doses; doses >25 mg/day; fluorinated steroids)
Vincristine

**Endocrine Disorders**

Adrenal disorders (Addison disease, Cushing disease)

Hyperparathyroidism

Hyperthyroidism (CK may be normal)
Hypothyroidism (CK may be mildly elevated)

**Infectious Agents**

Coxsackie A and B viruses

Human immunodeficiency virus (HIV)

Influenza

Lyme disease

*Staphylococcus aureus* muscle infection (frequent cause of pyomyositis)

Toxoplasmosis

Trichinosis

**Miscellaneous**

Licorice

Certain edible wild mushrooms

Lead poisoning

Malignant hyperthermia

Organophosphates

Red yeast rice

Snake venom

European migratory quail (quail eat toxic hemlock, hellebore seeds)

Any medication that alters serum concentrations of sodium, potassium, calcium, phosphorus, or magnesium

Alcohol remains the most common cause of toxic myopathy. Two clinical syndromes are prevalent: (1) an acute attack of muscle weakness, pain, and swelling after a drinking binge; or (2) a more chronic, progressive proximal weakness in a long-term drinker. The incidence of acute alcoholic myopathy has been estimated as being up to 20% of individuals admitted with acute alcoholic withdrawal.

The pathologic abnormalities include necrosis of individual muscle fibers; whole segments can be found in the same stage of degeneration. The mechanism by which alcohol affects the muscle fiber is uncertain, but a direct toxic effect and nutritional deficiency have both received experimental support.

Acute alcoholic myopathy can range from benign cramps and pain resolving in a matter of hours to severe weakness and markedly increased CK level associated with myoglobinuria and renal failure. Individuals are prone to repeated attacks following recovery. The only treatment is abstinence from alcohol and improved nutrition. The individual with chronic alcoholic myopathy often has coexisting peripheral neuropathy that complicates the diagnosis.

The most severe complication of toxic myopathy is rhabdomyolysis (acute muscle fiber necrosis with leakage of muscle protein into the bloodstream) that leads to myoglobinuria and acute renal failure. Most individuals with toxic myopathy present with acute muscle weakness. Pain is an unreliable indicator because many toxic myopathies are painless, but necrotizing toxic myopathies can cause severe pain. Dark-colored urine may indicate rhabdomyolysis, a serious complication that can lead to death (see p. 997). Other serious complications can include involvement of respiratory and cardiac muscles.

Measurement of serum creatine levels is helpful in determining muscle damage. Other tests such as electromyography (EMG) may show characteristic changes in function. Magnetic resonance imaging (MRI) can demonstrate muscle edema. Features of myopathy can be seen on muscle biopsy.

Repeated intramuscular injections have also been associated with changes in muscle fibers. Local necrosis of muscle fibers and elevated CK level have been reported after intramuscular injections of cephalothin, lidocaine, diazepam, and digoxin; these effects were not produced with injections of saline. When drugs are injected over long periods, a chronic focal myopathy develops. Proliferation of connective tissue in both the muscle fiber and the overlying skin and subcutaneous tissue has been reported. Over time, segments of the muscles, particularly the deltoid and quadriceps, are converted into fibrotic bands. Pathophysiologic mechanisms for these changes include repeated needle trauma and infection, along with the nonphysiologic acidity or alkalinity of the injected material.

Treatment primarily consists of removing or stopping the offending agent and providing supportive care. Supportive care may include hemodialysis and
respiratory or cardiovascular support, depending on severity of symptoms.

Musculoskeletal Tumors

Many different types of tumors involve the skeleton. Although the skeleton is the major site for metastatic spread of multiple myeloma and breast, lung, and prostate cancers, primary bone tumors are relatively rare. **Bone tumors** may originate from bone cells, cartilage, fibrous tissue, marrow, or vascular tissue. Based on the tissue of origin, bone tumors are classified as osteogenic, chondrogenic, collagenic, or myelogenic. **Box 39-6** contains the classification of primary bone tumors. Each of the types arises from one of the four stem cells that are ultimately derived from the primitive mesoderm (Figure 39-26). In addition, bone tumors may be classified as being of histiocytic, notochordal, lipogenic, or neurogenic origin.

The mesoderm contributes the primitive fibroblast and reticulum cells. The fibroblast is the progenitor of the osteoblast and chondroblast cells. Each cell synthesizes a specific type of intercellular ground substance, and the type of ground substance produced by the cell generally characterizes the tumor derived from that cell. For example, osteogenic tumors usually contain cells that have the appearance of osteoblasts and produce an intercellular substance that can be recognized as osteoid. Chondrogenic tumors contain chondroblasts and produce an intercellular substance similar to chondroid (cartilage). Collagenic tumors contain fibrous tissue cells and produce an intercellular substance similar to the type of collagen found in fibrous connective tissue.

Tumors are also classified as benign or malignant, based on characteristics of the tumor cells (see Chapter 10). The criteria used to identify tumor cells as malignant are (1) an increased nuclear/cytoplasmic ratio, (2) an irregular nuclear border, (3) an excess of chromatin, (4) a prominent nucleolus, and (5) an increase in the number of cells undergoing mitosis. However, many young, rapidly growing normal cells and cells subjected to inflammation and change in their blood supply also exhibit many of these same characteristics. (Tumor characteristics in general are described in Chapter 10.)

**Epidemiology**

The incidence rate of bone tumors varies with age. In children younger than 15
years, the rate of bone tumors is relatively low, constituting approximately 5% of all malignancies. Adolescents have the highest incidence of bone tumors, and adults between the ages of 30 and 35 have the lowest incidence. After age 35 years, the incidence rate slowly increases until at age 60 years it nearly equals the incidence rate in adolescents, primarily related to secondary metastatic tumors.

**Patterns of Bone Destruction**

The general pathologic features of bone tumors include bone destruction, erosion or expansion of the cortex, and periosteal response to changes in underlying bone. The least amount of pathologic damage occurs with benign bone tumors, which push against neighboring tissue. Because they usually have a symmetric, controlled growth pattern, benign bone tumors tend to compress and displace neighboring normal bone tissue, which weakens the bone's structure until it is incapable of withstanding the stress of ordinary use, leading to pathologic fracture. Other tumors invade and destroy adjacent normal bone tissue by producing substances that promote resorption by increasing osteoclast activity or by interfering with a bone's blood supply. Three patterns of bone destruction by bone tumors have been identified: (1) the geographic pattern, (2) the moth-eaten pattern, and (3) the permeative pattern (Table 39-7).

Tumors that erode the cortex of the bone usually stimulate a periosteal response—that is, new bone formation at the interface between the surface of the bone and the periosteum. Slow erosion of the cortex usually stimulates a uniform periosteal response. Additional layers of bone are added to the exterior surface of the bone to buttress the cortex. Eventually, the additional layers expand the bone's contour. Aggressive penetration of the cortex, often seen with malignant tumors, usually elevates the periosteum and stimulates erratic patterns of new bone formation.
Examples of erratic patterns include concentric layers of new bone; a sunburst pattern, in which delicate rays of new bone radiate toward the periosteum from a single focus on the underlying surface; and rays of new bone that grow perpendicularly, creating a brush or bristle pattern.

**Evaluation**

A malignant bone tumor must be identified early to allow survival of the individual and preservation of the affected limb. However, individuals often have only vague symptoms that may be attributed to minor trauma, degenerative changes, or inflammatory conditions. In addition, other conditions may obscure the diagnosis.

Thorough diagnostic studies are needed to determine the exact type and extent of bone tumor present, which also helps determine the optimal treatment regimen. Serum alkaline phosphatase levels are elevated in bone lytic tumors and significantly elevated in osteosarcoma. Radiologic studies, including plain radiographic films, radionucleotide bone scans, CT scan, MRI, and positron emission tomography combined with CT (PET/CT), are used to evaluate bone lesions. MRI and PET/CT have become the examination of choice for the local staging of bone tumors, especially the staging of peripheral osteosarcomas (Table 39-8). MRI and PET/CT are used to monitor the response of osteosarcomas to radiation or chemotherapy and to detect recurrent disease. A PET/CT, particularly when augmented by injection of the radioisotope fluorodeoxyglucose (FDG), provides earlier, more detailed information on tumor location, differentiation, metastases, and response to therapy than other imaging modalities.276 (Tumor staging is discussed in Chapter 10.)

Additional diagnostic studies done for specific bone tumors include a complete blood count and erythrocyte sedimentation rate (to rule out infection or myeloma) and measurement of serum levels of calcium and phosphorus to detect
hypercalcemia. Serum glucose levels may be elevated in chondrosarcoma. Bone-specific alkaline phosphatase is elevated when there is bone metastasis.\textsuperscript{277} Acid phosphatase level may be moderately elevated in bone metastases, multiple myeloma, and advanced Paget disease. Serum protein electrophoresis and immunoelectrophoresis are performed to exclude other diseases. To determine the exact tumor type, core needle biopsy is usually done at the time of surgery.\textsuperscript{278}

**Types**

A large number of lesions are classified as bone tumors. Bone tumors are typically classified according to their origin—osteogenic, chondrogenic, collagenic, and myelogenic tumors. They are described in the following sections (Figure 39-27).

![Figure 39-27](image)

**Osteogenic tumors: osteosarcoma.**

**Osteogenic (bone-forming) tumors** are characterized by the formation of bone or osteoid tissue with a sarcomatous tissue. The tissue can have the appearance of callus or compact or spongy bone. The most common malignant bone-forming tumor is the **osteosarcoma.**

The incidence of osteosarcomas, the most commonly diagnosed primary bone tumor, peaks around the second decade, with a slight preference for males.\textsuperscript{279,280} Sixty percent of osteosarcomas occur in persons younger than 20 years. A secondary peak incidence for osteosarcoma occurs in the 50- to 60-year age group,
primarily in individuals with a history of radiation therapy several years previously for pelvic or other malignancies or for Paget disease of bone. Though considered a bone-forming tumor because of formation of immature osteoid that shows a “lace-like” pattern of bone growth, the radiologic appearance of sarcoma is quite variable and often shows a moth-eaten (lytic) pattern of destruction with the tumor extending into the adjacent soft tissue. Occasionally, the tumor may spread to nonadjacent bone or across a joint with normal-appearing areas of bone between tumors (i.e., “skip lesions”). Radionuclide bone scans are used to find skip lesions. MRI and PET/CT are useful in determining bony changes associated with the tumor.

The borders of the tumor are indistinct and merge into adjacent normal bone. Osteosarcomas contain osteoid produced by anaplastic stromal cells, which are atypical, abnormal cells not seen in normal developing bone; they are neither normal nor embryonal. Many tumors are heterogeneous; for example, the osteosarcoma also may contain chondroid (cartilage) and fibrinoid tissue that may form the bulk of the tumor. The osteoid is deposited as thick masses or “streamers,” which infiltrate the normal compact bone, destroy it, and replace it with masses of osteoid. Bone tissue produced by osteosarcomas never matures to compact bone.

Ninety percent of osteosarcomas are located in the metaphyses of long bones, especially the distal femoral metaphysis, with 50% around the knee area. The tumor typically impregnates the cortex, lifts the periosteum, and forms a soft tissue mass that is not covered by a smooth shell of new bone. Lifting of the periosteum stimulates bizarre patterns of new bone formation called a periosteal reaction. Distinct osteosarcomas occur on the surface of long bones, called parosteal, periosteal, and high-grade surface osteosarcomas; dedifferentiated parosteal and central osteosarcomas also occur.

The most common initial symptoms are pain and an enlarging mass. Initially, the pain is slight and intermittent, but within a short time the pain increases in severity and duration. Pain is usually worse at night and gradually requires medication. Systemic symptoms are uncommon. Often, a coincidental history of trauma is noted. Occasionally, the individual may present with a pathologic fracture.

Bone biopsy is critical to diagnosis. Because the most frequent site of metastasis is the lung, a chest CT or MRI of the thorax also should be performed. There are no specific laboratory tests that aid in diagnosing sarcoma but laboratory studies are helpful in assessing overall health before beginning treatment. Once osteosarcoma has been diagnosed, measuring serum alkaline phosphatase and LDH levels can be useful in following response to treatment. The best clinical outcomes occur in those who receive both preoperative and postoperative chemotherapy in addition to surgery. Surgery is directed at salvaging the affected limb.

Surgery is the major treatment of choice, with the tumor's location and size, the
extent of malignancy, and evidence of metastasis dictating the type and extent of surgery (see Table 39-8). Preoperative chemotherapy has greatly increased the number of individuals qualifying for limb salvage surgery. Limb-salvaging procedures have been made possible by advances in reconstructive techniques and endoprosthetics. If an amputation is done, individuals are monitored closely with chest radiographs and CT. Pulmonary metastases are surgically resected, and chemotherapy is now a common therapy given both before and after surgery, using combinations of chemotherapeutic agents. Despite advances in chemotherapy and surgical techniques, overall long-term survival in osteosarcoma with metastases has not significantly improved in the past 30 to 40 years. Osteosarcomas are very difficult to treat with current chemotherapeutic agents.287,288

Other sarcomas include Ewing sarcoma and synovial sarcoma, each of which demonstrates specific genetic alterations.289,290 Others include rhabdomyosarcoma (a soft tissue sarcoma that likely originates in the skeleton but with features more like skeletal muscle) and sarcomas that have no definite morphologic pattern, such as leiomyosarcoma and pleomorphic liposarcoma.

**Chondrogenic tumors: chondrosarcoma.**

Chondrogenic (cartilage-forming) tumors produce cartilage or chondroid, a primitive cartilage or cartilage-like substance. The most common chondrogenic tumor is chondrosarcoma.

**Chondrosarcoma** is the second most common primary malignant bone tumor291 and is a tumor of middle-aged and older adults. Chondrosarcomas that develop from a preexisting benign bone lesion (such as an enchondroma) are known as secondary chondrosarcomas. Individuals with certain conditions, such as multiple osteochondromas, may be at greater risk for developing secondary chondrosarcoma. Secondary chondrosarcomas are rare, occurring most often in young adults between 20 and 30 years of age. The tumor is more common in men than in women.

A chondrosarcoma is a large, cartilage-producing, ill-defined malignant tumor that infiltrates trabeculae in spongy bone. It occurs most often in the metaphysis or diaphysis of long bones, especially the femur or proximal humerus, and in the bones of the pelvis.292 If located near the end of the bone, the tumor will infiltrate into the joint space. The tumor expands and enlarges the contour of the bone, causes extensive erosion of the cortex, and grows into the soft tissues.

Symptoms associated with a chondrosarcoma have an insidious onset. Local swelling and pain are the usual presenting symptoms. At first the pain is dull and intermittent, then gradually intensifies and becomes constant; it may awaken the
person at night.

Diagnostic studies include radiographs, which must be reviewed carefully for an accurate diagnosis. MRI is useful in determining the extent of soft tissue involvement.\textsuperscript{293,294} Biopsy is done at the time of surgery. (If biopsy is conducted before scheduled surgical incision, seeding of tumor cells could occur.) Sufficient tumor material must be obtained to facilitate an accurate diagnosis.

Surgical excision is generally regarded as the treatment of choice because chemotherapy is generally ineffective.\textsuperscript{291} Tumors more centrally located (in the appendicular skeleton) are more likely to metastasize. Consequently, individuals with tumors located in the limbs may have a better prognosis than those with pelvic lesions. Recent advances in understanding the pathophysiology of bone sarcomas has led to development of targeted therapies that show promise for improving outcomes.\textsuperscript{295,296}

\textbf{Collagenic tumors: fibrosarcoma.}

\textbf{Collagenic (collagen-forming) tumors} originate from mesenchymal cells and produce fibrous connective tissue. Fibrosarcoma is the most common collagenic tumor and can affect bone or soft tissue.

Fibrosarcomas represent 4\% of the primary malignant bone tumors, with a broad age distribution. They may occur at any age but are most common in adults between 30 and 50 years of age. The incidence is slightly greater in females. Fibrosarcoma also may be a secondary complication of radiation therapy, Paget disease, and long-standing osteomyelitis.

\textbf{Fibrosarcoma} is a rare, malignant, solitary tumor that most often affects the metaphyseal region of the femur or tibia. The tumor is composed of a firm, fibrous mass of tissue that contains collagen, malignant fibroblasts, and occasional osteoclast-like giant cells. Secondary fibrosarcoma, which tends to have a worse prognosis, can occur after prior radiation to an area.

The tumor begins in the marrow cavity of the bone and infiltrates the trabeculae. It demonstrates a permeative growth pattern, destroys the cortex, and extends into the soft tissue. Metastasis to the lung is common.

Symptoms associated with the tumor have an insidious onset, which delays diagnosis. Pain and swelling are the usual presenting symptoms and usually indicate that the tumor has infiltrated the cortex. Local tenderness, a palpable mass, and limitation of motion also may be present. A pathologic fracture in the affected bone is often the reason for seeking medical help. Diagnostic studies include radiographs and MRI.

Radical surgery and amputation are the treatments of choice for fibrosarcoma.
There is a high probability of metastases. Radiation therapy is generally considered ineffective treatment for this tumor. Promising investigations of matrix metalloproteinase inhibitors and even injectable compounds may alter future treatment of fibrosarcoma.²⁹⁷,²⁹⁸

**Giant cell tumor.**

Giant cell tumor, along with myeloma (see Chapter 21), are myelogenic tumors, ones that originate from various bone marrow cells. Giant cell tumor (GCT) is the sixth most common of the primary bone tumors, accounting for 4% to 5% of bone tumors. It is generally benign but can become malignant after radiation treatment. Giant cell tumors have a wide age distribution; however, they are rare in persons younger than 10 years or older than 70 years. Most giant cell tumors are found in persons between 20 and 40 years of age. Unlike most other bone tumors, giant cell tumors affect females more often than males.

The giant cell tumor is a solitary, circumscribed tumor that causes extensive bone resorption because of its osteoclastic origin and RANKL overexpression.²⁹⁹ GCTs are typically located in the epiphyseal regions of the femur, tibia, radius, or humerus.³⁰⁰ The tumor has a slow, relentless growth rate and is usually contained within the original contour of the affected bone. It may, however, extend into the articular cartilage. When the tumor extends, it is usually covered by periosteum or periosteal bone growth; it may extend into surrounding soft tissue. GCTs have a low rate of metastasis to other organs or tissues, although they have a high rate of recurrence.

The most common symptoms associated with GCT are pain, local swelling, and limitation of movement. Diagnostic studies include radiographs, CT, and MRI. Cryosurgery and resection of the tumor with the use of adjuvant polymethylmethacrylate (PMMA) for bone grafts decrease recurrence and are more successful treatments than curettage and radiation.²⁹⁹ The monoclonal antibody denosumab has been approved for treating GCTs in cases of recurrence or where surgery is not feasible.³⁰¹,³⁰² Depending on the extent of the tumor and its recurrence, amputation may be necessary.

**Muscle Tumors**

**Rhabdomyoma**

Rhabdomyoma is an extremely rare benign tumor of muscle that generally occurs in the tongue, neck muscles, larynx, uvula, nasal cavity, axilla, vulva, and heart. These tumors are usually treated by surgical excision and typically do not recur.
**Rhabdomyosarcoma**

About 3% to 5% of childhood cancers are malignant tumors of striated muscle called **rhabdomyosarcoma**. Infants, children, and teenagers account for more than 85% of cases; there is a slight preference in males. This tumor is highly malignant with rapid metastasis. Rhabdomyosarcomas are located in the muscle tissue of the head, neck, and genitourinary tract in 75% of cases, with the remainder found in the trunk and extremities. Recent animal studies have established a link between chemical, biologic, and physical triggers of rhabdomyosarcoma.\(^{303}\) Recent advances in treatment have improved the 5-year survival for children to greater than 80% in cases of localized tumors.\(^{304}\) Unfortunately, survival in adults remains poor.

Three types of rhabdomyosarcoma are differentiated on pathologic section: anaplastic (formerly known as pleomorphic), embryonal, and alveolar. Each type differs from the other molecularly; they are all aggressive tumors and are typically more resistant to therapy. Although rare, the anaplastic, or spindle cell, type is considered to be one of the most highly malignant tumors of the extremities seen in adulthood. Microscopically, embryonal tumors resemble a tadpole or tennis racquet and are most often seen in infancy and childhood. Alveolar-type tumors appear lattice-like, similar to lung tissue alveoli, and are more often found in adolescents and adults.

The diagnosis of rhabdomyosarcoma is made by careful incisional biopsy or core needle aspiration and examination of the specimen by a pathologist. CT scan also helps define the tissue borders. PET/CT is useful in identifying involvement of bones, lymph nodes, and bone marrow. Staging is based on the tumor's size, location, presence of metastases, and lymph node involvement. Pathologic grading of the tumor is helpful in determining prognosis and treatment.

Treatment consists of a combination of surgical excision, systemic chemotherapy, and radiation therapy. Cure is unlikely when distant metastases are present.

**Other Tumors**

Metastatic tumors in muscles are rare in spite of the extensive vascular supply of skeletal muscles. It is suggested that local pH or metabolic changes within muscles prevent metastatic involvement from other tumors. When adjacent carcinomas do cause muscle damage, it is usually related to the compression of tissue and resultant muscle atrophy.

[Quick Check 39-5]
1. From what cells do bone tumors originate?

2. Compare five major characteristics of benign bone tumors with those of malignant bone tumors.

3. How does the presence of metastatic tumors affect treatment options and prognosis of persons with osteosarcoma?
Did You Understand?

Musculoskeletal Injuries

1. The most serious musculoskeletal injury is a fracture. A bone can be completely or incompletely fractured. A closed fracture leaves the skin intact. An open fracture has an overlying skin wound. The direction of the fracture line can be linear, oblique, spiral, or transverse. Greenstick, torus, and bowing fractures are examples of incomplete fractures that occur in children. Stress fractures occur in normal or abnormal bone that is subjected to repeated stress. Fatigue fractures occur in normal bone subjected to abnormal stress. Normal weightbearing can cause an insufficiency (or fragility) fracture in abnormal bone.

2. Dislocation is complete loss of contact between the articular surfaces of two bones. Subluxation is partial loss of joint contact between two bones. As a bone separates from a joint, it may damage adjacent nerves, blood vessels, ligaments, tendons, and muscle.

3. Tendon tears are called strains, and ligament tears are called sprains. A complete separation of a tendon or ligament from its attachment is called an avulsion.

4. Rhabdomyolysis, often manifested by the presence of myoglobinuria, can be a life-threatening complication of severe muscle trauma, genetic predisposition, or toxic effects of certain medications.

Disorders of Bones

1. Metabolic bone diseases are characterized by abnormal bone structure. In osteoporosis, the density or mass of bone is reduced because the bone remodeling cycle is disrupted. Osteomalacia is a metabolic bone disease characterized by inadequate bone mineralization. Excessive and abnormal bone remodeling occurs in Paget disease.

2. Osteomyelitis is a bone infection caused most often by bacteria. Bacteria can enter bone from outside the body (exogenous osteomyelitis) or from infection sites within the body (hematogenous osteomyelitis).

Disorders of Joints
1. Because of improved imaging technology, inflammation has been identified as an important feature of osteoarthritis.

2. Osteoarthritis (OA) is a common, age-related disorder of synovial joints. The primary defect in OA is loss of articular cartilage.

3. Rheumatoid arthritis is an inflammatory joint disease characterized by inflammatory destruction of the synovial membrane, articular cartilage, joint capsule, and surrounding ligaments and tendons. Rheumatoid nodules also may invade the skin, lung, and spleen and involve small and large arteries. Rheumatoid arthritis is a systemic disease that affects the heart, lungs, kidneys, and skin, as well as the joints.

4. Ankylosing spondylitis is a chronic, systemic autoimmune disease characterized by stiffening and fusion of the sacroiliac and spine joints.

5. Gout is a syndrome caused by defects in uric acid metabolism with high levels of uric acid in the blood and body fluids. Uric acid crystallizes in the connective tissue of a joint where it initiates inflammatory destruction of the joint.

**Disorders of Skeletal Muscle**

1. A pathologic contracture is permanent muscle shortening caused by muscle spasticity, as seen in central nervous system (CNS) injury or severe muscle weakness.

2. Stress-induced muscle tension is presumably caused by increased activity in the reticular activating system and gamma loop in the muscle fiber. The use of progressive relaxation training and biofeedback has been advocated to reduce muscle tension.

3. Fibromyalgia is a chronic musculoskeletal syndrome characterized by diffuse pain and tender points. Theories have proposed that the muscle is the end organ responsible for the pain and fatigue, although this has not been confirmed. Most cases of FM involve women, and the peak age is 30 to 50 years. Genetic factors are being increasingly recognized as agents in developing fibromyalgia.

4. Atrophy of muscle fibers and overall diminished size of the muscle are seen after prolonged inactivity. Isometric contractions and passive lengthening exercises decrease atrophy to some degree in immobilized persons.
5. Because of ion channel disorders, hyperexcitable membranes cause the physical and electrical phenomenon of myotonia. The disorder is treated with drugs that reduce muscle fiber excitability. The biochemical defect is related to changes in the muscle membrane and sarcoplasmic reticulum.

6. Metabolic muscle diseases are caused by endocrine disorders, glycogen storage diseases, enzyme deficiencies, and abnormal lipid function. The muscle depends on a complex system of carbohydrates and fats converted by enzymes to produce energy for the muscle cell. Abnormalities in these pathways can inhibit function or cause damage to the muscle fiber. These illnesses are rare, yet they account for significant functional abnormalities.

7. Viral, bacterial, and parasitic infections of muscles produce the characteristic clinical and pathologic changes associated with inflammation. These are usually treatable and self-limiting disorders.

8. Polymyositis (generalized muscle inflammation) and dermatomyositis (polymyositis accompanied by skin rash) are characterized by inflammation of connective tissue and muscle fibers and muscle fiber necrosis. Cell-mediated and humoral immune factors have been implicated. Treatment with immunosuppressive agents is effective in many cases.

9. The most common cause of toxic myopathy is alcohol abuse. It has been suggested that alcohol use affects muscle fibers both directly (by causing necrosis) and indirectly (by the concomitant nutritional deficiencies typically associated with excessive use of alcohol). Drug administration can also lead to toxic myopathy; a needle used during an injection, secondary infection, and alterations in the acidity and alkalinity of muscle fibers can mechanically damage muscle fibers.

**Musculoskeletal Tumors**

1. Sarcomas of muscle tissue are rare. Rhabdomyosarcoma has a uniformly poor prognosis, particularly in adults, because of an aggressive invasion and early, widespread dissemination. The usual treatment includes surgical excision, radiation therapy, and systemic chemotherapy.

2. Bone tumors originate from bone cells, cartilage cells, fibrous tissue cells, or vascular marrow cells. Each cell produces a specific type of ground substance that is used to classify the tumor as osteogenic (bone cell), chondrogenic (cartilage
cell), collagenic (fibrous tissue cell), or myelogenic (vascular marrow cell). Malignant bone tumors are usually large, aggressively destroy surrounding bone, invade surrounding tissue, and initiate independent growth outside the site of origin. Benign bone tumors are generally less destructive, limit their growth to the anatomic confines of the bone, and have a well-demarcated border. Certain benign tumors can become malignant.

Musculoskeletal Tumors, 1048
Musculoskeletal problems in children can be either congenital or acquired. Both pathology and treatment can cause long-term sequelae because of the growing nature of the immature skeleton. In addition, the emotional trauma of an injured or malformed child is substantial and requires that careful attention be paid to the emotional health of both the child and his or her family.
Congenital Defects

Clubfoot

*Clubfoot* describes a range of foot deformities in which the foot turns inward and downward. It can affect one or both feet. Technically called *congenital equinovarus* (Table 40-1), the heel is positioned varus (inwardly deviated) and equinus (plantar flexed) (Figures 40-1 and 40-2). The clubfoot deformity can be positional (correctable passively), idiopathic, or teratologic (as a result of another syndrome, such as spina bifida). The idiopathic clubfoot occurs in 1 per 1000 live births, with males twice as likely as females to be affected.

**NOTE:** The positions listed can all be achieved by voluntary movement of the normal foot; an abnormality exists if the foot is fixed in one or more of the positions while at rest.
FIGURE 40-1  A, Infant with Bilateral Congenital Talipes Equinovarus. B, Ponseti Casting. (A courtesy Dr. A.E. Chudley, Section of Genetics and Metabolism, Department of Pediatrics and Child Health, Children's Hospital and University of Manitoba, Winnipeg, Manitoba, Canada. In Moore KL et al, editors: The developing human, ed 10, Philadelphia, 2016, Saunders.)
The clubfoot deformity can be corrected by an above-knee casting regimen popularized by Ponseti. In almost 90% of idiopathic and up to 70% of teratologic clubfeet, the Ponseti method of serial casting infants' feet is effective (see Figure 40-1, B). The hindfoot equinus portion of the deformity often requires lengthening of the Achilles tendon, which can be performed in a clinic with the use of a local anesthetic. Achilles tenotomy (complete transection of the tendon) can be safely performed with local anesthetic until 8 or 9 months after birth. After this age, a formal lengthening and repair procedure using a general anesthetic is required. Bracing is required until age 3. Idiopathic feet resistant to these procedures require repeat casting or, in very rare cases, a surgical posteromedial release (PMR). The posteromedial release includes lengthening of the Achilles, posterior tibialis, and flexor tendons, and surgical release of the capsules of the ankle, subtalar, and midfoot joints. Teratologic clubfeet require surgical intervention more often than idiopathic clubfeet (see Figure 40-1, B) and more prolonged bracing, often through childhood. The Ponseti technique has revolutionized clubfoot treatment around the world. The ability to correct such a crippling deformity without the need for surgery has helped countless children.

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) describes imperfect development of the
hip joint and can affect the femur, the acetabulum, or both (Figure 40-3). Although most often present congenitally, dysplasia may develop later in the newborn or infant period. Like clubfoot, DDH can be idiopathic or teratologic. Teratologic hips (i.e., those attributable to another disorder such as cerebral palsy, spina bifida, or arthrogryposis) are more difficult to treat and often need operative intervention. In idiopathic DDH, 70% of cases involve the left side only and 10% to 15% are bilateral. Girls are four times as likely as boys to be affected. Positive family history, breech presentation, and oligohydramnios (low levels of intrauterine fluid) all predispose children to DDH. Children in these groups are considered high risk and must be carefully evaluated with physical examination and, possibly, ultrasound. Variants of idiopathic DDH are dislocated hip (no contact between the femoral head and acetabulum), subluxated hip (partial contact only), and acetabular dysplasia (the femoral head is located properly but the acetabulum is shallow). Idiopathic instability of the hip ranges from 3 to 7 per 1000 live births, but a true dislocation is present in only 1 of 1000 live births.

FIGURE 40-3 Hip Dysplasia in Children. Development dysplasia of the hip (DDH) with residual acetabular dysplasia. Radiographs at birth, 3, 10, and 19 years (top to bottom) show persisting dysplasia.

Clinical examination is the mainstay of diagnosis. The examination must be
performed on a relaxed infant for accuracy. Absolute indications for treatment include a positive Barlow sign (hip reduced, but dislocatable) (Figure 40-4, A) or positive Ortolani sign (hip dislocated, but reducible) (Figure 40-4, B). Other indicators for further evaluation are limitation of abduction or apparent shortening of the femur (Galeazzi sign). Asymmetric skin folds at the groin also can be a clinical sign of hip pathology.

In children younger than 4 months old, bracing with a Pavlik harness is successful in 90% of DDH cases. A Barlow positive hip (hip reduced, but dislocatable) is easier to treat with a Pavlik harness, and success rates approach 95% to 98% (Figure 40-5). An Ortolani positive hip (hip dislocated, but reducible) must be followed closely with ultrasound and exam; the success rate with Pavlik harness is 70% in this situation. If a stable reduction is not attained within 2 to 3 weeks of treatment, the Pavlik harness should be abandoned and casting or surgery pursued instead. A partially reduced hip applies pressure on the rim of the acetabulum by the femoral head and can worsen dysplasia and make treatment more difficult. In older
children (6 to 12 months), or those who failed bracing with a Pavlik harness, closed reduction of the hip and spica (body) casting performed using a general anesthetic are required. The spica cast is worn for 3 months. Children older than 12 months require surgery on the joint, the femur, or the acetabulum, or all three (see Figure 40-3). The incidence of good or excellent outcome falls to only 20% by age 4, underscoring the need for early diagnosis and treatment.⁵
Osteogenesis Imperfecta

Osteogenesis imperfecta (OI; brittle bone disease) is a spectrum of disease caused by genetic mutation in the gene that encodes for type I collagen, the main component of bone and blood vessels. The Sillence classification defines six types. Types I and IV are milder forms and are inherited in an autosomal dominant pattern. Types II and III are more severe and are inherited in a recessive pattern. Types V and
VI are very rare and are autosomal recessive. Children with type II often die during infancy because of extreme bone fragility.

The classic clinical manifestations of osteogenesis imperfecta (OI) are osteopenia (decreased bone mass) and an increased rate of fractures. Children can also have fatigue, pain, hearing loss, and abnormal dentition. With recurrent fractures, bone deformity (bowing) often occurs. In type III OI, the most severe form compatible with life, children have short stature and triangular faces, possibly blue sclerae, and poor dentition. Because type I collagen also is the main component of blood vessels, vascular deformity, such as aortic aneurysm, can occur. Type IV OI can be subtle with the child presenting with more normal stature and with fractures often not occurring until the child is older; it can be misdiagnosed as child abuse. Analysis of skin fibroblasts is diagnostic in 85% of children with OI.

Treatment is a combination of medical and surgical approaches (Figure 40-6). For fractures and deformity, intramedullary rodding of the long bones improves position and also splints new fractures. Telescoping rods, which grow with the child, are improving in efficacy. Unfortunately, these children may have to undergo multiple surgeries and re-roddings with growth. The medical treatment, classically involving calcium and vitamin D supplementation, is under intense study. Pamidronate and other bisphosphates, such as alendronate (Fosamax), which decrease bone resorption by inhibiting osteoclasts, are now frequently used. In a multicenter trial, pamidronate was given at 2- to 4-month intervals to children with severe (type III) and mild (type IV) OI. In the 30 children in the study, bone mineral density increased by 41.9%, fractures decreased by 1.7% per year, and mobility increased in 51% of the children. All children claimed their fatigue and chronic bone pain improved. A Cochrane review, however, states it is unclear whether oral or intravenous bisphosphonate treatment consistently decreases fractures and no studies report an increased fracture rate with treatment. Further long term studies are needed. Fracture healing remained unchanged. A large multicenter study is now trying to refine these treatments for all children with OI.
FIGURE 40-6  Osteogenesis Imperfecta Treated with Osteotomies and Telescoping Medullary Rods. A, Severe deformity of both femurs. B, Same individual after multiple osteotomies with telescoping medullary rod fixation. C, Same individual 4 years later demonstrating growth of femurs, no recurrence of deformity, and elongation of rods. (Plaster casts are in place for immobilization of tibial osteotomies.) (From Crenshaw AH, editor: Campbell’s operative orthopaedics, ed 8, vol 3, St Louis, 1992, Mosby)
Bone Infection

Osteomyelitis

Osteomyelitis, or bone infection, is caused by either bacterial or granulomatous (e.g., tuberculosis) infective processes (Box 40-1, Figures 40-7 and 40-8). Antibiotic drugs and often surgical interventions are used to treat these infections. Morbidity and mortality resulting from osteomyelitis declined drastically until the 1980s. Unfortunately, with the escalation of methicillin-resistant *Staphylococcus aureus* (MRSA) infections, serious increases in morbidity and mortality have developed.

*Neisseria gonorrhoeae*
Adolescents and Adults

Pseudomonas

Mycobacterium tuberculosis

FIGURE 40-7  Pathogenesis of Acute Osteomyelitis Differs with Age. A, In infants younger than 1 year the epiphysis is nourished by arteries penetrating through the physis, allowing development of the condition within the epiphysis. B, In children up to 15 years of age, the infection is restricted to below the physis because of interruption of the vessels.
**Acute hematogenous osteomyelitis** is the most common form in children. The infection usually begins as an abscess in the metaphysis of a long bone where blood flow is sluggish and bacteria can collect. With increasing pressure, the infection will rupture out of the periosteum and spread along the diaphysis of the bone. A new shell of bone can develop under the elevated periosteum and can become an **involucrum**. The portion of bone that is separated from adequate blood supply by the infection can die, thereby leading to an involucrum. All three of these changes are apparent on radiograph and signify the need for surgical débridement as well as antibiotic treatment.

These radiographic bone changes take 2 to 3 weeks to develop. Initially, osteomyelitis presents as pain, swelling, and warmth. Children often will have fever, decreased appetite, fatigue, elevated white blood cell (WBC) count (50% to 70%), elevated C-reactive protein (CRP) (98%) level, and elevated erythrocyte sedimentation rate (ESR) (90%). Blood culture is positive in only 40% to 60% of cases. Without changes on plain radiograph, magnetic resonance imaging (MRI) can help define the location and extent of the infectious process. In infants, where osteomyelitis can be multifocal in up to 40% of cases, bone scan identifies other locations of infection that may need surgical intervention.

Treatment of osteomyelitis consists of appropriate antibiotic management for 6 weeks. If blood cultures are negative, bone aspirate must be analyzed to determine the bacterial source of the infection. With MRSA or bone changes on MRI, surgical débridement is required. MRSA often leads to more systemic illness, such as endocarditis (infection of the heart valves), organ failure, and infected thrombotic events.
Septic Arthritis

**Septic arthritis** is a bacterial or granulomatous infection of the joint space. This is always a surgical emergency. The bacteria, and the lysosomes created by white blood cells fighting the bacteria, can quickly destroy the articular cartilage of the joint and affect the blood supply to the epiphyseal bone nearby. Both of these complications have poor outcomes and can lead to a lifetime of disability.

Septic arthritis can occur primarily or secondary to osteomyelitis that spreads from the metaphysis of the bone into the joint space. The metaphyses of the pediatric hip, shoulder, proximal radius, and distal lateral tibia are all located within the joint capsule, and therefore osteomyelitis in these regions must be carefully monitored for secondary septic arthritis. The most common sites for septic arthritis are knees, hips, ankles, and elbows.

Children with septic arthritis present with severe joint pain, “pseudoparalysis” or marked guarding to motion of the joint, inability to bear weight, and malaise, often with anorexia. Children appear quite ill with this diagnosis. Nonpyogenic arthritis, such as juvenile idiopathic arthritis, can be difficult to distinguish clinically from septic arthritis because both can lead to malaise and elevated ESR. The Kocher criteria are often used to distinguish septic joints from joint pain of another cause. There is a greater than 90% chance of a septic joint if three of the five following criteria are met\(^9,10\):

1. WBC >12,000 cells/µL
2. Inability to bear weight on the joint
3. Fever >101.3°F (38.5°C)
4. ESR >40 mm/hr
5. CRP >2 mg/dl

Fever and CRP level >2 mg/dl appear to have the most influence in the differential diagnosis.

Blood cultures are positive in 30% to 40% of cases. Joint aspirate positive for a white blood cell (WBC) count of greater than 7000 per high-power field (HPF) defines the diagnosis, and culture of this fluid often determines bacterial etiology. As in osteomyelitis, *Staphylococcus aureus* is the most common bacteria; however, MRSA is now present in up to 30% of affected children.\(^8,8A\) Emerging is the understanding that *Kingella kingae* is an important pathogen, occurs in children
between 6 months and 4 years of age, and can involve many joints and bone, less frequently the endocardium and other locations.\textsuperscript{BA}

After surgical débridement of the joint, antibiotics are required for 2 to 3 weeks. Long-term follow-up to assess articular or physeal damage is required.
**Juvenile Idiopathic Arthritis**

*Juvenile idiopathic arthritis (JIA)* is the childhood form of rheumatoid arthritis (see Chapter 39) and accounts for 5% of all cases of rheumatoid arthritis. Juvenile idiopathic arthritis has three distinct modes of onset: *oligoarthritis* (fewer than three joints), *polyarthritis* (more than three joints), and *Still disease* (severe systemic onset) (Table 40-2). JIA differs from rheumatoid arthritis in several ways:

1. Large joints are most commonly affected.

2. Chronic uveitis (inflammation of the anterior chamber of the eye) is common if the blood test for antinuclear antibody (ANA) is positive; slit lamp examination by a trained ophthalmologist is required every 6 months to avoid vision loss.

3. Serum tests may be negative for rheumatoid factor (RF); RF-positive children have a worse prognosis.

4. Subluxation and ankylosis may occur in the cervical spine if disease progresses.

5. Rheumatoid arthritis that continues through adolescence can have severe effects on growth and adult morbidity.

ANA, Antinuclear antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; HLA, human leukocyte antigen; JIA, juvenile idiopathic arthritis; RF, rheumatoid factor.

Many children with oligoarthritis who are “seronegative” (blood tests negative for RF or ANA) will resolve their symptoms over time. Systemic onset, or “seropositivity,” of the disease is more likely consistent with lifelong arthritis. Therefore, treatment is supportive, not curative. Nonsteroidal anti-inflammatory drugs are a mainstay of treatment, and methotrexate is also being used with success. The goals are to minimize inflammation and deformity.

Quick Check 40-1

1. Why is an early diagnosis of developmental dysplasia of the hip imperative?
2. How does osteomyelitis develop?
3. How does juvenile idiopathic arthritis differ from the adult form?
4. How has MRSA changed musculoskeletal infections in children?
Osteochondroses

The osteochondroses are a series of childhood diseases involving areas of significant tensile or compressive stress (e.g., tibial tubercle, Achilles insertion, hip epiphysis). The pathophysiology is partial loss of blood supply, death of bone (osseous necrosis), progressive bony weakness, and then microfracture. The cause of the decreased blood supply is controversial; trauma, a change in clotting sensitivity, vascular injury, genetic predisposition, or a combination of these factors is presently considered most likely. Additionally, during the years of rapid bone growth, blood supply to the growing ends of bones (epiphyses) may become insufficient, resulting in necrotic bone, usually near joints. Because bone is normally undergoing a continuous rebuilding process, the necrotic areas can self-repair over a period of weeks or months.

Use of anti-inflammatory medications, modification of activities, immobilization, and rest are recommended during active stages of the disease. Reparative correction by revascularization is the rule, although years may be required for full healing, and deformity from compression during the period of osseous necrosis can persist.

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes (LCP) disease is a common osteochondrosis usually occurring in children between the ages of 3 and 10 years, with a peak incidence at 6 years. The disorder is bilateral in 10% to 20% of children, and boys are affected five times more often than girls. Boys have a more poorly developed blood supply to the femoral head than do girls of the same age, and this is thought to be the reason for male predilection. The role of genetics is unclear, but LCP is more common in northern European and Japanese children and rare in black children; family history is positive in 20% of cases. This self-limited disease of the hip, which runs its natural course in 2 to 5 years, is presumably created by recurrent interruption of the blood supply to the femoral head. The ossification center first becomes necrotic (osteonecrosis) and then is gradually replaced by live bone.

Pathophysiology

Several causative theories have been proposed, including a generalized disorder of epiphyseal cartilage growth, thyroid hormone deficiency, trauma, infection, and blood clotting disorders. However, a Harvard study did not show increases in thrombotic disorders in consecutive children with LCP. Boys with a hypercoagulable state are three times more likely to acquire LCP than girls with the same disorder. Another study has shown the risk of LCP is five times greater in
children exposed to passive smoke as opposed to children living in a smoke-free environment. Increased risk has been associated with smoke from indoor use of a wood stove.

In the first stage of LCP, the soft tissues of the hip (synovial membrane and joint capsule) are swollen, edematous, and hyperemic, often with fluid present in the joint (Figure 40-9). In the second necrotic stage, the anterior 50% or more of the epiphysis of the femoral head dies because of a lack of blood supply, and the metaphyseal bone at the junction of the femoral neck and capital epiphyseal plate is softened because of increased blood supply and decalcification. Granulation tissue (procallus) and blood vessels then invade the dead bone. The third, or regenerative healing, stage ordinarily lasts 2 to 4 years. The dead bone in the femoral head is replaced by procallus, and new bone is established (see Figure 40-9). In the fourth, or residual, stage, remodeling takes place and the newly formed bone is organized into a live spongy bone.

**Clinical manifestations**

Injury or trauma precedes the onset of LCP in approximately 30% to 50% of children with Legg-Calvé-Perthes disease. For several months the child complains of a limp and pain that can be referred to the knee, inner thigh, and the groin, following the path of the obturator nerve. The pain is usually aggravated by activity and relieved by rest and administration of anti-inflammatory medications.

The typical physical findings include spasm on rotation of the hip, limitation of internal rotation and abduction, and hip flexion–adduction deformity. If the child is walking, an early abnormal gait termed an antalgic (painful) abductor lurch, or a “Trendelenburg gait” (gluteus medius gait pattern), is apparent. If the hip pain or limp has been present for a prolonged period, muscles of the hip and thigh atrophy.

**Evaluation and treatment**
The goals of treatment are to preserve normal congruity of the femoral head and acetabulum and maintain spasm-free and pain-free range of motion in the hip joint. Currently, most children can be managed with anti-inflammatory medications and activity modification during periods of synovitis. Serial radiographs are obtained to monitor the progress of the disease and to ensure that the femoral head remains congruent in the acetabulum. Surgery may be necessary if the femoral head becomes subluxated or incongruent with the acetabulum (Figure 40-10).\textsuperscript{14-16}

Children older than age 6 (by bone age) have a worse prognosis attributable to poorer remodeling potential. Older children require surgery more often to avoid poor congruence of the hip. Poor congruence predisposes to early osteoarthritis, with nearly 50% requiring hip replacement surgery by age 40.
FIGURE 40-10 Pelvis of a 7-Year-Old Boy with Legg-Calvé-Perthes Disease. A, The femoral head is flat and extruded from the edge of the joint. This hip is at risk for early arthritis if left to revascularize and heal in this position. B, Surgical replacement of the femoral head. As the Perthes heals, the ball has assumed a round shape that matches the socket well.

Osgood-Schlatter Disease
Osgood-Schlatter disease consists of osteochondrosis of the tibia tubercle and associated patellar tendonitis. Osgood-Schlatter disease occurs most often in preadolescents and adolescents who participate in sports and is more prevalent in boys than in girls. Osgood-Schlatter disease is one of the most common ailments reported in the 30 million children who are involved in sports.\(^\text{17}\)

The severity of the lesion varies from mild tendonitis to a complete separation of the anterior tibial apophysis, a part of the tibial tubercle. The mildest form of Osgood-Schlatter disease causes ischemic (avascular) necrosis in the region of the bony tibial tubercle, with hypertrophic cartilage formation during the stages of repair. In more severe cases, the abnormality involves a true apophyseal separation of the tibial tubercle with avascular necrosis.

The child complains of pain and swelling in the region around the patellar tendon and tibial tubercle, which becomes prominent and is tender to direct pressure. The pain is most severe after physical activity that involves vigorous quadriceps contraction (jumping or running) or direct local trauma to the tibial tubercle area.

The goal of treatment for Osgood-Schlatter disease is to decrease the stress at the tubercle. Often a period of 4 to 8 weeks of restriction from strenuous physical activity, administration of anti-inflammatory medications, and stretching of the quadriceps muscle are sufficient. Bracing with a tubercle band can be very helpful. If the pain is not relieved, a cast or knee immobilizer is required, a situation that is particularly difficult if the condition is bilateral.

Gradual resumption of activity is permitted after 8 weeks, but return to unrestricted athletic participation requires an additional 8 weeks to allow for revascularization, healing, and ossification of the tibial tubercle.\(^\text{14,18}\) With skeletal maturity and closure of the apophysis, Osgood-Schlatter disease resolves.

**Sever Disease**

Sever disease is the “Osgood-Schlatter” of the calcaneus (heel bone). The insertion of the Achilles pulls on the cartilaginous apophysis of the calcaneus, causing pain. It is more common in athletic children and children who have underlying Achilles tendon tightness, for example, soccer players between the ages of 8 and 12. It is relieved by a heel lift in the shoe, rest, stretching, and anti-inflammatory medications.
Scoliosis

Scoliosis is a rotational curvature of the spine most obvious in the anteroposterior plane (Figure 40-11). It can be classified as nonstructural or structural. **Nonstructural scoliosis** results from a cause other than the spine itself, such as posture, leg length discrepancy, or splinting from pain. **Structural scoliosis** is a curvature of the spine associated with vertebral rotation. Nonstructural scoliosis can become structural if the underlying cause is not found and treated.

There are three main types of structural scoliosis: idiopathic; congenital (attributable to bony deformity such as hemivertebrae); and teratologic (caused by another systemic syndrome such as cerebral palsy). Eighty percent of all scoliosis is idiopathic, which may have a genetic component. Although girls and boys are equally affected, once the curve becomes more than 20 degrees, girls are five times more likely to be affected. Ninety-eight percent of curves are apex right thoracic. If a left thoracic curve appears in the adolescent with idiopathic scoliosis, MRI is performed to rule out a neurologic cause. MRI should be performed in scoliotic children with loss of abdominal reflexes and those who have exertional headaches or a congenital curve.18,19

Idiopathic curves progress while a child is growing, and progression can be very rapid during growth spurts. When idiopathic curves progress to 25 degrees or greater, and the child is skeletally immature, bracing is required. The total number
of hours a brace is worn correlates to efficacy of treatment; 82% of children who wore the brace as prescribed had minimal progression.\textsuperscript{20} In braced curves, 72% required no surgery compared with only 48% of those who wore no brace.\textsuperscript{21}

Curves of more than 50 degrees will progress after skeletal maturity, so spinal fusion is required to stop progression. Bracing is the only nonoperative measure known to slow scoliotic progression. Chiropractic manipulation, physical therapy, exercise, and diet regimens have not been shown to alter natural history. Bracing is less successful in teratologic or congenital curves; therefore, these conditions may require surgical intervention more often.
Muscular Dystrophy

The **muscular dystrophies** are a group of inherited disorders that cause progressive muscle fiber loss leading to weakness, mostly of the voluntary muscles. Some dystrophies cause disease in infancy, others in childhood, and others not until adulthood. Muscular dystrophies have different inheritance patterns and different biochemical alterations that cause each specific type. Three are discussed in detail in this chapter. Individuals with Duchenne muscular dystrophy (DMD) have a mutation in a specific gene that leads to alterations in the muscle protein dystrophin. Individuals with myotonic muscular dystrophy (MMD) have a genetic alteration that leads to systemic disease. Although there is no cure for any of the muscular dystrophies, aggressive preventive management has increased the life expectancy and quality of life of children with these disorders. Common forms of muscular dystrophy are described in Table 40-3.

Duchenne Muscular Dystrophy

**Pathophysiology**

**Duchenne muscular dystrophy (DMD)** is X-linked, generally occurring in boys, and is present in about 1 in 3500 male births. It is the most common childhood dystrophy. DMD is caused by mutations in the **dystrophin** gene, which lead to alterations or deletions of the muscle protein dystrophin.

The protein dystrophin mediates anchorage of the actin cytoskeleton of skeletal muscle fibers to the basement membrane through a membrane-glycoprotein complex. With lack of dystrophin, the poorly anchored fibers tear themselves apart under the repeated stress of contraction. Free calcium then enters the muscle cells, causing cell death and fiber necrosis (**Figure 40-12**).
Clinical manifestations

Boys with DMD will present in the preschool years with muscle weakness, difficulty walking, and large calves (pseudohypertrophy) caused by normal muscle fiber replacement with fat and connective tissue (see Figure 40-12, B and C). Although the calves are large the muscle is actually weak. Clinical weakness starts in the pelvic girdle, initially causing difficulty rising from the floor (Gower sign) and climbing stairs, and a waddling gait because of weakness in the lumbar and gluteal muscles. Boys with DMD often toe-walk because of weakness of the anterior tibial and peroneal muscles, causing the feet to assume a talipes equinovarus position. The weakness worsens over the subsequent few years, resulting in the loss of ability to ambulate by 8 to 13 years of age. Muscle weakness also leads to contractures of the knees, hips, and other joints, and scoliosis develops in most boys with DMD. Once scoliosis begins, it is relentlessly progressive. Curves of more than 20 degrees are treated surgically to maintain pulmonary function. Muscle weakness and inactivity, particularly once a person is in a wheelchair full time, lead to osteoporosis and pathologic fractures. If fracture occurs, bisphosphonates may be used to strengthen
bone, although long-term studies on safety have not been performed in this population.

As children age, muscle weakness progresses and respiratory weakness leads to breathing difficulty, particularly when sleeping. Susceptibility to respiratory tract infections and progressive deterioration of pulmonary function generally lead to premature death, usually in the twenties. Cardiomyopathy also may occur and, despite treatment, is generally progressive. Bowel and bladder functions are often mildly affected, with constipation and urinary urgency as frequent symptoms. Mild to moderate cognitive problems are common but not universal.

**Evaluation and treatment**

Diagnosis is suggested (a high creatine kinase [CK] level does not confirm the diagnosis because many other alterations can also increase CK) by measuring the blood creatine kinase level, which can be 100 times the normal level, with confirmation by genetic testing for mutations in the dystrophin gene.

Management involves maintaining function for as long as possible. Treatment with steroids can prolong the ability to walk by several years and improves life expectancy. Prednisone is used in the United States, although many families prefer to use deflazacort (however, it is not currently approved in the United States but is available from the internet), which is a steroid that may have fewer side effects than prednisone. Treatment also involves range-of-motion exercises, bracing, and surgical release of contracture deformities and scoliosis when necessary. Children with DMD require a multidisciplinary approach to care, including attention to heart and breathing problems, weight loss/gain, constipation, rehabilitative/developmental problems, psychosocial needs, and neurologic and orthopedic problems (Figure 40-13). New guidelines for the evaluation and treatment of Duchenne muscular dystrophy were developed after reviewing thousands of clinical scenarios and are presented as a multisystem, two-part approach. One part is for diagnosis and the other part for management.
If appropriate, families should receive genetic counseling for recurrence risk and prenatal screening. Family support is necessary throughout the life span of the child because needs vary depending on the stage of the disease.

**Becker Muscular Dystrophy**

Although **Becker muscular dystrophy (BMD)** has been designated historically as a separate muscular dystrophy, it is actually caused by alterations of the same dystrophin gene (i.e., dystrophinopathies) and protein as seen in DMD. Children with BMD present later and have a longer life expectancy than those with DMD; however, they are part of the same clinical spectrum.
Facioscapulohumeral Muscular Dystrophy

Facioscapulohumeral (FSH) muscular dystrophy, one of the most common muscular dystrophies, is inherited in an autosomal dominant fashion. It is more variable in presentation than Duchenne muscular dystrophy. FSH muscular dystrophy is usually observed in late childhood. Progression is usually slow and life span is normal or near normal. FSH muscular dystrophy occurs because of a deletion on chromosome 4 that is not associated with any particular gene and causes disease by still unknown mechanisms.

Muscle weakness, which is often asymmetric, usually begins in the face and is then observed in the shoulders and legs. Individuals with FSH muscular dystrophy often have weak eye closure, are not able to whistle or inflate a balloon, and have scapular winging.

Diagnosis is by genetic testing, although sometimes biopsies or electrodiagnostic testing may also be performed as part of the diagnostic evaluation. FSH muscular dystrophy also may be associated with mild hearing loss, retinal abnormalities, and mild cardiac problems. Unlike DMD or BMD, children with FSH muscular dystrophy often have muscle pain, particularly in their arms and shoulders.

Treatment involves administration of nonsteroidal anti-inflammatory drugs to decrease pain and inflammation. Massage and heat treatments also may be helpful. Bracing may be performed for function; for example, dorsiflexion of the feet with ankle-foot orthotics to prevent tripping or to provide support and comfort.

Myotonic Muscular Dystrophy

Pathophysiology

Myotonic muscular dystrophy (MMD) is a multisystem disease that can occur because of mutations in either of two genes resulting in type 1 (DMPK gene) and type 2 (CNBP gene) MMD. MMD1 may demonstrate a genetic mechanism called anticipation, in which children born to a mother with MMD usually have a more severe form of the disease.

Clinical manifestations

MMD affects the brain, skeletal and smooth muscles, the eyes, the heart, and the endocrine system, manifesting as distal muscle weakness, learning problems or intellectual disability, or both. Additionally, children can have dysphagia, constipation, cardiac dysrhythmias that if untreated may be life-threatening, diabetes, and cataracts. Boys with MMD also may manifest testicular atrophy and
early male pattern baldness. A hallmark of the disease is myotonia—individuals have difficulty relaxing muscles; for example, they may have difficulty relaxing their hand grip after a handshake or opening their eyes after closing them tightly. Children with mild disease do not develop symptoms until adolescence or older and may display mild muscle weakness (usually more pronounced in the distal muscles), cataracts, and myotonia, but have normal life spans. Children with a more classic form of the disease also have onset of symptoms in the teenage years but have progressive muscle weakness, cataracts, and cardiac conduction abnormalities; they may have a shortened life span and require a wheelchair for mobility. The congenital form, the most severe, may be present at birth or become obvious over the first few years of life.

**Evaluation and treatment**

Diagnosis is made by genetic testing for the two genes known to cause MMD. In each case, an abnormal segment of DNA, caused by an abnormally large trinucleotide, repeat expansion (CTG) in an untranslated region of a gene, causes abnormal functioning of muscle and other cells. Type 1 is more common and can present in infancy (the congenital form). Infants with MMD may have life-threatening breathing and swallowing problems and developmental delay or intellectual disability, although MMD is not observed until childhood or even adolescence.

Steroids are not useful for the treatment of MMD; however, maintaining muscle function is important, including range-of-motion exercises, bracing, and surgical release of contractures when necessary. Children need to be followed closely by neurologists and primary care providers with treatment for the various aspects of the disease, such as dysphagia, heart dysrhythmias, and constipation, as well as other problems.

**Quick Check 40-2**

1. What is the pathophysiology of osteochondrosis?
2. What is the cause of Duchenne muscular dystrophy?
3. Discuss the clinical manifestations of Duchenne muscular dystrophy.
4. Which dystrophy is really a systemic disease?
5. What is the difference between Becker and Duchenne muscular dystrophies?
Musculoskeletal Tumors

Benign Bone Tumors

The two most common forms of benign bone tumors are osteochondroma and nonossifying fibroma.

Osteochondroma

Osteochondroma (or exostosis) can occur as a solitary lesion or as an inherited syndrome of hereditary multiple exostoses (HME). HME is an autosomal dominant condition with exostoses occurring throughout the skeleton. Osteochondromas appear as bony protuberances because of \( \text{EXT1} \) and \( \text{EXT2} \) genetic anomalies near active growth plates of the proximal humerus, distal femur, or proximal tibia. The most common presentation is a palpable mass that is painful when traumatized. Rarely, the lesion can cause neurologic or vascular problems, or tendon rupture from local compression. The lesions can lead to growth disturbance and mildly short stature. Knee valgus (knock-knee), ankle valgus, and hip problems are common. Upper extremity lesions can lead to a pronounced deformity in the forearm with a very short ulna bone. These lesions grow until skeletal maturity; growth or pain after skeletal maturity is a sign of possible malignant transformation, especially in the pelvis or scapular region. Transformation to chondrosarcoma is very rare, occurring in less than 1% of children.

Treatment involves minimizing growth disturbance, local tissue compression, and pain by resection of symptomatic lesions. The regrowth rate is 30% when lesions are removed in early childhood; therefore only symptomatic lesions should be surgically addressed in the growing child.  

Nonossifying Fibroma

Of all benign bone tumors, 50% are nonossifying fibromas or fibrous cortical defects. Nonossifying fibromas are sharply demarcated, cortically based lesions of fibrocytes that have replaced normal bone. The lesion can occur in any bone, at any age. Nearly 30% of all children have at least one.

Microscopically, these benign nonmetastasizing lesions appear as whorled bundles of fibroblasts and osteoclast-like giant cells. As the tumor grows, lipids make the fibroblasts foamy in appearance, and they are known as foam cells.

Treatment is observational only. If these lesions grow too large, however, they will compromise the biomechanical strength of the bone and lead to pathologic fractures. Curettage and bone grafting is suggested after pathologic fracture or if impending fracture (nonossifying fibroma greater than 50% of the diameter of the
bone or greater than 3 or 4 cm) is noted radiographically.

**Malignant Bone Tumors**

*Malignant bone tumors* are uncommon tumors in childhood, accounting for fewer than 5% of childhood malignancies and occurring mostly during adolescence. The two main tumors are osteosarcoma and Ewing sarcoma.

**Osteosarcoma**

*Osteosarcoma* is the most common malignant bone tumor found during childhood and originates in bone-producing mesenchymal cells. Tumors can be broadly classified as those arising within the bone and those arising on the surface of bone. Approximately 75% of these tumors occur in persons between the ages of 10 and 25 years, with most being diagnosed between 15 and 19 years of age during the adolescent growth spurt. Incidence is the same for males and females.

Osteosarcoma may develop as a result of rapid local growth, which increases the likelihood of mutation. It can be induced by ionizing radiation, even with relatively low doses, and can be a tragic consequence of therapeutic radiation for other forms of cancer. The latent period after radiation exposure is 5 to 40 years. There also has been a link to individuals with retinoblastoma (a hereditary eye tumor).

Osteosarcoma has not been linked to chemical carcinogens or viruses. No deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) virus has been isolated.

Molecular analysis has demonstrated deletion of genetic material on the long arm of chromosome 13, which led to the identification of a tumor-suppressor gene as being part of the mechanism for tumor development. The oncogene *src* also has been associated with osteosarcoma.

**Pathophysiology**

Osteosarcoma occurs mainly in the metaphyses of long bones near sites of active physeal growth. The tumor most commonly occurs at the distal femur, proximal tibia, or proximal humerus. As a tumor of mesenchymal cells, osteosarcoma demonstrates production of osteoid cells.

Osteosarcoma is a bulky tumor that extends beyond the bone into a soft tissue mass. It may encircle the bone and destroy the trabeculae of the diseased area. Osteosarcoma disseminates through the bloodstream, usually to the lung. As many as 25% of children diagnosed with osteosarcoma exhibit lung metastases at diagnosis. Other sites of metastatic spread include other bones and visceral organs.

**Clinical manifestations**
The most common presenting complaint is pain. Night pain, awakening a child from sleep, is a particularly foreboding sign. There may be swelling, warmth, and redness caused by the vascularity of the tumor. Symptoms also may include cough, dyspnea, and chest pain if lung metastasis is present. If a lower extremity is involved, a child may limp or suffer a pathologic fracture. Although osteosarcoma is not the result of trauma, trauma may call attention to a preexisting tumor.

**Evaluation and treatment**

The five histologic types of osteosarcoma are determined by the predominant cell type. The tumor is graded according to degree of malignancy; the higher the grade, the worse the prognosis.

Surgery and chemotherapy are the primary treatments for osteosarcoma. The tumor is resistant to radiation. Traditionally, surgery includes amputation at the joint above the involved bone; however, more recent limb salvage procedures have gained acceptance, and amputation may be avoided in many children.

Chemotherapy is an important component of treatment. Children routinely receive chemotherapy preoperatively; then the disease is restaged with MRI and surgical biopsy to determine rate of “tumor kill.” If more than 90% of tumor cells are killed by chemotherapy, the prognosis is markedly improved. Chemotherapy is then used after surgery for any additional cell spill during surgery. The use of chemotherapy with surgery has increased the 5-year survival rate to 60% or more.24

A number of approaches have been used to treat pulmonary metastases. Because pulmonary metastases are generally solitary, thoracotomy with wedge resection has proven to be the most effective treatment.

**Ewing Sarcoma**

Ewing sarcoma is the second most common and most lethal malignant bone tumor that occurs during childhood. This tumor is named after James Ewing, who first identified it as a separate clinical diagnosis in 1921. The most common period of diagnosis is between 5 and 15 years of age; it is rare after age 30 years. Ewing sarcoma is slightly more common in males than females. Cytogenic studies have shown a translocation of chromosomes 11 and 22 resulting in a fusion protein (EWS-FLI 1) forming at the chromosomal junction.

**Pathophysiology**

Ewing sarcoma is most commonly located in the midshaft of long bones or in flat bones. The most common sites include the femur, pelvis, and humerus (Figure 40-14).
Arising from bone marrow, Ewing sarcoma can penetrate the cortex of the bone to form a soft tissue mass. Unlike osteosarcoma, Ewing sarcoma does not make bone and radiographically appears as a permeative, destructive lesion (Figure 40-15). Ewing sarcoma metastasizes to nearly every organ. Metastasis occurs early and is usually apparent at diagnosis or within 1 year. The most common sites are the lung, other bones, lymph nodes, bone marrow, liver, spleen, and central nervous system.
Clinical manifestations
As with osteosarcoma, the most common complaint is pain that increases in severity. A soft tissue mass is often present. Additional symptoms may include fever, malaise, and anorexia. The radiographic appearance is similar to that of osteomyelitis, and diagnosis is only confirmed with biopsy.

Evaluation and treatment
Evaluation is determined from genetic testing, elevated sedimentation rate, and lactic acid dehydrogenase (LDH) levels. Biopsy is used to conclusively establish the diagnosis of a small round cell tumor.

Treatment includes radiation, chemotherapy, and, if possible, surgical débridement. Chemotherapy is continued for 12 to 18 months after resection.
Present 5-year survival with this tritherapeutic approach is 60%; however, tumors of the pelvis have a markedly worse prognosis. Metastasis at diagnosis is another poor prognostic indicator, with 5-year survival rate dropping to less than 40%.

Quick Check 40-3

1. What are the most common benign bone tumors of children?
2. What are the two malignant bone tumors found in children?
3. What is the most lethal bone tumor in children?
Nonaccidental Trauma

It is estimated that more than 2.0 million children are abused per year in the United States. Maltreatment may be psychologic, sexual, or physical.25 Thirty percent of children who have been physically abused are seen by an orthopedist. Accurate and appropriate referrals to child protection agencies not only are legally mandated but also are essential for the well-being of the child. An abused child who is returned to the same situation without intervention has a 10% to 15% chance of subsequent mortality.

Fractures in Nonaccidental Trauma

Children who are not yet ambulatory and present with a long bone fracture have more than a 75% chance of that fracture being caused by nonaccidental trauma (NAT).26 “Corner” metaphyseal fractures are nearly always from abuse but occur only 25% of the time (Figure 40-16). Fractures at multiple stages of healing also suggest abuse; however, osteogenesis imperfecta or other causes of systemic osteomalacia must be ruled out. The most common presentation is a transverse tibia fracture. After walking age, only 2% of long bone fractures are the result of nonaccidental trauma.27
Evaluation

Nonaccidental trauma necessitates early consultation with child protective services. The child should undergo skeletal survey (especially if less than 2 years of age) and have a complete physical examination to evaluate for pattern bruising, burns, or multiple soft tissue injuries. A thorough history must be obtained for all identified injuries. It is important to remember that social isolation can lead to an increased likelihood of abuse, but no social status is immune. One study reported that racial differences may exist in the evaluation and reporting of nonaccidental trauma. Skeletal trauma is present in a significant number of abused children.28-30

When the cause of injury is unclear, bone scan can be helpful in diagnosing subtle injuries, especially rib fractures. Posterior rib fractures are especially likely to be the result of abuse. MRI/CT of the brain to check for subdural hematoma and retinal examination to look for hemorrhages are essential.

Treatment
The treating healthcare provider must have a nonjudgmental attitude. The child and family involved in nonaccidental trauma are emotionally delicate and require not only physical but also emotional care. Social workers need to be involved early to ensure that the child receives appropriate medical care. Fortunately, fractures tend to heal quickly for those in this age group. Neurologic injury and social disease, however, are much more difficult to cure.

Quick Check 40-4

1. Describe the incidence and types of child maltreatment or abuse.

2. What is the most common orthopedic injury in NAT?
Did You Understand?

Congenital Defects

1. Clubfoot is a common deformity in which the foot is twisted out of its normal shape or position. Clubfoot can be positional, idiopathic, or teratologic.

2. Developmental dysplasia of the hip (DDH) is an abnormality in the development of the femoral head, acetabulum, or both. Like clubfoot, DDH can be idiopathic or teratologic. It is a serious and disabling condition in children if not diagnosed and treated early, with best outcomes when treated before walking age.

3. Osteogenesis imperfecta (brittle bone disease) is an inherited disorder of collagen that affects primarily bones and results in serious fractures of many bones.

Bone Infection

1. Osteomyelitis is a local or generalized bacterial or granulomatous (e.g., tuberculosis) infection of bone and bone marrow. Bacteria are usually introduced by direct extension from a nearby infection, through the bloodstream, or by trauma.

2. Septic arthritis can occur de novo or secondary to osteomyelitis in very young children in which the metaphysis is still located within the joint capsule of certain joints.

Juvenile Idiopathic Arthritis

1. Juvenile idiopathic arthritis is an inflammatory joint disorder characterized by pain and swelling. Large joints are most commonly affected.

Osteochondroses

1. Avascular diseases of the bone are collectively referred to as osteochondroses and are caused by an insufficient blood supply to growing bones.

2. Legg-Calvé-Perthes disease is one of the most common osteochondroses. This disorder is characterized by epiphyseal necrosis or degeneration of the head of the femur followed by regeneration or recalcification. Children older than age 7 years
at onset have a worse prognosis.

3. Osgood-Schlatter disease is characterized by tendonitis of the anterior patellar tendon and inflammation or partial separation of the tibial tubercle caused by chronic irritation, usually as a result of overuse of the quadriceps muscles. The condition is seen primarily in muscular, athletic adolescent males.

**Scoliosis**

1. Scoliosis is a rotational curvature of the spine most obvious in the anteroposterior plane, and can be classified as nonstructural or structural. Nonstructural scoliosis results from a cause other than the spine itself, such as posture, leg length discrepancy, or splinting from pain. Structural scoliosis is a curvature of the spine associated with vertebral rotation.

**Muscular Dystrophy**

1. The muscular dystrophies are a group of genetically transmitted diseases characterized by progressive atrophy of skeletal muscles. There is an insidious loss of strength in all forms of the disorder with increasing disability and deformity. The most common type in childhood is Duchenne muscular dystrophy.

**Musculoskeletal Tumors**

1. The two most common forms of benign bone tumors are osteochondroma and nonossifying fibroma.

2. The two main types of malignant childhood bone tumors are osteosarcoma and Ewing sarcoma.

3. Osteosarcoma, the most common malignant childhood bone tumor, originates in bone-producing mesenchymal cells and is most often located near active growth plates, such as the distal femur, proximal tibia, or proximal humerus.

4. Most children with osteosarcoma are diagnosed between 15 and 19 years of age, and osteosarcoma occurs equally in males and females.

5. Ewing sarcoma originates from cells within the bone marrow space and is most
often located in the midshaft of long bones or in flat bones. The most common sites include the femur, pelvis, and humerus.

6. Ewing sarcoma is more common in males and is diagnosed most often between the ages of 5 and 15 years.

7. Pain is the usual presenting symptom for either osteosarcoma or Ewing sarcoma.

8. The primary treatments for osteosarcoma are surgery and chemotherapy. The primary treatment for Ewing sarcoma is a combination of chemotherapy, radiation, and surgery.

**Nonaccidental Trauma**

1. Nonaccidental trauma must be considered with any long bone injury in the preambulatory child.

2. The presence of soft tissue injury, corner fractures, and multiple fractures at different stages of healing is extremely helpful for making a diagnosis of nonaccidental trauma.

3. When nonaccidental trauma is suspected, a child must be evaluated radiographically for other fractures, heat trauma, and retinal hemorrhage.

4. All social strata are at risk.

5. The healthcare provider is legally responsible to report suspected nonaccidental trauma.

The skin covers the entire body and is the largest organ of the body, accounting for about 20% of body weight. Combined with the accessory structures of hair, nails, and glands, it forms the integumentary system. The skin's primary function is protection from the environment by serving as a barrier against microorganisms, ultraviolet radiation, loss of body fluids, and the stress of mechanical forces. The skin regulates body temperature and is involved in immune surveillance and the activation of vitamin D. Touch and pressure receptors provide important protective functions and pleasurable sensations. The commensal (normal) microorganisms of the skin protect against pathologic bacteria.
Structure and Function of the Skin

Layers of the Skin

The skin is formed of two major layers: (1) a superficial or outer layer of **epidermis** and (2) a deeper layer of **dermis** (the true skin) (**Figure 41-1**). The **subcutaneous layer (hypodermis)** is the lowest lying layer of connective tissue that contains macrophages, fibroblasts, fat cells, nerves, fine muscles, blood vessels, lymphatics, and hair follicle roots. Each skin layer contains cells that represent progressive stages of skin cell differentiation and function as the skin grows. These are summarized in **Table 41-1**.

### Dermal Appendages

The **dermal appendages** include the nails, hair, sebaceous glands, and the eccrine and apocrine sweat glands. The **nails** are protective keratinized plates that appear at the ends of fingers and toes. They have the following structures: (1) the proximal nail fold, (2) the eponychium (cuticle), (3) the matrix from which the nail grows and its nail root, (4) the hyponychium (nail bed), (5) the nail plate, and (6) the paronychium (lateral nail fold) (**Figure 41-2**). Nail growth continues throughout life at 1 mm or less per day.
Hair color, density, grain, and pattern of distribution vary considerably among people and depend on age, sex, and race. Hair follicles arise from the matrix (or bulb) located deep in the dermis. They extend from the dermis at an angle and have an erector pili muscle attached near the mid-dermis that straightens the follicle when contracted, causing the hair to stand up. Hair growth begins in the bulb, with cellular differentiation occurring as the hair progresses up the follicle. Hair is fully hardened, or cornified, by the time it emerges at the skin surface. Hair color is determined by melanin-secreting follicular melanocytes. Hair growth is cyclic, with periods of growth and rest that vary over different body surfaces.

The sebaceous glands open onto the surface of the skin through a canal. They are found in greatest numbers on the face, chest, and back, with modified glands on the eyelids, lips, nipples, glans penis, and prepuce. Sebaceous glands secrete sebum, composed primarily of lipids, which oils the skin and hair and prevents drying. Androgens stimulate the growth of sebaceous glands, and their enlargement is an early sign of puberty.

The eccrine sweat glands are distributed over the body, with the greatest numbers in the palms of the hands, soles of the feet, and forehead. They open onto the surface of the skin and are important in thermoregulation and cooling of the body through evaporation. The apocrine sweat glands are fewer in number but produce significantly more sweat than the eccrine glands. They are located near the bulb of hair follicles in the axillae, scalp, face, abdomen, and genital area. Their ducts open into the hair follicle. The interaction of sweat with commensal (normal) flora bacteria contributes to the odor of perspiration.
Blood Supply and Innervation

The blood supply to the skin is limited to the papillary capillaries, or plexus, of the dermis. These capillary loops are supplied by a deeper arterial plexus. Branches from the deep plexus also supply hair follicles and sweat glands. A subpapillary network of veins drains the capillary loops. Arteriovenous anastomoses in the dermis facilitate the regulation of body temperature. Heat loss is regulated by (1) variations in skin blood flow through the opening and closing of arteriovenous anastomoses and (2) the evaporative heat loss of sweat. The sympathetic nervous system regulates both vasoconstriction and vasodilation through α-adrenergic receptors in the skin. The lymphatic vessels of the skin arise in the papillary dermis and drain into larger subcutaneous trunks, removing cells, proteins, and immunologic mediators.

The structure and function of the skin change with advancing age. A summary of aging changes is included in the box titled Geriatric Considerations: Aging and Changes in Skin Integrity (p. 1079).

Quick Check 41-1

1. Describe the two layers of the skin.

2. How do the skin blood vessels and sweat glands regulate body temperature?

3. What are some changes that occur in skin with aging?

Clinical Manifestations of Skin Dysfunction

Lesions

Identification of the morphologic structure of the skin, including differentiation between primary and secondary lesions, and assessment of the appearance of the skin in combination with obtaining a health history are essential to identify underlying pathophysiology. Tables 41-2 and 41-3 describe and illustrate the basic lesions of the skin. Clinical manifestations of select skin lesions are described in Table 41-4.
**Macule**
A flat, circumscribed area that is a change in color of skin; less than 1 cm in diameter
Examples: Freckles, flat moles (nevi), petechiae, measles, scarlet fever

**Macules**

**Papule**
An elevated, firm, circumscribed area less than 1 cm in diameter
Examples: Wart (verruca), elevated moles, lichen planus, fibroma, insect bite

**Lichen planus**

**Patch**
A flat, nonpalpable, irregular-shaped macule more than 1 cm in diameter
Examples: Vitiligo, port-wine stains, mongolian spots, café au lait spots
**Vitiligo**

**Plaque**
Elevated, firm, and rough lesion with flat top surface greater than 1 cm in diameter
Examples: Psoriasis, seborrheic and actinic keratoses

**Wheal**
Elevated, irregular-shaped area of cutaneous edema; solid, transient; variable diameter
Examples: Insect bites, urticaria, allergic reaction
Wheal

Nodule
Elevated, firm, circumscribed lesion; deeper in dermis than a papule; 1-2 cm in diameter
Examples: Erythema nodosum, lipomas

Lipoma

Tumor
Elevated, solid lesion; may be clearly demarcated; deeper in dermis; more than 2 cm in diameter
Examples: Neoplasms, benign tumor, lipoma, neurofibroma, hemangioma
Neurofibroma

**Vesicle**
Elevated, circumscribed, superficial; does not extend into dermis; filled with serous fluid; less than 1 cm in diameter
Examples: Varicella (chickenpox), herpes zoster (shingles), herpes simplex

**Vesicles**

**Bulla**
Vesicle more than 1 cm in diameter
Examples: Blister, pemphigus vulgaris
Bulla

Pustule
Elevated, superficial lesion; similar to a vesicle but filled with purulent fluid
Examples: Impetigo, acne

Acne

Cyst
Elevated, circumscribed, encapsulated lesion; in dermis or subcutaneous layer; filled with liquid or semisolid material
Examples: Sebaceous cyst, cystic acne

Sebaceous cyst

Telangiectasia
Fine (0.5-1.0 mm), irregular red lines produced by capillary dilation; can be associated with acne rosacea (face), venous hypertension (spider veins in legs), systemic sclerosis, or developmental abnormalities (port-wine birthmarks)
Example: Telangiectasia in rosacea
### Telangiectasia

<td>flaking of skin following a drug reaction; dry skin</td>
</tr>
<tr>
<td>oily; variation in size</td>
<td></td>
</tr>
</tbody>
</table>
Fine scaling

**Lichenification**
Rough, thickened epidermis secondary to persistent rubbing, itching, or skin irritation; often involves flexor surface of extremity
Example: Chronic dermatitis

---

Atopic dermatitis of arm

**Keloid**
Irregular-shaped, elevated, progressively enlarging scar; grows beyond boundaries of wound; caused by excessive collagen formation during healing
Examples: Keloid formation following surgery
Scar
Thin to thick fibrous tissue that replaces normal skin following injury or laceration to the dermis
Examples: Healed wound or surgical incision

Hypertrophic scar
Excoriation
Loss of epidermis; linear, hollowed-out, crusted area
Examples: Abrasion or scratch, scabies

Scabies
**Fissure**
Linear crack or break from the epidermis to the dermis; may be moist or dry
Examples: Athlete’s foot, cracks at the corner of mouth, anal fissure, dermatitis

Fissures from infected dermatitis

**Erosion**
Loss of part of the epidermis; depressed, moist, glistening; follows rupture of a vesicle or bulla or chemical injury
Example: Chemical injury

Erosion on leg

**Ulcer**
Loss of epidermis and dermis; concave; varies in size
Examples: Pressure ulcer, stasis ulcers
Pressure ulcer on heel

**Atrophy**
Thinning of skin surface and loss of skin markings; skin appears translucent and paper-like
Examples: Aged skin, striae

_Aged skin*

Pressure ulcers.

Pressure ulcers are ischemic ulcers resulting from unrelieved pressure, shearing forces, friction, and moisture. The term decubitus ulcer refers to ulcers or pressure sores that develop when unrelieved pressure interrupts normal blood flow to the skin and its underlying tissues. The risks for pressure ulcers are summarized in Risk Factors: Pressure Ulcer.¹

Risk Factors

Pressure Ulcer

External Factors

• Prolonged pressure

• Immobilization

• Lying in bed or sitting in chair or wheelchair without changing position or relieving pressure over an extended period

• Lying for hours on hard x-ray, emergency department, and operating room tables

• Prolonged moisture exposure

• Neurologic disorders (coma, spinal cord injuries, cognitive impairment, or cerebrovascular disease)

• Fractures or contractures

• Debilitation: elderly persons in hospitals and nursing homes
• Pain
• Sedation
• Friction and shearing forces
• Coarse bed sheets used for turning by dragging, which produces friction and a shearing force
• Inadequate caretaking staff
• Lack of communication/education regarding pressure ulcer care

**Disease/Tissue Factors**

• Impaired perfusion; ischemia
• Fecal or urinary incontinence; prolonged exposure to moisture
• Malnutrition, dehydration
• Chronic diseases accompanied by anemia, edema, renal failure, malnutrition, peripheral vascular disease, or sepsis
• Previous history of pressure ulcers
• Thin skin associated with aging or prolonged use of steroids

Pressure sores usually develop over bony prominences, such as the sacrum, heels, ischia, and greater trochanters. Continuous pressure on tissue between the bony prominence and a resistant outside surface distorts capillaries and occludes the blood supply. Pressure ulcers also can occur in soft tissues from unrelieved pressure, for example, from nasal cannulas or endotracheal tubes. If the pressure is relieved within a few hours, a brief period of reactive hyperemia (redness) occurs and there may be no lasting tissue damage. If the pressure continues unrelieved, the endothelial cells lining the capillaries become disrupted with platelet aggregation, forming microthrombi that block blood flow and cause anoxic necrosis of
surrounding tissues (Figure 41-3). Shearing and friction are mechanical forces moving parallel to the skin (dragging) and can extend to the bony skeleton, causing detachment and injury of tissues. Pressure ulcers are staged or graded and one classification scheme is as follows²:

*Stage 1*—Nonblanchable erythema of intact skin, usually over a bony prominence; darkly pigmented skin may not have visible blanching

*Stage 2*—Partial-thickness skin loss (erosion or blistering) involving epidermis or dermis

*Stage 3*—Full-thickness skin loss involving damage or necrosis of subcutaneous tissue that may extend to, but not through, underlying fascia

*Stage 4*—Full-thickness tissue loss with exposure of muscle, bone, or supporting structures (tendons or joint capsules); can include undermining and tunneling

*Suspected deep tissue injury*—Localized in an area of purple or maroon discolored intact skin or blood-filled blister caused by underlying soft tissue damage from pressure and/or shear

*Unstageable*—Full-thickness tissue loss with base of ulcer covered by slough or eschar, or both, in the wound bed
Superficial damage results in a layer of dead tissue that forms as an abrasion, blister, erosion, or nonblanchable red/darkened skin or as a reddish blue discoloration when there is deeper tissue damage. Superficial sores are more common on the sacrum as a result of shearing or friction forces (forces parallel to the skin). Deep sores develop closer to the bone as a result of tissue distortion and vascular occlusion from pressure perpendicular to the tissue (over the heels, trochanter, and ischia). Bacteria colonize the dead tissue, and infection is usually localized and self-limiting. Proteolytic enzymes from bacteria and macrophages dissolve necrotic tissues and cause a foul-smelling discharge that resembles, but is not, pus. The necrotic tissue initiates an inflammatory response with potential pain, fever, and leukocytosis. If the ulceration is large, toxicity and pain lead to a host of possible complications, including loss of appetite, debility, local/systemic infections, and renal insufficiency.

The primary goal for those at risk for pressure ulcers is prevention and early detection. Preventive techniques include frequent assessment of the skin with repositioning and turning of the individual; promotion of movement; implementation of pressure reduction (type of positioning and use of specialty beds), pressure removal (positioning interval), and pressure distribution (positioning aids) devices; and elimination of excessive moisture and drainage. Adequate nutrition, oxygenation, and fluid balance must be maintained.3,4
Superficial ulcers should be covered with flat, moisture-retaining dressings (e.g., hydrogel dressings) that cannot wrinkle and cause increased pressure or friction. Successful healing requires continued adequate relief of pressure, débridement of necrotic tissue, opening of deep pockets for drainage, and repair of damaged tissue by construction of skin flaps for large, deep ulcers. Infection requires treatment with antibiotics, and pain should be controlled.\textsuperscript{5,6}

**Keloids and Hypertrophic Scars**

**Keloids** are rounded, firm elevated scars with irregular clawlike margins that extend beyond the original site of injury. They are most common in darkly-pigmented skin types and generally appear weeks to months after a stable scar has formed. **Hypertrophic scars** are elevated erythematous fibrous lesions that do not extend beyond the border of injury. Hypertrophic scars appear within 3 to 4 months and usually regress within 1 year. Both lesions are caused by abnormal wound healing with excessive fibroblast activity and collagen formation, and loss of control of normal tissue repair and regeneration.\textsuperscript{7} Genetic susceptibility is likely.\textsuperscript{8}

Excessive or poorly aligned tension on a wound, introduction of foreign material into the skin, infection, and certain types of trauma (e.g., burns) are all provocative factors. Those parts of the body at risk include shoulders, back, chin, ears, and lower legs. Individuals 10 to 30 years of age develop lesions much more commonly than do prepubescent children or older adults.

Keloids start as pink or red, firm, well-defined, rubbery plaques that persist for several months after trauma. Later, uncontrolled overgrowth causes extension beyond the site of the original wound, and the overgrowth becomes smoother, irregularly shaped, hyperpigmented, harder, and more symptomatic. The fibrous tissue that accumulates in keloids is associated with increased cellularity and metabolic activity of fibroblasts. The tendency to form \textit{clawlike prolongations} is typical (Figure 41-4).
Various treatments are available for the management of keloids and hypertrophic scars. There also is a need for research to improve treatment outcome.\(^7\)

**Pruritus**

Pruritus, or itching, is a symptom associated with many primary skin disorders, such as eczema, psoriasis, or insect infestations, or it can be a manifestation of systemic disease (e.g., chronic renal failure, cholestatic liver disease, thyroid disorders, iron deficiency, neuropathies, or malignancy) or the use of opiate drugs. It may be acute or chronic (neuropathic itch), localized or generalized, and migratory (moves from one location to another).\(^9\) Multiple stimuli can produce itching, and there is interaction between itch and pain sensations. There are many itch mediators, including histamine, serotonin, prostaglandins, bradykinins, neuropeptides, acetylcholine, and interleukins-2 and -31. Small unmyelinated type C nerve fibers transmit itch sensations and specific spinal pathways may carry itch sensations to the brain.\(^10\)

Management of pruritus is challenging and depends on the cause, and the primary condition must be treated. Both topical and systemic therapies are used.\(^11\)

Disorders of the Skin

Disorders of the skin may be precipitated by trauma, abnormal cellular function, infection, immune responses and inflammation, and systemic diseases.

Inflammatory Disorders

The most common inflammatory disorders of the skin are eczema and dermatitis. Eczema and dermatitis are general terms that describe a particular type of inflammatory response in the skin and can be used interchangeably. Eczematous disorders are generally characterized by pruritus, lesions with indistinct borders, and epidermal changes. These lesions can appear as erythema, papules, or scales; they can present in an acute, subacute, or chronic phase. Edema, serous discharge, and crusting occur with continued irritation and scratching. In chronic eczema, the skin becomes thickened, leathery, and hyperpigmented from recurrent irritation and scratching. The location of eczema is related to the underlying cause. Eczematous inflammations need to be differentiated from other rashes and dermatoses, particularly psoriasis.

Allergic Contact Dermatitis

Allergic contact dermatitis is a common form of T-cell–mediated or delayed hypersensitivity. (See Chapter 8 for different types of allergic responses.) The response is an interaction of skin barrier function, reaction to irritants, and neuronal responses, such as pruritus. Genetic susceptibility involves several genes including loss-of-function mutations in the gene encoding the epidermal protein filaggrin. Various allergens (e.g., microorganisms, chemicals, foreign proteins, latex, drugs, metals) can form the sensitizing antigen. Contact with poison ivy is a common example (Figure 41-5). As the allergen contacts the skin, the allergen is bound to a carrier protein, forming a sensitizing antigen. The Langerhans cells (antigen presenting dendritic cells) process the antigen and present it to T cells. T cells then become sensitized to the antigen, inducing the release of inflammatory cytokines and the symptoms of dermatitis. In latex allergy, there is either a type IV hypersensitivity reaction to chemicals used in latex rubber processing or a type I immediate hypersensitivity reaction with immunoglobulin E (IgE) antibodies formed in response to latex rubber protein.
In delayed hypersensitivity (type IV), several hours pass before an immunologic response is apparent. The T cells play an important role because they differentiate and secrete lymphokines that affect macrophage (Langerhans cells) movement and aggregation, coagulation, and other inflammatory responses (see Chapter 8). Sensitization usually develops with first exposure to the antigen, and symptoms of dermatitis occur with reexposure.

The manifestations of allergic contact dermatitis include erythema and swelling with pruritic (itching) vesicular lesions in the areas of allergen contact. The pattern of distribution provides clues to the source of the antigen (e.g., hands exposed to chemical solutions or boundaries from rings and bracelets). The antigen must be removed for the inflammatory response to resolve and tissue repair to begin. Treatment may require topical or systemic steroids.

**Irritant Contact Dermatitis**

**Irritant contact dermatitis** is a nonspecific inflammatory dermatitis caused by activation of the innate immune system by proinflammatory properties of chemicals. The severity of the inflammation is related to the concentration of the irritant, length of exposure, and disruption of the skin barrier. Chemical irritation from acids and prolonged exposure to soaps, detergents, and various agents used in
industry can cause inflammatory lesions. The skin lesions resemble allergic contact dermatitis. Removing the source of irritation and using topical agents provide effective treatment.

**Atopic Dermatitis**

*Atopic dermatitis (allergic dermatitis)* is common in individuals with a history of hay fever or asthma and is associated with IgE antibodies. It is more common in infancy and childhood; however, some individuals are affected throughout life. Specific details of this disorder are presented in Chapter 42.

**Stasis Dermatitis**

*Stasis dermatitis* usually occurs on the lower legs as a result of chronic venous stasis and edema and is associated with varicosities, phlebitis, and vascular trauma (see Chapter 24). Pooling of venous blood traps neutrophils that may release oxidants and proteolytic enzymes. Increased venous pressure widens interendothelial pores with deposition of red blood cells, fibrin, and other macromolecules, making them unavailable for repair while promoting inflammation. First, erythema and pruritus develop followed by scaling, petechiae, and hyperpigmentation. Progressive lesions become ulcerated, particularly around the ankles and pretibial surface (Figure 41-6).

![Stasis Ulcer](image)

**FIGURE 41-6**  Stasis Ulcer. (Courtesy Department of Dermatology School of Medicine, University of Utah, Salt Lake City Utah.)

Treatment includes elevating the legs as often as possible, not wearing tight clothes around the legs, and not standing for long periods. Defined infections are treated with antibiotics. Chronic lesions with ulceration are treated with moist
dressings, external compression/dressings, and vein ablation surgery.\textsuperscript{16}

**Seborrheic Dermatitis**

Seborrheic dermatitis is a common chronic inflammation of the skin involving the scalp, eyebrows, eyelids, ear canals, nasolabial folds, axillae, chest, and back (Figure 41-7). In infants it is known as cradle cap. The cause is unknown. Proposed theories include genetic predisposition, phospholipases from *Malassezia* yeasts, immunosuppression, and epidermal hyperproliferation.\textsuperscript{17}

![Seborrheic Dermatitis](image)

The lesions develop from infancy to old age with periods of remission and exacerbation. The lesions appear as scaly, white or yellowish inflammatory plaques with mild pruritus. Topical therapy includes antifungal shampoos, calcineurin inhibitors, and low-dose steroids for acute flares. Corticosteroids should not be used for maintenance therapy.

**Papulosquamous Disorders**

Psoriasis, pityriasis rosea, lichen planus, acne vulgaris, acne rosacea, and lupus erythematosus are characterized by papules, scales, plaques, and erythema. Collectively they are described as *papulosquamous disorders*.

**Psoriasis**

Psoriasis is a chronic, relapsing, proliferative, inflammatory disorder that involves
the skin, scalp, and nails and can occur at any age. Psoriasis affects about 1% to 4% of the population in countries north of the equator. The onset is generally established by 40 years of age. A family history of psoriasis is common and the genetic mechanisms are complex. The onset of psoriasis later in life is less familial and more secondary to comorbidities, such as obesity, smoking, hypertension, and diabetes.

The inflammatory cascade of psoriasis involves the complex interactions between macrophages, fibroblasts, dendritic cells, natural killer cells, T helper cells, and regulatory T cells. These immune cells lead to the secretion of numerous inflammatory mediators, such as interferon (IFN), tumor necrosis factor-alpha (TNF-α), and various other cytokines including interleukin-12 (IL-12), IL-23, and IL-17. These inflammatory markers are the target for several therapeutic drugs known as the biologics (biotherapy).

Both the dermis and the epidermis are thickened because of cellular hyperproliferation, altered keratinocyte differentiation, and expanded dermal vasculature. The turnover time for shedding the epidermis is decreased to 3 to 4 days from the normal of 14 to 20 days, with many more germinative cells and increased transit time through the dermis. Cell maturation and keratinization are bypassed, and the epidermis thickens and plaques form. The loosely cohesive keratin gives the lesion a silvery appearance. Capillary dilation and increased vascularization accommodate the increased cell metabolism but also cause erythema. The disease can be mild, moderate, or severe, depending on the size, distribution, and inflammation of the lesions. Psoriasis is marked by remissions and exacerbations.

The types of psoriasis include plaque (psoriasis vulgaris), inverse, guttate, pustular, and erythrodermic. **Plaque psoriasis** is the most common and affects 80% to 90% of individuals with psoriasis. The typical plaque psoriatic lesion is a well-demarcated, thick, silvery, scaly, erythematous plaque surrounded by normal skin (Figure 41-8). Small erythematous papules enlarge and coalesce into larger inflammatory lesions on the face, scalp, elbows, and knees and at sites of trauma (Koebner phenomenon).
Inverse psoriasis is rare and involves lesions that develop in skin folds (i.e., axilla or groin). In guttate psoriasis, small papules appear suddenly on the trunk and extremities (Figure 41-9) a few weeks after a streptococcal respiratory tract infection. Guttate psoriasis may resolve spontaneously in weeks or months. Pustular psoriasis appears as blisters of noninfectious pus (collections of neutrophils), and erythrodermic (exfoliative) psoriasis is often accompanied by pruritus or pain with widespread red, scaling lesions that cover a large area of the body.
Psoriatic arthritis of hands, feet, knees, and ankle joints develops in 5% to 30% of cases. Psoriatic nail disease can occur in all psoriasis subtypes with pitting, onycholysis, subungal hyperkeratosis, and nail plate dystrophy. A number of comorbidities are associated with the inflammatory mechanisms of psoriasis (see Health Alert: Psoriasis and Comorbidities).

**Health Alert**

**Psoriasis and Comorbidities**

In addition to skin and joint manifestations including rheumatoid arthritis, severe psoriasis is associated with inflammatory bowel disease metabolic syndrome, which includes hypertension, insulin resistance, dyslipidemias, abdominal obesity, nonalcoholic fatty liver disease, and increased risk for atherosclerosis and myocardial infarction that is independent of traditional risk factors for these diseases. The underlying mechanisms are thought to be related to increased levels of systemic proinflammatory mediators, such as tumor necrosis factor-alpha (TNF-α) and chemokines, which are central to the chronic inflammation, oxidative stress, and angiogenesis of psoriasis. The increased prevalence of cancer, particularly lymphoma, may be related to the pathogenesis of psoriasis or be a consequence of immune modulation therapies. Crohn disease also is associated
with psoriasis and there may be a genetic overlap between these two diseases. Treatment considerations need to include screening, monitoring, and managing these comorbidities.

Treatment is individualized and related to maintaining skin moisture, reducing epidermal cell turnover and pruritus, and promoting immunomodulation. Mild psoriasis is treated with skin-directed therapy, such as medium- to high-strength topical corticosteroids, vitamin D analogs, emollients, and keratolytic agents (such as salicylic acid), and narrow-band ultraviolet light therapy. Systemic therapy is indicated for moderate to severe disease or in the presence of psoriatic arthritis. Current FDA-approved medications include methotrexate, acitretin, and cyclosporine (short term). Newer FDA-approved biologics are being used with more frequency as our understanding of the pathophysiology of psoriasis continues to grow. These biologics include the anti-TNF medications infliximab, adalimumab, and etanercept. Ustekinumab is the most recent FDA-approved injectable biologic targeting IL-12 and IL-23. The IL-17 inhibitors are currently under investigation for their safety and efficacy.\(^{21,22}\) A potential complication of biotherapy is the development of anti–drug antibodies.\(^{23}\)

### Pityriasis Rosea

**Pityriasis rosea** is a self-limiting inflammatory disorder that occurs more often in young adults. The cause is thought to be a herpes-like virus (e.g., human herpesvirus 6 [HHV6] and HHV7).\(^{24}\) Pityriasis rosea begins as a single lesion (herald patch) that is circular, demarcated, and salmon-pink, approximately 3 to 10 cm in diameter, and usually located on the trunk. Early lesions are macular and papular. Secondary lesions develop within 14 to 21 days and extend over the trunk and upper part of the extremities (Figure 41-10), although rarely on the face. The small erythematous rose-colored papules expand into characteristic oval lesions that are bilateral and symmetrically distributed. The pattern of distribution on the back follows the skin lines around the trunk and resembles a drooping pine tree. The scales are sloughed from the margin of the lesions, forming a collarette pattern. Itching is the most common symptom. Occasionally headache, fatigue, or sore throat precedes the development of the lesions.
The diagnosis of pityriasis rosea follows the clinical appearance of the lesion. Secondary syphilis, psoriasis, drug eruption, nummular eczema, and seborrheic dermatitis are among the differential diagnosis considerations. The disorder is usually self-limiting and resolves in a few months with symptomatic treatment for pruritus or cosmetic concerns. Ultraviolet light (with some risk for hyperpigmentation) or systemic corticosteroids may be used to control pruritus. Acyclovir and erythromycin also may be used for treatment.

Lichen Planus

Lichen planus (LP) is a benign autoimmune inflammatory disorder of the skin and mucous membranes. The age of onset is usually between 30 and 70 years. The cause is unknown but T cells, adhesion molecules, inflammatory cytokines, perforin, and antigen-presenting cells are involved. LP also is linked to numerous drugs and hepatitis C virus. The disorder begins with nonscaling, purple-colored, flat-topped, polygonal pruritic papules 2 to 4 mm in size, usually located symmetrically on the wrists, ankles, lower legs, and genitalia (Figure 41-11). New lesions are pale pink and evolve into a dark violet color. Persistent lesions may be thickened and red, forming hypertrophic lichen planus. Oral lesions (oral lichen planus) appear as lacy white rings that must be differentiated from leukoplakia or oral candidiasis. Usually, oral lesions do not ulcerate, but localized or extensive painful ulcerations can occur, and there may be increased risk for oral cancer. Chronic ulcerated lesions become malignant in 1% of individuals with the disease. Thinning and splitting of nails are common, and part or the entire nail may be shed.
Pruritus is the most distressing symptom. The lesions are self-limiting and may last for months or years, with an average duration of 6 to 18 months. Postinflammatory hyperpigmentation is a common consequence of the lesion. Approximately 20% of individuals have a recurrence. Diagnosis is made by the clinical appearance and histopathology of the lesion. Treatment is individualized and includes topical, intraleisional, or systemic corticosteroids (second line for resistant LP), and systemic acitretin with or without adjuvant light therapy. Antihistamines are given for itching, and short-term use of topical or systemic corticosteroids may be used to control inflammation. Mucous membrane lesions are treated with topical steroids, topical retinoids or immunomodulators (or both), and systemic glucocorticoids.\(^{29}\)

Quick Check 41-3

1. Why does inflammation occur with contact dermatitis?
2. What factors are associated with atopic dermatitis?
3. What lesions are associated with papulosquamous disorders?
4. Give three examples of papulosquamous disorders.

Acne Vulgaris

*Acne vulgaris* is an inflammatory disorder of the pilosebaceous follicle (the
sebaceous gland contiguous with a hair follicle) that usually occurs during adolescence. It is discussed in Chapter 42.

**Acne Rosacea**

*Acne rosacea* is a chronic inflammation of the skin that develops in middle-aged adults. There are four subtypes of lesions: erythematotelangiectatic, papulopustular, phymatous, and ocular (eyelids and ocular surface). The exact cause is unknown but factors that trigger an altered innate immune response are involved (i.e., sun exposure and damage, drinking alcohol or hot beverages, hormonal fluctuations, and *Demodex folliculorum* [mites]). The most common lesions are erythema, papules, pustules, and telangiectasia. They occur in the middle third of the face, including the forehead, nose, cheeks, and chin (Figure 41-12). The lesions are associated with chronic, inappropriate vasodilation resulting in flushing and sun sensitivity. Sebaceous hypertrophy, fibrosis, and telangiectasia may be severe enough to produce an irreversible bulbous appearance of the nose (rhinophyma). Disorders of the eye often accompany rosacea, particularly conjunctivitis and keratitis, which can result in visual impairment. Facial application of fluorinated topical steroids may increase the severity of telangiectasias.
Photoprotection, using sunscreens, is essential along with avoidance of other triggers. Both topical (metronidazole, azelaic acid) and oral drugs (tetracyclines and doxycycline) may be effective. Surgical excision of excessive tissue may be required for rhinophyma.\textsuperscript{31}

**Lupus Erythematosus**

**Lupus erythematosus** is a systemic inflammatory, autoimmune disease with cutaneous manifestations (see Chapter 8). Discoid (or cutaneous) lupus erythematosus (DLE) is limited to the skin and can progress to systemic lupus erythematosus.\textsuperscript{32}

**Discoid (cutaneous) lupus erythematosus.**

**Discoid (cutaneous) lupus erythematosus (DLE)** usually occurs in genetically susceptible adults, particularly women in their late thirties or early forties, but people of any age can be affected. The disease can be acute, subacute, intermittent, or chronic. Differentiation of subtypes is by physical examination, laboratory studies, histologic analysis, and antibody serology direct immunofluorescence.\textsuperscript{33}
The lesions may be single or multiple and vary in size. Often the lesions are located on light-exposed areas of the skin, and photosensitivity is common. The face is the most common site of lesion involvement with a butterfly pattern of distribution found over the nose and cheeks.

The cause is unknown but is related to genetic and environmental factors and an altered immune response to an unknown antigen or to ultraviolet B wavelengths. There is development of self-reactive T and B cells, decreased number of regulatory T cells, and increased levels of proinflammatory cytokines. Autoantibodies and immune complexes cause tissue damage and inflammation\(^3\)\(^4\) (Figure 41-13). On skin biopsy with immunofluorescent observation, there are lumpy deposits of immunoglobulins, especially IgM (lupus band test).\(^3\)\(^5\)

![Figure 41-13 Subacute Cutaneous Lupus (Discoid Lupus Erythematosus).](image)

The early lesion is asymmetric, with a 1- to 2-cm raised red plaque with a brownish scale. The scale penetrates the hair follicle and leaves a visible follicle opening (carpet-tack appearance) when removed. The lesions persist for months and then resolve spontaneously or atrophy. Healing progresses outward from the center of the lesion, with residual telangiectasia and hypopigmented scarring. Atrophy of the dermis and epidermis can cause a depressed scar. Treatment options include protection from the sun and use of topical steroids, calcineurin inhibitors, antimalarial drugs (e.g., hydroxychloroquine sulfate), and immunosuppressors.
These medications must be used with caution to prevent serious side effects.\textsuperscript{35}

**Vesiculobullous Diseases**

Vesiculobullous skin diseases share a common characteristic of vesicle, or blister, formation. Two such diseases are pemphigus and erythema multiforme.

**Pemphigus**

Pemphigus (meaning to blister or bubble) is a group of rare autoimmune blistering diseases of the skin and oral mucous membranes caused by circulating autoantibodies directed against the cell surface adhesion molecule desmoglein at the desmosomal cell junction in the suprabasal layer of the epidermis. Immunoglobulin G (IgG) autoantibodies and C3 complement bind to the desmoglein adhesion molecules, resulting in the destruction of cell-to-cell adhesion (acantholysis) in the basal layer of the epidermis (see Table 41-1) with fluid accumulation and the resulting symptom of blister formation (Figure 41-14). Pemphigus can occur in all age groups but is more prevalent in persons between 40 and 50 years of age. There is a genetic predisposition as well as environmental (viral infections, drug-induced, dietary intake, or physical effects such as radiation or surgery) and endogenous (emotional or hormonal stressors) influences. Pemphigus presents in varying forms often with painful, superficial erosions prone to infection\textsuperscript{36,37}:

- **Pemphigus vulgaris** is the most common form. Oral lesions precede the onset of skin blistering, which is more prominent on the face, scalp, and axilla. The blisters rupture easily because of the thin, fragile overlying portion of the epidermis.

- **Pemphigus vegetans** is a variant of pemphigus vulgaris in which large blisters develop in tissue folds of the axilla and groin.

- **Pemphigus foliaceus** is a milder form of the disease and involves acantholysis at the more superficial, subcorneal level of the epidermis (see Table 41-1) with blistering, erosions, scaling, crusting, and erythema usually of the face and chest. Oral mucous membranes are rarely involved.

- **Pemphigus erythematous** is a subset of pemphigus foliaceus often associated with system lupus erythematosus with positive antinuclear antibodies. The lesions are generally less widely distributed.

- **Paraneoplastic pemphigus** is the most severe form of pemphigus and is associated with lymphoproliferative neoplasms.

- **IgA pemphigus** is the most benign form of pemphigus characterized by tissue-bound and circulating IgA antibodies targeting desmosomal or nondesmosomal
cell surface components in the basement membrane of the epidermis.

- **Pemphigus herpetiformis** is a very rare form of pemphigus that resembles dermatitis herpetiformis (blistering lesions that have the appearance of herpes lesions) but with immunologic and histologic findings consistent with pemphigus.

The diagnosis of pemphigus is made from the clinical and histologic findings of the skin. Immunofluorescence demonstrates the presence of antibodies at the site of blister formation. The clinical course of the disease may range from rapidly fatal to relatively benign. The primary treatment for pemphigus is systemic corticosteroids in combination with adjuvant immunosuppressants. Newer methods of treatment and a clearer understanding of the pathogenesis have improved the prognosis and decreased mortality.

**Erythema Multiforme**

**Erythema multiforme** is a syndrome characterized by inflammation of the skin and mucous membranes, often associated with a T-cell–mediated immunologic reaction to a drug or microorganisms (e.g., herpes simplex virus) that targets small blood vessels in the skin or mucosa. **Bullous erythema multiforme** involves the mucous membranes. It is relatively rare and occurs more often during the second to fourth decade of life; however, it can occur at any age. Immune complex formation and deposition of C3, IgM, and fibrinogen around the superficial dermal blood vessels,
basement membrane, and keratinocytes are common histologic findings. Edema develops in the superficial dermis, so vesicles and bullae form. The lesions vary in clinical presentation and may involve the skin or mucous membranes, or both. The characteristic “bull's-eye,” or “target,” lesions occur on the skin surface with a central erythematous region surrounded by concentric rings of alternating edema and inflammation. The lesions usually occur suddenly in groups over a period of 2 to 3 weeks. Urticarial plaques, 1 to 2 cm in diameter, can develop without the target lesion. A vesiculobullous form is characterized by mucous membrane lesions and erythematous plaques on the extensor surfaces of the extremities. Single or multiple vesicles or bullae may arise on a part of the plaque accompanied by pruritus and burning. The lesions heal within 3 to 4 weeks.

The most common forms of erythema multiforme are usually associated with severe drug reactions and include Stevens-Johnson syndrome (severe mucocutaneous bullous form involving 10% of body surface area) and toxic epidermal necrolysis (TEN) (severe mucocutaneous bullous form involving 30% of body surface area). Cytotoxic T lymphocytes (CTLs) in an HLA-restricted fashion mediate the immune mechanism related to drug reactions\(^{40,41}\) (see Chapter 42 for pediatric considerations).

Prodromal symptoms of erythema multiforme, including fever, headache, malaise, sore throat, and cough, develop in approximately one third of the cases. The bullous lesions form erosions and crusts when they rupture. There is necrosis of the epidermis in TEN. The mouth, air passages, esophagus, urethra, and conjunctiva may be involved when mucous membranes are affected. Blindness can result from corneal ulcerations. Difficulty eating, breathing, and urinating may develop with severe consequences. The disease can involve the kidneys and extend from the upper respiratory passages into the lungs. Severe forms of the disease can be fatal.

Recognizing the person's medication history that preceded the target lesion and performing a skin biopsy are required to establish the diagnosis. Mild acute forms of the disease last 10 to 14 days and require no treatment. Any ongoing drug therapy should be withdrawn and reevaluated and underlying infections treated. Fluid and electrolyte balance should be monitored in severe forms of the disease, and mucous membranes should be carefully managed with a bland diet, warm saline eyewashes, topical anesthetics, or corticosteroids to maintain comfort and prevent infection. Cutaneous blisters can be treated with wet compresses of Burow solution. Ophthalmic, kidney, and lung involvement require special care. Resolution occurs in 8 to 10 days, usually without scarring. Mucosal lesions may take 6 weeks to heal.
Quick Check 41-4

1. Describe the inflammatory lesion associated with lupus erythematosus.

2. Compare the three forms of pemphigus.

3. What is the characteristic lesion of erythema multiforme?

Infections

Cutaneous infections are common forms of skin disease. They generally remain localized, although serious complications can develop with systemic involvement that can be life-threatening. The types of skin infection include bacterial, viral, and fungal. The commensal (normal) flora of the skin consists of aerobes, yeast, and anaerobes and often provides protection against pathogens that cause skin infections, including Staphylococcus and Streptococcus.

Bacterial Infections

Most bacterial infections of the skin are caused by local invasion of pathogens. Coagulase-positive Staphylococcus aureus and, less often, beta-hemolytic streptococci are the common causative microorganisms. Community-acquired methicillin-resistant Staphylococcus aureus (CA-MRSA [see Chapter 8]) also is a cause of serious skin infection, particularly skin abscesses.

Folliculitis.

Folliculitis is an infection of the hair follicle and can be caused by bacteria, viruses, or fungi, although S. aureus is the common culprit. The infection develops from proliferation of the microorganism around the opening and inside the follicle. Inflammation is caused by the release of chemotactic factors and enzymes from the bacteria. The lesions appear as pustules with a surrounding area of erythema. They are most prominent on the scalp and extremities and rarely cause systemic symptoms. Prolonged skin moisture, skin trauma (e.g., shaving facial hair), occlusive clothing, topical agents, and poor hygiene are associated contributing factors. Cleaning with soap and water and topical application of antibiotics are effective treatments.

Furuncles and carbuncles.

Furuncles, or “boils,” are inflammations of hair follicles (Figure 41-15). They may
develop after folliculitis that spreads through the follicular wall into the surrounding dermis. The invading microorganism is usually *S. aureus*, including community-acquired methicillin-resistant *S. aureus* (CA-MSRA [see Chapter 8]). The infecting strain may spread to the skin from the anterior nares. Any skin area with hair can be infected, and one or several lesions may be present. The initial lesion is a deep, firm, red, painful nodule 1 to 5 cm in diameter. Within a few days, the erythematous nodules change to a large, fluctuant, and tender cystic nodule accompanied by cellulitis. No systemic symptoms are present, and the lesion may drain large amounts of pus and necrotic tissue.

**Carbuncles** are a collection of infected hair follicles and usually occur on the back of the neck, the upper back, and the lateral thighs. The lesion begins in the subcutaneous tissue and lower dermis as a firm mass that evolves into an erythematous, painful, swollen mass that drains through many openings. Abscesses may develop. Chills, fever, and malaise can occur during the early stages of lesion development.

Furuncles and carbuncles are treated with warm compresses to provide comfort and promote localization and spontaneous drainage. Abscess formation, recurrent infections, extensive lesions, or lesions associated with cellulitis or systemic symptoms require incision and drainage and are treated with systemic antibiotics.

**Cellulitis.**
**Cellulitis** is an infection of the dermis and subcutaneous tissue usually caused by *Staphylococcus aureus*, CA-MRSA, or group B streptococci. Cellulitis can occur as an extension of a skin wound, as an ulcer, or from furuncles or carbuncles. The infected area is warm, erythematous, swollen, and painful. The infection is usually in the lower extremities and responds to systemic antibiotics, as well as therapy to relieve pain. Cellulitis also can be associated with other diseases including chronic venous insufficiency and stasis dermatitis.

Cellulitis must be differentiated from necrotizing fasciitis. **Necrotizing fasciitis** is a rare, rapidly spreading infection. It is commonly caused by *Streptococcus pyogenes* starting in the fascia, muscles, and subcutaneous fat with subsequent necrosis of the overlying skin. Treatment requires antibiotics and often surgical débridement.

**Erysipelas.**

**Erysipelas** is an acute superficial infection of the upper dermis most often caused by *Streptococcus pyogenes*, *beta-hemolytic streptococci*, and *Staphylococcus aureus*. The face, ears, and lower legs are involved. Chills, fever, and malaise precede the onset of lesions by 4 hours to 20 days. The initial lesions appear as firm, red spots that enlarge and coalesce to form a clearly circumscribed, advancing, bright red, hot lesion with a raised border. Vesicles may appear over the lesion and at the border. Pruritus, burning, and tenderness are present. Cold compresses provide symptomatic relief, and systemic antibiotics are required to arrest the infection.

**Impetigo.**

**Impetigo** is a superficial lesion of the skin that is caused by coagulase-positive *Staphylococcus* or beta-hemolytic streptococci. The disease occurs in adults but is more common in children (see Chapter 42).

**Lyme disease.**

**Lyme disease** is a multisystem inflammatory disease caused by the spirochete *Borrelia burgdorferi* transmitted by *Ixodes* tick bites and is the most frequently reported vector-borne illness. The highest incidence of Lyme disease is among children. The microorganism is difficult to culture, escapes immunodefenses, and hides in tissue. It spreads to other tissues by entering capillary beds.

Symptoms of the disease occur in three stages, although 50% of infected individuals are symptom free. **Localized infection** occurs soon after the bite (within 3 to 32 days) with erythema migrans (bull's-eye rash), a T-cell–mediated response usually with fever. Within days to weeks after the onset of the illness, there
is disseminated infection with secondary erythema migrans, usually with myalgias, arthralgias, and more rarely meningitis, neuritis, or carditis. Late persistent infection (more common in Europe) can continue for years with arthritis, encephalopathy, polyneuropathy, or heart failure. The diagnosis of Lyme disease is based on the clinical presentation and history of the tick bite, if known. Serologic tests are used to confirm the diagnosis, although there is a delayed antibody response and the test may be negative during the first 3 weeks after infection. Antibiotics (e.g., doxycycline [not used in children younger than 8 years or in pregnant or breast-feeding women] or amoxicillin) are used for treatment. Reinfection can occur. There is currently no vaccine for Lyme disease.

Viral Infections

**Herpes simplex virus.**

Skin infections with herpes simplex virus (HSV) are commonly caused by two types of HSV: HSV-1 and HSV-2. Either type can occur in different parts of the body, including oral and genital locations. Their differences are distinguished by laboratory tests. HSV-1, transmitted by contact with infected saliva, is generally associated with oral infections (cold sore or fever blister) or infection of the cornea (herpes keratitis), mouth (gingivostomatitis), and orolabia (lips/labialis), but it can also cause genital herpes. With initial (primary) infection, the virus is imbedded in sensory nerve endings and it moves by retrograde axonal transport to the dorsal root ganglion, where the virus develops lifelong latency. During the secondary phase, the lesions occur at the same site from reactivation of the virus. The virus travels down the peripheral nerve to the site of the original infection, where it is shed. Exposure to ultraviolet light, skin irritation, fever, fatigue, or stress may cause reactivation.

The lesions for HSV-1 appear as a rash or clusters of inflamed and painful vesicles (e.g., within the mouth, over the tongue, on the lips, around the nose) (Figure 41-16). Increased sensitivity, paresthesias, pruritus, and mild burning may occur before onset of the lesions. The vesicles rupture, forming a crust. Lesions may last from 2 to 6 weeks but usually resolve within 2 weeks. Treatment is symptomatic and includes topical or oral antiviral agents.
Genital infections are more commonly caused by HSV-2. The virus is spread by skin-to-skin mucous membrane contact during viral shedding. Risk of infection is high in immunosuppressed persons or in persons who have sexual contact with infected individuals. Vertical transmission from mother to neonate is associated with significant neonatal neurologic morbidity and mortality. The initial infection is asymptomatic. With recurrent exposure, the lesions begin as small vesicles that progress to ulceration within 3 to 4 days with pain, itching, and weeping. Treatment is symptomatic and includes topical or oral antiviral agents. A vaccine has been effective in controlling recurrent infection, and progress is being made with prophylactic vaccines.

**Herpes zoster and varicella.**

**Herpes zoster (shingles)** and **varicella (chickenpox, see Chapter 42)** are caused by the same herpesvirus—varicella-zoster virus (VZV). VZV occurs as a primary infection followed years later by activation of the virus to cause herpes zoster (shingles). During this time, the virus remains latent in trigeminal and dorsal root
ganglia.

Herpes zoster has initial symptoms of pain and paresthesia localized to the affected dermatome (the cutaneous area innervated by a single spinal nerve; see Chapter 13), followed by vesicular eruptions that follow a facial, cervical, or thoracic lumbar dermatome (Figure 41-17). Local symptoms are alleviated with compresses, calamine lotion, or baking soda. Approximately 15% to 20% of individuals experience postherpetic neuralgia (pain) with reactivation of the virus. Antiviral drugs, tricyclic antidepressants, and analgesics are helpful treatments. The varicella vaccine is safe and effective in both children and adults, particularly those older than age 60. In children, the vaccine is given to prevent chickenpox; and in adults, particularly the elderly, the vaccine is given to prevent herpes zoster (shingles).

Warts.

Warts (verrucae) are benign lesions of the skin caused by the many different types of human papillomavirus (HPV) that infect the stratified epithelium of skin and mucous membranes. The lesions can occur anywhere and are flat, round, or fusiform and elevated with a rough, grayish surface. Warts are transmitted by touch.
Common warts (verruca vulgaris) occur most often in children and are usually on the fingers (Figure 41-18). Plantar warts are usually located at pressure points on the bottom of the feet. Warts are commonly treated with cryotherapy or topical salicylic acid; new agents are being investigated.\textsuperscript{57,58}

\textbf{Condylomata acuminata (venereal warts)} are highly contagious and sexually transmitted. The cauliflower-like lesions occur in moist areas, along the glans of the penis, vulva, and anus. Oncogenic types of HPV are a primary cause of cervical and other types of cancer\textsuperscript{59} (see Chapter 33).

\textbf{Fungal Infections}

The fungi causing superficial skin infections are called \textit{dermatophytes}, and they thrive on keratin (stratum corneum, hair, nails). Fungal disorders are known as \textit{mycoses}; when caused by dermatophytes, the mycoses are termed \textit{tinea} (dermatophytosis or ringworm).

\textbf{Tinea infections.}

\textit{Tinea infections} are classified according to their location on the body. The most common sites are summarized in Table 41-5 (Figure 41-19).
### TABLE 41-5
Common Sites of Tinea Infections

<table>
<thead>
<tr>
<th>Site</th>
<th>Clinical Manifestations</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tinea capitis (scalp)</td>
<td>Scaly, pruritic scalp with bald areas; hair breaks easily</td>
</tr>
<tr>
<td>Tinea corporis (skin areas, excluding scalp, face, hands, feet, groin)</td>
<td>Circular, clearly circumscribed, mildly erythematous scaly patches with slightly elevated ringlike border; some forms are dry and macular, and other forms are moist and vesicular</td>
</tr>
<tr>
<td>Tinea cruris (groin, also known as “jock itch”)</td>
<td>Small, erythematous, and scaling vesicular patches with well-defined borders that spread over inner and upper surfaces of thighs; occurs with heat and high humidity</td>
</tr>
<tr>
<td>Tinea pedis (foot; also known as “athlete’s foot”)</td>
<td>Occurs between toes and may spread to soles of feet, nails, and skin or toes; slight scaling; macerated, painful skin, occasionally with fissures and vesication</td>
</tr>
<tr>
<td>Tinea manus (hand)</td>
<td>Dry, scaly, erythematous lesions, or moist, vesicular lesions that begin with clusters of intensely pruritic, clear vesicles; often associated with fungal infection of feet</td>
</tr>
<tr>
<td>Tinea unguium or onychomycosis (nails)</td>
<td>Superficial or deep inflammation of nail that develops yellow-brown accumulations of brittle keratin over all or portions of nail</td>
</tr>
</tbody>
</table>

![Figure 41-19](image.png)

**FIGURE 41-19**  Tinea Pedis. Inflammation has extended from the web area onto the dorsum of the foot. (Courtesy Department of Dermatology School of Medicine, University of Utah, Salt Lake City Utah.)

Tinea is diagnosed by culture, microscopic examination of skin scrapings prepared with potassium hydroxide wet mount, or observation of the skin with an ultraviolet light (Wood's lamp). Cultures establish the particular type of fungus; identification is necessary for diagnosis of hair and nail infections. Fungi have characteristic spores and filaments known as *hyphae* that are more prominent when prepared in potassium hydroxide. The spores fluoresce blue-green when exposed to ultraviolet light. Treatment is related to the type of fungi and includes both topical and systemic antifungal medication.60

### Candidiasis.
Candidiasis is caused by the yeastlike fungus Candida albicans and normally can be found on mucous membranes, on the skin, in the gastrointestinal tract, and in the vagina. C. albicans can, under certain circumstances, change from a commensal (normal) microorganism to a pathogen, particularly in the critically ill and those who are immunosuppressed.\(^6^1\)

Factors that predispose to infection include (1) local environment of moisture, warmth, maceration, or occlusion; (2) systemic administration of antibiotics; (3) pregnancy; (4) diabetes mellitus; (5) Cushing disease; (6) debilitated states; (7) infants younger than 6 months of age, as a result of decreased immune reactivity; (8) immunosuppressed persons; and (9) certain neoplastic diseases of the blood and monocyte/macrophage system. The commensal (normal) bacteria on the skin, mainly cocci, inhibit proliferation of C. albicans. C. albicans can activate the complement system by the alternative pathway and produce small abscesses. Candidiasis affects only the outer layers of mucous membranes and skin and occurs in the mouth, vagina, uncircumcised penis, nail folds, interdigital areas, and large skin folds. Table 41-6 lists the points of differentiation of various sites of candidiasis habitation.

</tbody>
</table>

The initial lesion is a thin-walled pustule that extends under the stratum corneum with an inflammatory base that may burn or itch. The accumulation of inflammatory cells and scale produces a whitish yellow curdlike substance over the infected area. The lesion ceases to spread when it reaches dry skin.\(^6^2\) Topical antifungal agents are commonly used for treatment.

### Vascular Disorders

Vascular abnormalities are commonly associated with skin diseases; they may be congenital or may involve vascular responses to local or systemic vasoactive
substances. Blood vessels may increase in number, dilate, constrict, or become obliterated by disease processes.

**Cutaneous Vasculitis**

Vasculitis (angiitis) is an inflammation of the blood vessel wall that can result in bleeding aneurysm formation, or occlusion with ischemia or infection of surrounding tissue. The extensive vascular bed in the skin results in vasculitic syndromes that may be localized and self-limiting or generalized with multiorgan involvement. The initiating site may be the blood, the vessel wall, or the adjacent tissue. Small vessels are usually affected.

**Cutaneous vasculitis** develops from the deposit of immune complexes in small blood vessels as a toxic response to drugs (phenothiazines, barbiturates, sulfonamides), allergens, or streptococcal or viral infection, or as a component of systemic vasculitic syndromes. The deposits activate complement, which is chemotactic for polymorphonuclear leukocytes, and proinflammatory cytokines.

The disorder is also known as *cutaneous leukocytoclastic angiitis* (from the presence of leukocytes [i.e., neutrophils] in and around vessel walls). A systemic form (cutaneous systemic vasculitis) can involve other organs, including the kidneys, lungs, and gastrointestinal tract. The pattern of skin involvement includes palpable purpura in the lower legs and feet (from the leakage of blood from damaged vessels) that may progress to hemorrhagic bullae with necrosis and ulceration from occlusion of the vessel. Lesions appear in clusters and persist for 1 to 4 weeks. The disease may be self-limiting and occur as a single episode. Biopsy confirms the diagnosis.

Identifying and removing the antigen (chemical, drug, or source of infection) is the first step of treatment. Corticosteroids and immunosuppressants may be used when symptoms are severe.\(^63\)

**Urticaria**

Urticaria (hives) is a circumscribed area of raised erythema and edema of the superficial dermis. Urticarial lesions are most commonly associated with type I hypersensitivity reactions to drugs (penicillin, aspirin), certain foods (strawberries, shellfish, food dyes), environmental exposure (pollen, animal dander, insect bites), systemic diseases (intestinal parasites, lupus erythematosus), or physical agents (heat or cold) (see Chapter 8). The lesions are mediated by histamine release from sensitized mast cells or basophils, or both, which causes the endothelial cells of skin blood vessels to contract. The leakage of fluid from the vessel appears as wheals, welts, or hives, and there may be few or many that may be distributed over the entire
body. Most lesions resolve spontaneously within 24 hours, but new lesions may appear. All possible causes of the reaction should be removed. Antihistamines usually reduce hives and provide relief of itching. Corticosteroids and β-adrenergic agonists may be required for severe attacks. **Chronic urticaria** (recurrent wheals for more than 6 weeks) is either idiopathic or autoimmune in origin and involves inappropriate activation of mast cells. Angioedema (welts or swelling deeper within the skin or mucous membranes) is associated with both groups and more commonly affects the eyes and mouth.

**Scleroderma**

**Localized scleroderma** (morphea) means sclerosis of the skin and underlying tissue. The disease is rare, more common in females, and the cause is unknown. Genetic predisposition, autoimmunity, and an immune reaction to a toxic substance are possible initiating mechanisms of the disease. Autoantibodies are often recovered from the skin and serum of individuals with scleroderma. Impaired regulation of collagen gene expression by fibroblasts probably underlies the persistent fibrosis. There are subtypes of localized scleroderma but all involve thickening of the skin. Localized scleroderma is differentiated from the systemic form of the disease by the absence of the following: sclerodactyly, Raynaud phenomenon, abnormalities of the nail bed capillaries, or internal organ involvement.

**Systemic scleroderma** involves the connective tissues of the skin and many organs, including the kidneys, gastrointestinal tract, and lungs. There are massive deposits of type I collagen with progressive fibrosis accompanied by inflammatory reactions as well as vascular changes in the capillary network with a decrease in the number of capillary loops, dilation of the remaining capillaries, formation of perivascular infiltrates, and development of occlusion and ischemia.

The clinical features of systemic scleroderma can be summarized using the CREST acronym as a guide:

- **Calcinosis**—calcium deposits in the subcutaneous tissue that cause pain
- **Raynaud phenomenon**—episodes of arteriolar vasoconstriction or spasm in response to cold or stress
- **Esophageal changes**—swallowing difficulty related to acid reflux and increased esophageal fibrosis
- **Sclerodactyly**—tightening of skin over the fingers and toes leading to tapering of
the digits with scarring and tissue atrophy

Telangiectasias—dilation of capillaries causing small (0.5-cm), weblike red marks on skin surface

The cutaneous lesions are most often on the face and hands, the neck, and the upper chest, although the entire skin can be involved. The skin is hard, hypopigmented, taut, shiny, and tightly connected to the underlying tissue. The tightness of the facial skin projects an immobile masklike appearance, and the mouth may not open completely. The nose may assume a beaklike appearance. The hands are shiny and sometimes red and edematous (Figure 41-20). Progression to body organs may occur, and death is caused by subsequent respiratory failure, renal failure, cardiac dysrhythmias, or esophageal or intestinal obstruction or perforation.67

Suitable clothing and a warm environment are essential for protecting the hands. Trauma and smoking should be avoided. Treatment is individualized and based on severity and progression of the disease. Immunosuppression, ultraviolet treatment, and other therapies are prescribed.68

Quick Check 41-5
1. Name two bacterial skin infections, and describe the typical lesions.
2. Compare herpes zoster and varicella.
3. What features distinguish urticarial lesions?

Benign Tumors

Most benign tumors of the skin are associated with aging. Benign tumors include seborrheic keratosis, keratoacanthoma, actinic keratosis, and moles.

Seborrheic Keratosis

Seborrheic keratosis is a benign proliferation of cutaneous basal cells that produces flat or slightly elevated lesions that may be smooth or warty in appearance. The pathogenesis is unknown. These benign tumors are usually seen in older people and occur as multiple lesions on the chest, back, and face. The color varies from tan to waxy yellow, flesh colored, or dark brown-black. Lesion size varies from a few millimeters to several centimeters, and they are often oval and greasy appearing with a hyperkeratotic scale (Figure 41-21). Cryotherapy with liquid nitrogen and laser therapy are effective treatments.

Keratoacanthoma
A **keratoacanthoma** is a benign, self-limiting tumor of squamous cell differentiation arising from hair follicles. It usually occurs on sun-damaged skin of elderly individuals. Incidence is highest among smokers and males. The most commonly affected sites are the face, back of the hands, forearms, neck, and legs. The lesion develops in stages (proliferative, mature, and involution) over a period of 1 to 2 months with a histologic pattern resembling squamous cell carcinoma. Although the lesions will resolve spontaneously, they can be removed by curettage or excision to improve cosmetic appearance and reduce the risk of evolution to squamous cell carcinoma (SCC). A biopsy is performed to rule out SCC.

**Actinic Keratosis**

**Actinic keratosis** is a premalignant lesion composed of aberrant proliferations of epidermal keratinocytes caused by prolonged exposure to ultraviolet radiation. The prevalence is highest in individuals with unprotected, light-colored skin and is rare in those with black skin. The lesions appear as rough, poorly defined papules, which may be felt more than seen. Surrounding areas may have telangiectasias. Treatment options include cryoablation, photodynamic therapy, laser surgery, and topical therapies, such as 5-fluorouracil, diclofenac, imiquimod cream, and ingenol mebutate. Excisions also may be performed, providing tissue for cellular analysis. The lesions should continue to be evaluated for progression to squamous cell carcinoma. Protection from the sun with clothing or a sun-blocking agent to prevent lesions from developing elsewhere is advised.

**Nevi (Moles)**

**Nevi** (sing., **nevus**) (also known as moles or birthmarks) are benign pigmented or nonpigmented lesions. Melanocytic nevi, formed from melanocytes, may be congenital or acquired and small (less than 1 cm) or large (greater than 20 cm). Congenital melanocytic nevi may be removed to reduce risk of cutaneous malignant melanoma. During the early stages of development, the cells accumulate at the junction of the dermis and epidermis and are macular lesions. Over time, the cells move deeper into the dermis and the nevi become nodular and symmetric without irregular borders. Nevi may appear on any part of the skin, vary in size, occur singly or in groups, and may undergo transition to malignant melanoma (see p. 1072). Classification of nevi is summarized in Table 41-7. Nevi irritated by clothing or trauma or large lesions may be excised. Multiple and changing moles require regular evaluation.
Quick Check 41-6

1. List two diseases caused by insect bites.

2. Compare keratoacanthoma and actinic keratosis.

TABLE 41-7
Classification of Nevi

Skin Cancer

Basal cell carcinoma and squamous cell carcinoma (collectively known as nonmelanoma skin cancers) are the most prevalent forms of cancer. Malignant melanoma is the most serious and most common cause of death from skin cancer. Important trends related to skin cancer are described in Box 41-1.

BOX 41-1

Important Trends for Skin Cancer

Incidence

• Skin cancer is the most commonly diagnosed cancer in the United States. An estimated 3.5 million cases of squamous and basal cell carcinoma were diagnosed in 2006.

• Malignant melanoma is the most serious form of skin cancer; it is not as common as the other forms of skin cancer; an estimated 73,870 new cases were predicted in 2015.

Mortality

• Total estimated deaths from skin cancer in 2015 were 13,340—9940 from
malignant melanoma and 3400 from other nonepithelial skin cancers

Survival

• Basal and squamous cell carcinoma can be cured when detected early

• 5-year survival for melanoma: localized 98%, regional metastasis 63%, distant metastasis 16%

Risk Factors

• Excessive exposure to ultraviolet radiation from the sun or tanning salons

• Fair complexion

• Occupational exposure to coal tar, pitch, creosote, arsenic compounds, and radium

• In people of color, skin cancer is less common, is diagnosed at a more advanced stage, and has higher morbidity and mortality than in people with light-colored skin; it is often found on the palms of hands and soles of feet

• Immunosuppression

Warning Signs

• Any unusual skin condition, especially a change in the size, borders, or color of a mole or other darkly pigmented growth or spot

Prevention and Early Detection

• Avoid the sun when ultraviolet light is strongest (e.g., 10 AM to 3 PM), avoid sun tanning beds, seek shade, use sunscreen preparations, especially those containing ingredients such as PABA (para-aminobenzoic acid), and wear protective clothing

• Basal and squamous cell skin cancers often form a pale, waxlike pearly nodule or a red, scaly, sharply outlined patch

• Melanomas usually have dark brown or black pigmentation; they start as small molelike growths that increase in size, change color, become ulcerated, and bleed easily from slight injury
Treatment

- Options for treatment include surgery, electrodesiccation (tissue destruction by heat), radiation therapy, cryosurgery (tissue destruction by freezing)

- Malignant melanomas require wide and often deep excisions and removal of nearby lymph nodes; selective lymphadenectomy or immunotherapy can be used; vaccines and gene therapy are in development

Survival

- For basal cell and squamous cell cancers, cure is virtually ensured with early detection and treatment; malignant melanoma, however, metastasizes quickly and accounts for a lower 5-year survival rate

Data from American Cancer Society: Cancer facts & figures 2015, Atlanta, 2015, Author.

Chronic exposure to ultraviolet (UV) radiation causes most skin cancers. Lesions are most common on the face, neck, hands, and other areas with intense sunlight exposure. Protection from the sun and avoidance of tanning beds, particularly during childhood, significantly reduce the risk of skin cancer in later years. Genetic mutations in oncogenes and tumor-suppressor genes (see Chapter 10) are associated with skin cancers. This leads to loss of keratinocyte repair functions and apoptosis resistance of DNA-damaged cells. Dark-skinned persons and those avoiding sunlight are significantly less likely to develop these malignant tumors. In dark-skinned persons, basal cells contain more of the pigment melanin, a protective factor against sun exposure. Vitamin D may be an important tumor-suppressor for the skin but more research is needed.

Basal Cell Carcinoma

Basal cell carcinoma (BCC) of the skin is the most common cancer in the world, making it the most common skin cancer by default. BCC is thought to be caused by UV radiation exposure and also is associated with arsenic in food or water.

BCCs have numerous subtypes, including superficial, nodular, pigmented, morpheaform, and combinations of each; thus, they can have very different clinical presentations—from superficial erythematous papules; to thick, pigmented nodules resembling melanomas; to erosive, necrotic, and ulcerating lesions (Figure 41-22). As the tumor grows it usually has a depressed center, a rolled border, and small blood vessels on the surface (telangiectasias) (see Figure 41-22). Early tumors are
so small they are not clinically apparent. The lesion grows slowly, often ulcerates, develops crusts, and is firm to the touch. If left untreated, basal cell lesions invade surrounding tissues and, over months or years, can destroy a nose, eyelid, or ear (for treatment, see Box 41-1). Metastasis is rare because these tumors do not invade blood or lymph vessels.

![Types of Basal Cell Carcinoma](image)

**Squamous Cell Carcinoma**

*Squamous cell carcinoma (SCC)* of the skin is a tumor of the epidermis and is the second most common human cancer. Two types are characterized: in situ (including Bowen disease) and invasive. Ultraviolet radiation exposure causes SCC and actinic keratosis is a precursor lesion. Other risk factors include arsenic at a higher level in drinking water, exposure to x-rays and gamma rays, immunosuppression, and light-
colored skin. P53 gene mutations are common in SCC and produce tumor cells resistant to apoptosis.\textsuperscript{72}

Premalignant lesions include actinic keratosis, leukoplakia (whitish discolored areas), scars, radiation-induced keratosis, tar and oil keratosis, and chronic ulcers. In situ SCC is usually confined to the epidermis (intraepidermal) but may extend into the dermis. Bowen disease is a dysplastic epidermal lesion often found on unexposed areas of the body such as the penis and demonstrated by flat, reddish, scaly patches. These lesions rarely invade surrounding tissue and, although they rarely metastasize, they do so more often than BCCs. Other components of the skin (e.g., sweat glands, hair follicles) can develop into skin cancer, but this is relatively uncommon.

SCC is the most common cause of lip cancer, prevalent in older white men, with about 3000 new cases per year.\textsuperscript{74} The lower lip is the most common site. Long-term environmental exposure results in dryness, chapping, hyperkeratosis, and predisposition to malignancy. Immunosuppression, pipe smoking, and chronic alcoholism increase the risk for lip cancer. The most common lesion is termed exophytic and usually develops in the outer part of the lip along the vermilion border. The lip becomes thickened and evolves to an ulcerated center with a raised border (Figure 41-23). These lesions have an irregular surface, follow cracks in the lip, and tend to extend toward the inner surface.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{lip_cancer.jpg}
\end{figure}

Invasive SCC can arise from premalignant lesions of the skin; it rarely develops from normal-appearing skin and is usually confined to the epidermis.
(intraepidermal), but may extend into the reticular layer of the dermis (see Table 41-1). Invasive SCCs grow more rapidly than basal cell carcinomas and can spread to regional lymph nodes. These tumors are firm and increase in both elevation and diameter. The surface may be granular and bleed easily (Figure 41-24). Treatment includes surgical excision and radiotherapy with consideration of adjuvant chemotherapy or epithelial growth factor receptor inhibitors for advanced disease.75

**FIGURE 41-24**  Squamous Cell Carcinoma. The sun-exposed ear is a common site for squamous cell carcinoma. (Courtesy Department of Dermatology School of Medicine, University of Utah, Salt Lake City Utah.)

**Cutaneous Melanoma**

*Cutaneous melanoma* is a malignant tumor of the skin originating from melanocytes, cells that synthesize the pigment melanin, and arise from the neural crest. Malignant melanoma is the most serious skin cancer with an estimated 73,870 new cases and 9940 deaths in the United States in 2015.74 Melanoma also can arise in the uvea of the eye and on mucous membranes.76 The incidence is increasing worldwide. Risk factors include a personal or family history, or both, ultraviolet radiation (UVR) exposure (including sunbed use before age 30 years), immunosuppression, fair hair, light skin with repeated sunburns, freckles, younger females and older males, geographic location, past pesticide exposure, and three or more clinically atypical (dysplastic) nevi77 (see *Health Alert: Melanoma in Non-White People*). Melanoma is the most common cancer in white women 25 to 29 years old.78
Melanoma in Non-White People

The risk of melanoma is lower in non-white people. However, they have more advanced disease when diagnosed and a higher death rate. Associated factors include location of the lesion on palms, soles, and subungual sites (e.g., acral lentiginous melanoma) and lower socioeconomic status and education level. These melanomas may represent molecular distinct cancers that are inherently more aggressive. The location of the lesions may contribute to delayed detection or misdiagnosis. The role of ultraviolet radiation in the risk for melanoma in non-white people is not clear and research is needed. Genetic mutations may be a contributing factor. Educational programs to increase awareness of risk for melanoma among non-white people, screening, and self-examination can improve outcomes.

Cutaneous melanomas arise as a result of malignant degeneration of melanocytes located either along the basal layer of the epidermis (see Figure 41-1) or in a benign melanocytic nevus. The clinical varieties of cutaneous melanoma include superficial spreading melanoma (SSM), the most common; lentigo malignant melanoma (LMM) (Figure 41-25), frequently found in the elderly and confused with age spots; primary nodular melanoma (PNM), an aggressive tumor; and acral lentiginous melanoma (ALM). It is rare and aggressive and occurs on non–hair-bearing surfaces (i.e., palms of the hands and soles of the feet) and mucous membranes in black people.
The pathogenesis of malignant melanoma is complex. Most familial melanomas are associated with cyclin-dependent kinase 4 gene (CDK4) and cyclin-dependent kinase inhibitor 2A gene (p16/CDKN2A), located on chromosome 9p21. The CDKN2A gene encodes two potent tumor-suppressor proteins (p16 and p14ARF) that are cell-cycle inhibitors. Both CDKN2A and CDK4 are highly penetrant susceptibility genes and result in melanomas. A number of proto-oncogenes have been identified, including BRAF point mutations and genes involved in the regulation of mitogen-activated protein kinase (MAPK), and other signaling pathways. Melanomas have a high mutation rate stimulated by UVR, making gene sequencing difficult.79

The relationship between nevi and melanoma makes it important for the clinician to understand the various forms of nevi (see Table 41-7). Most nevi never become suspicious; however, suspicious pigmented nevi need to be evaluated and removed.71 Indications for biopsy, including sentinel lymph node biopsy, are color change, size change, irregular notched margin, itching, bleeding or oozing, nodularity, scab formation, and ulceration or an unusual pattern of presentation. The ABCDE rule is used as a guide: Asymmetry, Border irregularity, Color variation, Diameter larger than 6 mm, and Elevation or Evolving, which includes raised appearance or rapid enlargement. Staging is determined by lesion thickness (presence of tumor), lymph node involvement, and presence of metastasis (TNM staging).80

Treatment of melanoma with no evidence of metastatic disease involves a wide
surgical excision of the primary lesion site. A lymph node biopsy of the peripherally draining lymph node (sentinel node) is warranted for lesions greater than 1 mm deep. Lesions on the extremities have the best surgical prognosis. Radiation therapy, chemotherapy, and immunotherapy inhibiting the MAPK pathway and BRAF mutations are used to treat metastatic disease and have demonstrated long-term improvement in disease outcome. Promising new immunotherapies are used for advanced disease, including checkpoint inhibitors (anti-PD1 antibodies [pembrolizumab, nivolumab], anti-CTLA4 antibody [ipilimumab]), and targeted therapy (BRAF and/or MEK inhibition). Vaccines, cell therapy, and biomarkers are under continuing investigation. Early detection is critical to decreasing mortality from metastatic disease.

**Kaposi Sarcoma**

*Kaposi sarcoma (KS)* is a vascular malignancy associated with immunodeficiency states and occurs among transplant recipients taking immunosuppressive drugs. Genetic and environmental cofactors determine disease progression. Human herpesvirus type 8 (HHV8) is found in the lesions of KS. Four forms of the disease have been described: classic (more benign), epidemic (rapidly progressive and associated with AIDS), African endemic, and iatrogenic (associated with immunosuppressant treatment including organ transplant).

The endothelial cell is thought to be the progenitor of KS. The lesions emerge as purplish brown macules and develop into plaques and nodules with angioproliferation. They tend to be multifocal rather than spreading by metastasis. The lesions initially appear over the lower extremities in the classic form (Figure 41-26). The rapidly progressive form associated with AIDS tends to spread symmetrically over the upper body, particularly the face and oral mucosa. The lesions are often pruritic and painful. About 75% of individuals with epidemic KS have involvement of lymph nodes, particularly in the gastrointestinal tract and lungs. Organ involvement is much less common in the classic form. The rapidly progressive form has a poor prognosis and shorter survival rates than the classic form. (See Chapter 8 for a further discussion of AIDS.)
Diagnosis is by medical history, physical examination, and skin biopsy, with a high index of suspicion for those with immunodeficiency. Chest x-ray reveals lesions in the lungs. Local lesions can be excised. Multiple disseminated lesions may be treated with a combination of α-interferon, radiotherapy, and cytotoxic drugs. Antiangiogenic agents are being tested. Individuals receiving highly active antiretroviral therapy (HAART) have a markedly reduced incidence of KS.85

**Primary Cutaneous Lymphomas**

**Primary cutaneous lymphomas** are cutaneous T-cell and B-cell lymphomas present in the skin without evidence of extracutaneous disease at the time of diagnosis (see Chapter 21 for classification and general pathophysiology of lymphomas). Cutaneous lymphomas are rare but are the second most common site of extranodal non-Hodgkin lymphoma. The incidence rate is about 1 per 100,000 and the cause of these lesions is unknown.86 Cutaneous lymphomas are more common in men and generally present after age 50 years.

Cutaneous lymphomas develop from clonal expansion of B cells, T-helper cells, and rarely T-suppressor cells. The most common is cutaneous T-cell lymphoma (66%), and mycosis fungoides is the most prominent subtype. **Mycosis fungoides** can present as focal or widespread erythematous patches or plaques, follicular papules, comedone-like lesions, and tumors. There may be patches of alopecia. The lesions progress over a period of months or years.

The differential diagnosis of the different types of cutaneous lymphomas is based on clinical manifestations, histologic appearance, immunologic and cytogenetic features, and response to appropriate treatment. Treatment is based on staging of the
disease and includes topical and systemic drugs and phototherapy.\(^\text{87,88}\)

Quick Check 41-7

1. What is the most common skin cancer?
2. What malignancy can arise from melanocytes?
3. How is Kaposi sarcoma related to AIDS?

Burns

The incidence of burn injuries has declined in the past several years. About 1 million people are burned in the United States each year, with 486,000 visits to hospital emergency departments, 40,000 hospitalizations, and 3240 smoke inhalation or burn-related deaths with a 96.7% survival rate. Most burns occur in the home, and the highest percentage (69%) occurs in men.\(^\text{89}\) Burns may be caused by thermal or nonthermal sources including chemical, electrical, or radioactive sources. Thermal injuries result from thermal contact, scalds, or radiation. Direct contact, inhalation, and ingestion of acids, alkalis, or blistering agents cause chemical burns. Electrical burns occur with the passage of electrical current through the body to the ground or electrical flames or flashes. In addition to cutaneous injury, burns can be associated with smoke inhalation and other traumatic injuries that exacerbate local and systemic responses. Ventilatory support is often needed with inhalation injury.\(^\text{90}\)

Burn Wound Depth

The depth of injury identifies the level of tissue destruction; the extent of injury determines clinical management, healing, and mortality. The depth of the burn is divided into four categories and is summarized in Table 41-8.
### TABLE 41-8
Depth of Burn Injury

**First-degree burns** require no treatment unless the person is elderly or an infant, in which case severe nausea and vomiting may lead to inadequate fluid intake and dehydration. Fluid therapy may be required in these cases. First-degree burns heal in 3 to 5 days without scarring.

**Second-degree burns** involve thin-walled, fluid-filled blisters that develop within just a few minutes after injury (Figure 41-27). Tactile and pain sensors remain intact throughout the healing process, and wound care can cause extreme pain. Wounds heal in 3 to 4 weeks with adequate nutrition and no wound complications. Scar formation is unusual and is genetically determined.
Deep partial-thickness burns (Figure 41-28) look waxy white and take weeks to heal. Necrotic tissue is surgically removed followed by an application of the person's own unburned skin from another body area (autograft). Healing commonly results in hypertrophic scarring with poor functional and cosmetic results (Figure 41-29).
Third-degree burns, or full-thickness burns, have a dry, leathery appearance from loss of dermal elasticity (Figure 41-30). In areas of circumferential burns,
distal circulation may be compromised from pressure caused by edema. **Escharotomies** (tissue decompression by cutting through burned skin) are performed to release pressure and prevent compartment syndrome (the compression of blood vessels, veins, muscles, or abdominal organs resulting in ischemia, necrosis, and irreversible injury).91 Full-thickness burns are painless because all nerve endings have been destroyed by the injury. **Fourth-degree burns** require skin grafting or reconstructive surgery.

The extent of **total body surface area (TBSA)** burned is estimated using either the “rule of nines” (**Figure 41-31**) or the modified Lund and Browder chart.92 The severity of burn injury also considers many factors, including age, medical history, extent and depth of injury, and body area involved. The American Burn Association has defined criteria to assist healthcare professionals in identifying who should be referred to a specialized multidisciplinary burn center (available at: http://ameriburn.org/BurnCenterReferralCriteria.pdf).
Pathophysiology and clinical manifestations

Burn injury results in dramatic changes in many physiologic functions of the body within the first few minutes after the event. Burns exceeding 20% of TBSA in most adults are considered to be major burn injuries and are associated with massive evaporative water losses and fluctuations of large amounts of fluids, electrolytes, and plasma proteins into the body tissues, manifested as generalized edema, circulatory hypovolemia, and hypotension.

The immediate (acute) systemic physiologic consequences of major burn injury focus on the profound, life-threatening hypovolemic shock that occurs in conjunction with cellular and immunologic disruption within a few minutes of injury (Figure 41-32). **Burn shock** is a condition consisting of a hypovolemic cardiovascular component and a cellular component.
Hypovolemia associated with burn shock results from massive fluid losses and shifts to the interstitial space from the circulating blood volume. The losses are caused by an increase in capillary permeability that persists for approximately 24 hours after burn injury. There is decreased cardiac contractility and decreased blood volume. Blood is shunted away from the liver, kidney, and gut—known as the “ebb phase” of the burn response. This phase lasts during the first 24 hours after burn injury and most organ systems are affected. Decreased perfusion of the viscera can decrease gut barrier function and result in translocation of bacteria and endotoxemia with sepsis. Intravenous fluid resuscitation is critical to restore the circulating blood volume during this phase, often using lactated Ringer solution. The rate of fluid replacement must be carefully monitored to prevent complications associated with fluid overload. Formulas are available (i.e., Parkland formula or the modified Brooke formula) to guide calculation of fluid volume replacement.\(^93,^94\)
Cellular metabolism is disrupted with onset of the burn wound, resulting in altered cell membrane permeability and loss of normal electrolyte homeostasis. Many cytokines and inflammatory mediators in burn serum play a role in these cellular processes. The cardiovascular and systemic responses to burn injury are integrated with the cellular response but are described separately for clarification.

**Cardiovascular and Systemic Response to Burn Injury**

The clinical manifestations of burn shock are the result of multiple physiologic alterations related to burn injury and release of inflammatory cytokines, in addition to the loss of fluid. The hallmark of burn shock is decreased cardiac contractility and decreased cardiac output with inadequate capillary perfusion in most tissues. Decreased cardiac output is related to myocardial depressant factor, as well as decreased intravascular volume.

Fluid and protein movement out of the vascular compartment results in an elevated hematocrit level and white blood cell count, and hypoproteinemia. If not treated immediately, profound hypovolemic shock and inadequate perfusion lead to irreversible shock and death within a few hours. Restoration of capillary integrity and renewal of a functional lymphatic system are required for resolution of the edema. Usually this occurs within 24 hours, but in extensive burns, it may take days or weeks. After the individual has reached the endpoint of burn shock, the term used to describe the person's condition is capillary seal.

The liver, with its metabolic, inflammatory, immune, and acute phase functions, plays a pivotal role in burn injury survival and recovery by modulating multiple metabolic pathways. Hepatic changes are common following a major burn, including fatty changes and hepatomegaly, which can influence burn wound recovery. The hepatic response also alters clotting factors, leads to a hypercoagulable state, and can increase the risk for disseminated intravascular coagulation (systemic formation of microthrombi and abnormal bleeding).

**Cellular Response to Burn Injury**

In addition to capillary endothelial permeability changes resulting in vascular fluid, electrolyte, and protein losses, there are transmembrane potential changes in cells not directly damaged by heat. Cellular dysfunction resulting from burn injury impairs the sodium-potassium pump and results in increased amounts of intracellular sodium and water and decreased potassium level with disruption of the transmembrane potential. Intracellular calcium concentration also may be elevated, thereby influencing myocardial function. Loss of intracellular magnesium and phosphate, hypocalcemia, and elevated serum lactic dehydrogenase (LDH) level
Metabolic Response to Burn Injury

Major burn injury (greater than 40% of total body surface area) initiates a systemic hypermetabolic response with an increase in metabolic rate and a hyperdynamic circulation that begins 24 hours after burn injury—known as the “flow phase.” This phase can persist for up to 2 years following a burn. Metabolic responses involve the sympathetic nervous system and other homeostatic regulators. Levels of catecholamines, cortisol, glucagon, and insulin (insulin resistance) are elevated with a corresponding increase in energy expenditure and increased gluconeogenesis, glycogenolysis, lipolysis, proteolysis, and lactic acidosis. Myocardial oxygen consumption is elevated and there is catabolic loss of muscle mass. Hyperglycemia and insulin resistance can be prolonged in severe burns and require management with intensive insulin therapy to improve postburn morbidity and mortality.

Burn injury initiates an inflammatory response with local activation and recruitment of inflammatory cells, such as leukocytes and monocytes, at the site of injury. These cells release inflammatory cytokines that contribute to the hypermetabolic state. The metabolic rate increases in proportion to burn size and compensates for the profound water and heat loss associated with the burn. The inflammatory response and the release of cytokines at the wound level are magnified into a generalized systemic inflammatory response syndrome that can lead to multiple organ dysfunction. Acute kidney injury is associated with hypovolemia, hypervolemia, and the inflammatory response.

Hypermetabolism also increases the thermal regulatory set point and core and skin temperatures. There is persistent tachycardia, hypercapnia, and body wasting. Wound healing may be impaired, contributing to increased risk for infection and sepsis. Increasing the ambient temperature and early excision and grafting can decrease resting energy expenditure and improve mortality after major burns. Inflammatory mediators circulating to the lung result in pulmonary edema that can be life-threatening.

Immunologic Response to Burn Injury

The immunologic/inflammatory response to burn injury is immediate, prolonged, and severe. The result in individuals surviving burn shock is immunosuppression with increased susceptibility to potentially fatal systemic burn wound sepsis. White blood cells are altered at a time when their need to inhibit sepsis is vital. Phagocytosis is impaired, and cellular and humoral immunity is abnormal.
Individuals with altered immunocompetence or chronic disease before burn injury are at additional risk for complications, including wound sepsis.\textsuperscript{112}

Macrophages, neutrophils, lymphocytes, and platelets release large amounts of inflammatory cytokines and antibodies, with their levels remaining elevated for weeks after burn injury. When combined with bacterial products, they produce peripheral vasodilation, pulmonary vasoconstriction, increased capillary permeability, and local tissue ischemia in the burn wound. There is distant organ dysfunction and multiple organ failure.\textsuperscript{113}

**Evaporative Water Loss**

With major burn injury, there is loss of the skin's barrier function and ability to regulate evaporative water loss. Normally, the skin is the major source of insensible water loss (75%), and the lungs are minor sources (25%), with a total loss of only approximately 600 to 800 ml/day. This changes dramatically with burns because both the skin and the lungs have increased loss of water as a result of hypermetabolism and hyperventilation, especially in an intubated individual. Total evaporative losses exceed many liters per day in an adult with large burn wounds. Replacement of the loss is mandatory to prevent volume deficit and shock.

**Evaluation and treatment**

Burn recovery is complex and prolonged with complications being the rule rather than the exception. Severity of inhalation injury is also a significant morbidity and mortality factor. The goal of burn management is wound débridement and closure in a manner that promotes survival. Scar formation with contractures is often a consequence of healing in deep partial-thickness and third-degree burns (Figure 41-33).
The essential elements of survival of major burn injury are (1) provision of adequate fluids and nutrition, (2) meticulous management of wounds with early surgical excision and grafting (Figure 41-34), (3) aggressive treatment of infection or sepsis, and (4) promotion of thermoregulation.\textsuperscript{113} Several drugs are used for the management of severe burns, including β-adrenergic antagonists, β-adrenergic agonists, recombinant human growth hormone, insulin, androgenic steroids, and antibiotics.\textsuperscript{101} Burn pain is almost always acute and severe, and treatment strategies are aggressive.\textsuperscript{114} The risk of developing stress ulcers (Curling ulcers) is reduced with antacids or histamine H2-receptor antagonists.
Nutritional therapy focuses on early enteral therapy to reduce gut-mediated sepsis and to reduce the catabolic state.\textsuperscript{115,116} Advancements in skin replacement procedures promote wound closure and healing.\textsuperscript{117,118} Reconstructive surgery reduces complications associated with scarring and contractures.\textsuperscript{119}

**Cold Injury**

Exposure to extreme cold includes a spectrum of injuries\textsuperscript{120}:

1. *Frostnip*—mild and completely reversible injury characterized by skin pallor and numbness

2. *Chilblains*—more serious than frostnip; violaceous skin color with plaques or nodules, pain, and pruritus, but no ice crystal formation; chronic vasculitis can develop and is usually located on the face, anterior lower leg, hands, and feet

3. *Frostbite*—tissues freeze and form ice crystals at temperatures less than 28° F (−2° C); progresses from distal to proximal and potentially reversible

4. *Flash freeze*—rapid cooling with intracellular ice crystals associated with contact with cold metals or volatile liquids

The most common areas affected are fingers, toes, ears, nose, and cheeks. Mild frostbite (frostnip) is cold exposure without tissue freezing. It causes pallor and pain
followed by redness and discomfort during rewarming, with no tissue damage. Frostbite occurs when tissues freeze slowly with ice crystal formation. Frozen skin becomes white or yellowish and has a waxy texture. There is numbness and no sensation of pain. Frostbite injury is related to direct cold injury to cells, indirect injury from ice crystal formation, and endothelial cell damage. During rewarming, there is progressive microvascular thrombosis followed by reperfusion injury with release of inflammatory mediators (including thromboxanes, prostaglandins, bradykinins, and histamines) and with impaired circulation and anoxia to the exposed area. Cyanosis and mottling develop followed by redness, edema, and burning pain on rewarming in more severe cases. Edema can cause capillary compression and vascular stasis. Within 24 to 48 hours, vesicles and bullae appear that resolve into crusts that eventually slough, leaving thin, newly formed skin. Frostbite may be classified by depth of injury: superficial includes partial skin freezing (first degree) and full-thickness skin freezing (second degree); deep includes full-thickness and subcutaneous freezing (third degree) and deep tissue freezing (fourth degree). Third-degree and fourth-degree frostbite result in gangrene with loss of tissue.\textsuperscript{121}

Immediate treatment of frostbite is to cover affected areas with other body surfaces and warm clothing. The area should not be rubbed or massaged. Rewarming for severe frostbite should occur after emergency transport. Immersion in a warm water bath (40° to 42° C, or 104° to 107.6° F) until frozen tissue is thawed is the best treatment. Pain is severe and should be treated with potent analgesics. Antibiotics may be given. Vasodilators, thrombolitics, hyperbaric oxygen, and sympathectomy may improve healing responses. Débridement or amputation of necrotic tissue occurs when there is a clear line of demarcation.\textsuperscript{122}
Disorders of the Hair

Alopecia

Alopecia means loss of hair from the head or body. Hair loss occurs when there is disruption in the growth phase of the hair follicle. Hair loss can be associated with systemic disorders such as hypothyroidism and iron deficiency, chemotherapy for cancer, malnutrition, compulsive hair pulling (trichotillomania), traction on hair from braiding and ponytails, use of hair treatment chemicals, hormonal alterations, and immune reactions.\(^{123}\)

Androgenic Alopecia

Androgenic alopecia is localized hair loss and occurs in about 80% of men. It is not a disease but a genetically predisposed response to androgens that clusters in families. Within the distribution of hair over the scalp, androgen-sensitive hair follicles are on top and androgen-insensitive follicles are on the sides and back. In genetically predisposed men, the androgen-sensitive follicles are transformed into vellus follicles. Male-pattern baldness begins with frontotemporal recession and progresses to loss of hair over the top of the scalp. Minoxidil may be used to stimulate hair growth and finasteride (a 5α-reductase inhibitor) may decrease the effect of androgens on hair follicles.\(^{124}\)

Female-Pattern Alopecia

Some genetically susceptible women in their twenties and thirties experience progressive thinning and loss of hair over the central part of the scalp, and prevalence increases with advancing age. Contrary to male-pattern baldness, there is usually no loss of hair along the frontal hairline but the hairs are shorter and thinner (follicular miniaturization). The mechanism of hair loss is unknown but related to genetic and hormonal changes.\(^{125}\)

Alopecia Areata

Alopecia areata is an autoimmune T-cell–mediated chronic inflammatory disease directed against hair follicles and results in hair loss. There is rapid onset of hair loss in multiple areas of the scalp, usually in round patches. The eyebrows, eyelashes, beard, and other areas of body hair are rarely involved. Stressful events, cell-mediated immune cytokines, genetic susceptibility, and metabolic disorders, such as Addison disease, thyroid disease, and lupus erythematosus, are associated with alopecia areata.\(^{126}\)
The affected areas of skin are smooth or may have short shafts of poorly developed hair that breaks at the surface (“exclamation mark” hair). Regrowth occurs within 1 to 3 months, but hair loss may recur at the same site. Permanent regrowth of hair usually occurs. Diagnosis is made by observation of the pattern of hair loss. Biopsy may show a lymphocytic infiltrate around the follicle. There are several treatments for alopecia areata, including corticosteroids and topical immunotherapy, and new treatments are being tested.\textsuperscript{127,128}

**Hirsutism**

**Hirsutism** occurs in women and is the abnormal growth and distribution of hair on the face, body, and pubic area in a male pattern. There is also frontotemporal hair recession. These areas of hair growth are androgen sensitive. Variations of hair growth in women are great, and a male pattern may be normal. Women who develop hirsutism may be secreting hormones associated with polycystic ovarian syndrome, adrenal hyperplasia, or adrenal tumors; and these disorders require treatment. If no hormonal pathologic conditions exist, treatment may include cosmetic removal of hair, suppression of excessive androgen production, or blockage of peripheral androgen receptors.\textsuperscript{129}
Disorders of the Nail

Paronychia

Paronychia is an acute or chronic infection of the cuticle. One or more fingers or toes may be involved. Individuals whose hands are frequently exposed to moisture are at greatest risk. The most common causative microorganisms are staphylococci and streptococci. Occasionally Candida will be present. Acute paronychia is manifested by the rapid onset of painful inflammation of the cuticle, usually after minor trauma. An abscess may develop requiring incision and drainage for relief of pain. The skin around the nail becomes more edematous and painful with progressive infection. Pus may be expressed from the proximal nail fold and an abscess may develop. The nail plate is usually not affected, although it can become discolored with ridges. Chronic paronychia develops slowly, with tenderness and swelling around the proximal or lateral nail folds.\textsuperscript{130}

Treatment includes prevention by keeping the hands dry. Oral antifungals are not effective because they do not penetrate the affected tissues. Topical application of thymol is usually effective.\textsuperscript{131}

Onychomycosis

Onychomycosis (tinea unguium) is a fungal or dermatophyte infection of the nail unit. The most common pattern is a nail plate that turns yellow or white and becomes elevated with the accumulation of hyperkeratotic debris within the plate. Fungal infections of the nail are differentiated from psoriasis, lichen planus, and trauma by culture and microscopy and the absence of pitting on the nail surface, which is characteristic of psoriasis. Treatment is difficult because topical or systemic antifungal agents do not penetrate the nail plate readily. Systemic antifungal drugs are more effective. Surgical excision of the nail may be required. Education is essential to preventing recurrence.\textsuperscript{132}

Quick Check 41-8

1. Describe the three degrees of burn injury.

2. What dangers accompany frostbite?

3. What is alopecia? Compare the different types.
4. What disorders of the nail are seen?
## Geriatric Considerations

### Aging & Changes in Skin Integrity

- Skin becomes thinner, dryer, and more wrinkled.
- DNA repair of damaged skin decreases.
- Epidermal cells contain less moisture and change shape.
- The dermis thins, producing translucent, paper-thin quality that is more susceptible to tearing.
- Dermis becomes more permeable and less able to clear substances, so they accumulate and cause irritation.
- There is a loss of epidermal rete pegs, which weakens the connection to the dermis and gives skin a smooth, shiny, and wrinkled appearance with an increased likelihood to tear from shearing forces.
- There is a loss of elastin, contributing to wrinkling.
- There is a loss of flexibility of collagen fibers, so skin cannot stretch and regain shape as readily.
- The barrier function of the stratum corneum is reduced, increasing risk for injury and infection.
- Significantly decreased number of Langerhans cells reduces the skin's immune response.
- The dermoeidermal border flattens, shortening and decreasing the number of capillary loops.

### Other Skin Changes with Aging

- Wound healing decreases as a result of decreased estrogen in both men and women, decreased blood flow, and slower rate of basal cell and fibroblast turnover.
• There are fewer melanocytes; pigmentation becomes irregular, giving decreased protection from ultraviolet radiation and leading to graying of hair.

• Atrophy of eccrine, apocrine, and sebaceous glands causes dry skin.

• Pressure and touch receptors and free nerve endings decrease in number, causing reduced sensory perception.

• With compromised temperature regulation, loss of cutaneous vasomotion, and decreased eccrine sweat production, there is an increased risk of heat stroke and hypothermia.

• The nail plate thins and nails are more brittle.

Did You Understand?

Structure and Function of the Skin

1. Skin is the largest organ of the body and equals 20% of body weight. The major functions are to provide a protective barrier and to regulate body temperature.

2. The skin has two layers—the dermis and epidermis. The underlying hypodermis contains connective tissue, fat cells, fibroblasts, and macrophages.

3. The epidermis contains basal and spinous layers with melanocytes, Langerhans cells, and Merkel cells.

4. The dermis is composed of connective tissue elements, hair follicles, sweat glands, sebaceous glands, blood vessels, nerves, and lymphatic vessels.

5. The dermal appendages include nails, hair, and eccrine and apocrine sweat glands.

6. The papillary capillaries provide the major blood supply to the skin, arising from deeper arterial plexuses.

7. Heat loss and heat conservation are regulated by arteriovenous anastomoses that lead to the papillary capillaries in the dermis.

8. Pressure ulcers develop from pressure and shearing forces that occlude capillary blood flow with resulting ischemia and necrosis. Areas at greatest risk are pressure points over bony prominences, such as the greater trochanters, sacrum, ischia, and heels.

9. Keloids are sharply elevated scars that extend beyond the border of traumatized skin. Hypertrophic scars do not extend beyond the border of injury.

10. Pruritus is itching and is associated with many skin disorders. Small unmyelinated type C nerve fibers transmit itch sensation.

Disorders of the Skin

1. Allergic contact dermatitis is a form of delayed hypersensitivity that develops with sensitization to allergens, such as metal, chemicals, or poison ivy.
2. Irritant contact dermatitis develops from prolonged exposure to chemicals, such as acids or soaps, with disruption of the skin barrier.

3. Atopic or allergic dermatitis is associated with a family history of allergies, hay fever, elevated IgE levels, and increased histamine sensitivity. Pruritus and scratching predispose the skin to infection, scaling, and thickening.

4. Stasis dermatitis occurs on the legs and results from chronic venous stasis and edema.

5. Seborrheic dermatitis involves scaly, yellowish, inflammatory plaques of the scalp, eyebrows, eyelids, ear canals, chest, axillae, and back. The cause is unknown but Malassezia yeasts have been implicated.

6. Papulosquamous disorders are characterized by papules, scales, plaques, and erythema.

7. Psoriasis is a chronic inflammatory skin disease associated with a complex inflammatory cascade involving multiple immune cells resulting in cellular proliferation of both the epidermis and the dermis; it is characterized by scaly, erythematous, pruritic plaques.

8. Pityriasis rosea is a self-limiting inflammatory disease characterized by oval lesions with scales around the edges; it is located along skin lines of the trunk and may be caused by a herpes-like virus.

9. Lichen planus is an autoimmune papular, violet-colored inflammatory lesion of unknown origin manifested by severe pruritus.

10. Acne vulgaris is an inflammation of the pilosebaceous follicle.

11. Acne rosacea develops on the middle third of the face with hypertrophy and inflammation of the sebaceous glands and is associated with altered innate immune responses.

12. Discoid (cutaneous) lupus erythematosus is an autoimmune disease that can affect only the skin. The systemic form also presents cutaneous lesions. The cutaneous inflammatory lesions usually occur in sun-exposed areas with a butterfly distribution over the nose and cheeks.

13. Pemphigus is a chronic, autoimmune, blistering disease that begins in the mouth
or on the scalp and spreads to other parts of the body, often with a fatal outcome.

14. Erythema multiforme is an acute inflammation of the skin and mucous membranes (bullous form) with lesions that appear target-like with alternating rings of edema and inflammation; it is often associated with T-cell–mediated allergic reactions to drugs.

15. Folliculitis is a bacterial infection of the hair follicle.

16. A furuncle is an infection of the hair follicle that extends to the surrounding tissue.

17. A carbuncle is a collection of infected hair follicles that forms a draining abscess.

18. Cellulitis is a diffuse infection of the dermis and subcutaneous tissue.

19. Erysipelas is a superficial streptococcal infection of the skin commonly affecting the face, ears, and lower legs.

20. Impetigo may have a bullous or an ulcerative form and is caused by *Staphylococcus* or *Streptococcus*.

21. Herpes simplex virus type 1 (HSV-1) causes cold sores but can infect the cornea, mouth, and labia. HSV-2 causes genital lesions and is usually spread by sexual contact.

22. Herpes zoster (shingles) and varicella (chickenpox) are both caused by the varicella-zoster virus.

23. Warts are benign, rough, elevated lesions caused by human papillomavirus. Condylomata acuminata, or venereal warts, are spread by sexual contact.

24. Tinea infections (fungal infections) can occur anywhere on the body and are classified by location (i.e., tinea pedis, tinea corporis, tinea capitis).

25. Candidiasis is a yeastlike fungal infection (*Candida albicans*) occurring on skin and mucous membranes and in the gastrointestinal tract.

26. Cutaneous vasculitis is an inflammation of skin blood vessels related to immune complex deposition with purpura, ischemia, and necrosis resulting from vessel
necrosis.

27. Urticarial lesions are commonly associated with type I hypersensitivity responses and appear as wheals, welts, or hives.

28. Scleroderma is an autoimmune-mediated sclerosis of the skin that may also affect systemic organs and cause renal failure, bowel obstruction, or cardiac dysrhythmias.

29. Ticks transmit numerous diseases including Lyme disease caused by an immune response to the spirochete *Borrelia burgdorferi*.

30. Seborrheic keratosis is a proliferation of basal cells that produce elevated, smooth, or warty lesions of varying size. They are most common among the elderly population.

31. Keratoacanthoma arises from hair follicles on sun-exposed areas. Three stages of development characterize the lesion, which results in a dome-shaped, crusty lesion filled with keratin that resolves in 3 to 4 months.

32. Actinic keratosis is a pigmented scaly lesion that develops in sun-exposed individuals with fair skin. The lesion may become malignant in the form of a squamous cell carcinoma.

33. Nevi arise from melanocytes and may be pigmented or fleshy pink. They occur singly or in groups and may undergo transition to malignant melanoma.

34. Basal cell carcinoma is the most common skin cancer and occurs most often on ultraviolet-exposed areas of the skin.

35. Squamous cell carcinoma is a tumor of the epidermis and can be localized (in situ) or invasive.

36. Cutaneous malignant melanoma arises from melanocytes, and if not excised early, metastasis occurs through the lymph nodes.

37. Kaposi sarcoma is a vascular malignancy associated with herpesvirus-8 and immunodeficiency.

38. Burns are classified according to depth and extent of injury as first-, second-, third-, or fourth-degree burns.
39. Severe burns cause profound edema and burn shock related to an inflammatory response throughout the cardiovascular system with loss of capillary seal. Fluid resuscitation is critical to prevent shock and death.

40. Burns cause a hypermetabolic response with increased cortisol, glucagon, and insulin levels and with gluconeogenesis.

41. Immune suppression associated with inflammatory cytokine release from burned tissue increases risk for infection and can delay wound healing.

42. Cold injury usually occurs on the face and digits, with direct injury to cells and impaired circulation.

**Disorders of the Hair**

1. Alopecia is loss of hair from the head or body.

2. Male-pattern alopecia is an inherited form of irreversible baldness with hair loss in the central scalp and recession of the frontotemporal hairline.

3. Female-pattern alopecia is a thinning of the central hair of the scalp beginning in women at 20 to 30 years of age.

4. Alopecia areata is an autoimmune-mediated loss of hair and may be associated with stress or metabolic diseases; it is usually reversible.

5. Hirsutism is a male pattern of hair growth in women that may be normal or the result of excessive secretion of androgenic hormones.

**Disorders of the Nail**

1. Paronychia is an inflammation of the cuticle that can be acute or chronic and is usually caused by staphylococci, streptococci, or fungi.

2. Onychomycosis is a fungal infection of the nail plate.

</table>
Children frequently develop alterations of the skin, which may be minor or severe and localized or generalized. Skin diseases in children may have different causative mechanisms and different patterns of distribution than those found in adults, although there may be similarities. Some skin diseases resolve spontaneously and require no treatment. Diagnosis is commonly made from the history, appearance, and distribution of the lesion or lesions. Common skin diseases of childhood are presented here.
Acne Vulgaris

Acne vulgaris is the most common skin disease and occurs primarily between the ages of 12 and 25 years. Acne tends to occur in families, and genetic susceptibility may determine the severity of the disease. The incidence of acne is the same in both genders, although severe disease affects males more often.\(^1\) Diets high in simple carbohydrates and dairy products are associated with acne.\(^2\)-\(^4\)

Acne develops at distinctive pilosebaceous units known as sebaceous follicles. Located primarily on the face and upper parts of the chest and back, these follicles have many large sebaceous glands, a small vellus hair (very short, nonpigmented, and very thin hair), and a dilated follicular canal that is visible as a pore on the skin surface. Acne lesions may be noninflammatory or inflammatory (cystic) (Figure 42-1). In noninflammatory acne, the comedones are open (blackheads) and closed (whiteheads), with the accumulated material causing distention of the follicle and thinning of follicular canal walls. Inflammatory (cystic) acne develops in closed comedones when the follicular wall ruptures, expelling sebum into the surrounding dermis and initiating inflammation. Pustules form when the inflammation is close to the surface; papules and cystic nodules can develop when the inflammation is deeper, causing mild to severe scarring. Both types of lesions may exist in the same individual.

![Image of acne lesions](image-url)

The principal causative factors are (1) hyperkeratinization of the follicular epithelium, (2) excessive sebum production, (3) follicular proliferation of anaerobic Propionibacterium acnes, and (4) inflammation and rupture of a follicle from accumulated debris and bacteria (see Figure 42-1). P. acnes shifts from being symbiotic to pathogenic and from being noninflammatory to inflammatory. The causal mechanism is unknown.\(^5\) Androgens (dehydroepiandrosterone sulfate and testosterone), synthesized in increasing amounts during puberty, increase the size
and productivity of the sebaceous glands, which promotes *P. acnes.* *P. acnes* produces extracellular porphyrins and proinflammatory molecules, including chemotactic factors and lipolytic and proteolytic enzymes. The hydrolytic action of the enzymes converts triglycerides into free fatty acids (FFAs). FFAs activate Toll-like receptors, T-cell–associated and Th17-associated inflammation, and edema that results in pus formation and breakdown of the follicle wall.\(^6\)

The treatment of acne should be individualized according to severity. Combinations of a topical retinoid, benzoyl peroxide, and antimicrobial agents are preferred. Retinoids are anticomedogenic and comedolytic and have some anti-inflammatory effects. Benzoyl peroxide is antimicrobial with some keratolytic effects. Antibiotics have anti-inflammatory and antimicrobial effects. Use of systemic therapies, including oral antibiotics, sex hormones, corticosteroids, and isotretinoin (requires pregnancy prevention), may be limited by side effects.\(^7\) Acne surgery, including comedo extraction, intralesional steroids, and cryosurgery, is useful in selected individuals. Severe scarring may be treated with dermabrasion, lasers, and resurfacing techniques. Diets should avoid high glycemic index foods. Psychologic support is important because acne negatively affects quality of life, self-esteem, and mood in adolescents and is associated with an increased risk of anxiety, depression, and suicidal ideation.\(^8\) Special consideration must be given to treatment for those with darker skin because they have greater risk for hyperpigmentation and keloidal scarring.\(^9\) Research is continuing on the development of vaccines to prevent acne.\(^{10}\)

**Acne conglobata** is a highly inflammatory form of acne with communicating cysts and abscesses beneath the skin that can cause scarring. Remissions tend to occur during the summer, perhaps from more exposure to sunlight. This type of acne requires the use of systemic and combination therapies to prevent drug resistance.

**Hydradinitis suppurativa (inverse acne)** is a chronic, inflammatory disease characterized by recurrent abscesses, sinus tract formation, and scarring. There is hyperkeratosis and occlusion of the pilosebaceous follicular ducts involving areas of skin where there are folds, hair follicles, and apocrine (sweat) glands (i.e., axillary, inguinal, inframammary, genital, buttocks, and perineal areas of the body). The cause is unknown but the incidence is estimated at 1% to 4% of the population and is more common in females. Aggravating factors include obesity, stress, and smoking. The lesions present as deep, firm, painful subcutaneous nodules that track and rupture horizontally under the skin. Treatment can include incision and drainage of nodules, culture of exudate, and administration of antibiotics (with concern about the presence of methicillin-resistant *Staphylococcus aureus* [MRSA]), topical or intralesional corticosteroids, and retinoids. The disease can recur for years with
negative effects on quality of life.\textsuperscript{11}
Dermatitis

Atopic Dermatitis

Atopic dermatitis (AD), also known as atopic eczema, is the most common cause of eczema in children. The prevalence is up to 20% in children and approximately 3% of adults in the United States and other industrialized countries. More than half of these individuals develop asthma and allergies later in life. Onset is usually from 2 to 6 months of age, and 85% of cases develop within the first 5 years of life.

The cause of this chronic relapsing form of pruritic eczema involves an interplay of genetic predisposition; altered skin barrier function associated with filaggrin gene mutations and filaggrin deficiency (proteins that bind keratin in the epidermis); reduced ceramide (a stratum corneum lipid) levels; decreased antimicrobial peptides; altered innate immunity; and altered immune responses to allergens, irritants, and microbes. Filaggrin gene mutations also are associated with increased risk for asthma in AD and ichthyosis vulgaris (dry, scaly skin) (Figure 42-2). There is an altered skin microbiome with formation of biofilm by S aureus that may act as super-antigens causing exacerbations of eczema.
AD has a constellation of clinical features that include severe pruritus and a characteristic eczematoid appearance with redness, edema, and scaling. The skin becomes increasingly dry, itchy, sensitive, and easily irritated because the barrier function of the skin is impaired. Itching is the hallmark of atopic dermatitis and rubbing and scratching to relieve the itch are responsible for many of the clinical skin changes of AD. In young children, a rash appears primarily on the face, scalp, trunk, and extensor surfaces of the arms and legs (Figure 42-2). In older children and adults, the rash tends to be found on the neck, antecubital and popliteal fossae, and hands and feet. Individuals with AD also tend to develop viral, bacterial, and fungal skin infections in the eczematous areas. There are no specific laboratory
features of AD that can be used for diagnostic and treatment purposes. Most affected individuals show increased serum levels of immunoglobulin E (IgE) level, interleukin-4, eosinophils (eosinophilia), and positive skin tests to a variety of common food and inhalant allergens.

Management of individuals with AD includes accurate diagnosis and comprehensive evaluation of triggers and response to treatment; management of confounding factors, including sleep disruption; and education of individuals and caregivers. Avoidance of triggers and promotion of skin hydration, including soaking baths and emollients, are key to good therapy. Anti-inflammatory agents, such as topical corticosteroids and calcineurin inhibitors, are necessary during active flare-ups of eczema. Immunomodulator therapy and wet wrap therapy are used for severe eczema. Systemic therapy includes the use of sedating antihistamines and antibiotics. Research is in progress to develop molecule-specific targets to produce long-term disease remission.

**Diaper Dermatitis**

Diaper dermatitis (diaper rash) is a form of irritant contact dermatitis initiated by a combination of factors including prolonged exposure to and irritation by urine and feces as well as maceration by wet diapers or airtight plastic diaper covers. Disposable diaper designs have decreased the incidence of diaper dermatitis in infants. Often, diaper dermatitis is secondarily infected with Candida albicans. The resulting inflammation affects the lower aspect of the abdomen, genitalia, buttock, and upper portion of the thigh.

The lesions vary from mild erythema to erythematous papular lesions. Candidal (monilial) diaper dermatitis is usually very erythematous, with sharp margination and pustulovesicular satellite lesions (Figure 42-3).
Treatment involves frequent diaper changes to keep the affected area clean and dry or regular exposure of the perineal area to air, use of superabsorbent diapers, and topical protection with a product containing petrolatum or zinc oxide, or both. Topical antifungal medication is used to treat *C. albicans* when present.\(^{21}\)

**Quick Check 42-1**

1. What causes the inflammation of acne vulgaris?

2. What lesions are typical of atopic dermatitis in children?
3. What causes diaper dermatitis?
Infections of the Skin

Infectious diseases caused by bacteria, viruses, and fungi constitute the major forms of skin disease. Breaks in the skin integrity, particularly those that inoculate pathogens into the dermis and epidermis, may cause or exacerbate infections. Most infections tend to occur superficially; however, systemic signs and symptoms develop occasionally and can be life-threatening in immunosuppressed children.

Bacterial Infections

**Impetigo Contagiosum**

*Impetigo* is the most common bacterial skin infection in children 2 to 5 years of age. *Staphylococcus aureus* (*S.* *aureus*) and, less commonly, *Streptococcus pyogenes* cause impetigo. The mode of transmission is by both direct and indirect contact. The disease is more common in midsummer to late summer, with a higher incidence in hot, humid climates. Impetigo is particularly infectious among people living in crowded conditions with poor sanitary facilities or in settings such as day-care facilities. It affects children in good health, but conditions such as anemia and malnutrition are predisposing factors.

Bacterial invasion occurs through minor breaks in the cutaneous surface or as a secondary infection of a preexisting dermatosis or infestation. The staphylococci produce bacterial toxins called *exfoliative toxins (ETs)* that cause a disruption in desmosomal adhesion molecules with blister formation. There are two types of impetigo: nonbullous and, more rarely, bullous (caused only by *S. aureus*), where blisters enlarge or coalesce to form bullae (*Box 42-1*). Both forms of impetigo begin as vesicles with a thin vesicular roof composed of stratum corneum that ruptures to form a honey-colored crust (*Figure 42-4*). The lesions are often located on the face, around the nose and mouth, but the hands and other exposed areas also are involved. Impetigo is clinically characterized by crusted erosions or ulcers that may arise as a primary infection or as a secondary infection of a preexisting dermatosis or infestation.

---

**Box 42-1**

**Impetigo**

**Vesicular Impetigo**

- Contagious, acute, superficial, vesiculopustular, and most common form
• Caused by group A *Streptococcus pyogenes* (alone or with *S. aureus*)

• Spread by direct physical contact with other infected individuals or through insect bites

• Presents as small vesicles with a honey-colored serum; yellow to white-brown crusts form as vesicles rupture and extend radially

• Untreated lesions last for weeks and cover large area

• Regional lymphadenitis common

• Most significant complication is acute glomerulonephritis

• Treatment is aggressive in light of this complication

**Bullous Impetigo**

• Caused by *Staphylococcus aureus*

• Bacterial toxin produced (exfoliative toxin [ET]) causes disruption in cellular adhesion with blister formation

• Occurs in neonates

• Highly contagious

• Source is family member with pustule or asymptomatic carrier with pathogen in anterior nares, perineal region, or fingernails

• Transmitted by contact with individual or contaminated equipment

• Presents with vesicles that enlarge or coalesce to form superficial bullae, few localized lesions, or many lesions scattered over the skin surface; as bullae rupture, thin, flat, honey-colored crust appears (hallmark of impetigo)

• Lesions found on face around the nose and mouth; hands and other exposed areas also susceptible
The treatment of choice for both types of impetigo is topical mupirocin or fusidic acid for uncomplicated lesions. For extensive or complicated impetigo, systemic antibiotics may be warranted but β-lactam antibiotics should be avoided if methicillin-resistant *S. aureus* (MRSA) is suspected. Prompt treatment avoids complications, such as glomerulonephritis, necrotizing fasciitis, and septic shock syndrome. Lesions usually resolve in 2 to 3 weeks without scarring. Using good handwashing techniques and isolating the infected child's washcloth, towels, drinking glass, and linen are important for prevention.

### Staphylococcal Scalded-Skin Syndrome

**Staphylococcal scalded-skin syndrome (SSSS)** is the most serious staphylococcal infection that affects the skin and is usually seen in infants and children younger than 5 years of age. SSSS is caused by virulent group II strains of staphylococci that produce an exfoliative toxin. The toxin attacks desmoglein and adhesion molecules and causes a separation of the skin just below the granular layer of the epidermis (see Figure 41-1). The toxin is usually produced at body sites other than the skin and arrives at the epidermis through the circulatory system. Staphylococci typically are not found in the skin lesions themselves. Adults have circulating antistaphylococcal antibodies and are better able to metabolize and excrete the toxin. Neonates are at the highest risk because of their lack of immunity with no prior exposure to the toxin. A source of the infection in neonates may be from healthcare workers who are nasal carriers of the microorganism. This reinforces the need for good infection control practices with all neonates.
The clinical symptoms begin with fever, malaise, rhinorrhea, and irritability followed by generalized erythema with exquisite tenderness of the skin. There may be an associated impetigo, but the infection often begins in the throat or chest. The erythema spreads from the face and trunk to cover the entire body except for the palms, soles, and mucous membranes. Within 48 hours, blisters and bullae may form, giving the child the appearance of being scalded. The pain is severe (Figure 42-5). Fluid loss from ruptured blisters and water evaporation from denuded areas may cause dehydration. Perioral and nasolabial crusting and fissures develop. In severe cases, the skin of the entire body may slough. When secondary infection can be prevented, healing of the involved skin occurs in 10 to 14 days, usually without scarring.

![Staphylococcal Scalded-Skin Syndrome (SSSS)](image)

**FIGURE 42-5** Staphylococcal Scalded-Skin Syndrome (SSSS). The skin lesions, showing desquamation and wrinkling of the skin margins, appeared 1 day after drainage of a staphylococcal abscess. (From Kliegman RM et al: Nelson textbook of pediatrics, ed 19, St Louis, 2011, Saunders.)

Before medical intervention is initiated, culture and histologic or exfoliative cytologic studies must be performed to differentiate SSSS from *erythema multiforme* and *toxic epidermal necrolysis* (TEN), both of which are usually caused by an immune reaction to drugs.²⁷ When SSSS infection is confirmed, treatment with oral or intravenous antibiotics begins. The skin should be treated in the same manner as a severe burn, with meticulous aseptic technique. Skin substitutes may be used for adjuvant therapy.²⁸ Special care is required when there is involvement of the lips and eyelids.

**Fungal Infections**
**Tinea Capitis**

*Tinea capitis*, a fungal infection of the scalp (scalp ringworm), is the most common fungal infection of childhood. It rarely affects infants and is seen in children between 2 and 10 years of age. The primary microorganism responsible for this disease is *Trichophyton tonsurans*. Microsporum canis also continues to be a pathogenic microorganism in this disease and is found on cats, dogs, and certain rodents. Humans appear to be a terminal host for *M. canis*. Children who handle such animals are possible hosts. Direct transmission between humans does not occur. However, there is direct human transmission of *T. tonsurans* in crowded areas, the most prevalent environment of the fungus.

The lesions are often circular and manifested by broken hairs 1 to 3 mm above the scalp, leaving a partial area of alopecia from 1 to 5 cm in diameter (Figure 42-6). A slight erythema and scaling with raised borders can be observed.

![Figure 42-6 Tinea Capitis](image)

*FIGURE 42-6  Tinea Capitis. (Courtesy Department of Dermatology School of Medicine, University of Utah, Salt Lake City, Utah.)*

Diagnosis is best confirmed by potassium hydroxide (KOH) examination, and fungal culture. Tinea capitis always requires systemic treatment because topical antifungal agents do not penetrate the hair follicle. Several oral antifungal agents, particularly griseofulvin, are available for treatment. Use of Wood's light examination has become less popular because there are a number of dermatophytes that fluoresce under an ultraviolet light.

**Tinea Corporis**
**Tinea corporis (ringworm)** is a common superficial dermatophyte infection in children. The organisms most commonly responsible for this disease are *M. canis* and *Trichophyton mentagrophytes*. As in tinea capitis, contact with young kittens and puppies is a common source of the disorder. Tinea corporis preferentially affects the nonhairy parts of the face, trunk, and limbs. Lesions are often erythematous, round or oval scaling patches that spread peripherally with clearing in the center, creating the ring appearance, which is why this disease is commonly referred to as ringworm. The lesions are distributed asymmetrically, and multiple lesions, when present, overlap. Transmission occurs by direct contact with an infected lesion and through indirect contact with personal items used by the infected person. Potassium hydroxide examination of the scale from the border of the lesions confirms the diagnosis. Most lesions respond well to applications of appropriate topical antifungal medications.

**Thrush**

**Thrush** is the term used to describe the presence of *Candida albicans* in the mucous membranes of the mouths of infants. It occurs less commonly in adults, and infected adults are usually immunocompromised. *C. albicans* penetrates the epidermal barrier more easily than other microorganisms because of its keratolytic proteases and other enzymes. Thrush is characterized by the formation of white plaques or spots in the mouth that lead to shallow ulcers caused by keratolytic proteases from the microorganism. The tongue may have a dense, white covering. The underlying mucous membrane is red and tender and may bleed when the plaques are removed. The disease is often accompanied by fever and gastrointestinal irritation. The infection commonly spreads to the groin, buttocks, and other parts of the body. Treatment may be difficult and includes oral antifungal washes, such as nystatin oral suspension. Simultaneous treatment of a *Candida* nipple infection or vaginitis in the mother is helpful in reducing the *C. albicans* surface colonization of the infant. Feeding bottles and nipples should be sterilized to prevent reinfection. The diaper area should be kept clean and dry.

**Viral Infections**

Viral infections of the skin in children are caused by poxvirus, papovavirus, and herpesvirus.

**Molluscum Contagiosum**

**Molluscum contagiosum** is a common, highly contagious viral infection of the skin
and, occasionally, conjunctiva that affects school-aged children, sexually active young adults, and immunocompromised individuals. The incidence is higher among children who swim or have eczema; however, the mechanism of disease is not clear. The disease is transmitted by skin-to-skin contact or from autoinoculation.

The poxvirus proliferates within the follicular epithelium and induces epidermal cell proliferation. The epidermis grows down into the dermis to form saccules containing clusters of virus. The characteristic molluscum body is composed of mature, immature, and incomplete viruses and cellular debris.

The lesions of molluscum are discrete, slightly umbilicated, dome-shaped papules 1 to 5 mm in diameter that appear anywhere on the skin or conjunctiva. The lesions are mainly on the trunk, face, and extremities in children (Figure 42-7). There is usually no inflammation surrounding molluscum lesions unless they are traumatized or secondary infection occurs. Scarring may occur with healing.

The three best diagnostic procedures are (1) staining smears of the expressed molluscum body, (2) examining a biopsy specimen, or (3) inoculating a molluscum suspension into cell cultures to demonstrate the cytotoxic reactions. Most lesions are self-limiting and clear in 6 to 9 months if not manipulated.

Treatment options include immunomodulatory and antiviral therapy and destructive procedures (cryotherapy, curettage, or laser ablation); however, no treatment is universally effective. Potassium hydroxide solution applications can be
safe, effective, and inexpensive. Treatment is recommended for genital molluscum to prevent sexual transmission and autoinoculation. Measures to prevent spread of infection must be taken. Recurrences are common.

**Rubella (German or 3-Day Measles)**

Rubella is a common communicable disease of children and young adults caused by a ribonucleic acid (RNA) virus that enters the bloodstream through the respiratory route. This disease is mild in most children. The incubation period ranges from 14 to 21 days. Prodromal symptoms include enlarged cervical and postauricular lymph nodes, low-grade fever, headache, sore throat, rhinorrhea, and cough. A faint-pink to red coalescing maculopapular rash develops on the face with spread to the trunk and extremities 1 to 4 days after the onset of initial symptoms (Figure 42-8). The rash is thought to be the result of virus dissemination to the skin. The rash subsides after 2 to 3 days, usually without complication. Children are usually not contagious after development of the rash (Table 42-1).
Rubella (3-Day Measles). A, Typical distribution of full-blown maculopapular rash with tendency to coalesce. B, Rash of rubella. (From Centers for Disease Control and Prevention Image Bank, Figure #712. Available at: http://phil.cdc.gov/phil/. Accessed June 8, 2013.)

</table>

Vaccination for rubella is usually combined with vaccines for mumps and measles (rubeola) (MMR). Measles is known to occur in previously immunized children. The Centers for Disease Control and Prevention vaccine recommendations are available at [www.cdc.gov/vaccines/recs/schedules/default.htm](http://www.cdc.gov/vaccines/recs/schedules/default.htm). Rubella has almost been eliminated in the United States because of vaccination campaigns. However, challenges to maintain elimination include large outbreaks of measles in highly traveled developed countries, frequent international travel, and clusters of U.S. residents who remain unvaccinated because of personal belief exemptions.\(^{38}\) Although MMR vaccine may rarely be associated with adverse neurologic events, studies conclude that MMR immunization does not cause autism.\(^{39}\) Lack of vaccination, however, leads to significant morbidity and mortality with pneumonia, croup, and encephalitis being causes of death worldwide.

Women of childbearing age are immunized if their rubella hemagglutination-inhibition titer is low. Pregnancy should be avoided for 3 months after vaccination because the attenuated virus in the vaccine may remain viable for this period. Pregnant women who have rubella early in the first trimester may have a fetus who develops congenital defects.

There is no specific treatment for rubella. Recovery is spontaneous, although lymph nodes may remain enlarged for weeks. Supportive therapy includes rest, fluids, and use of a vaporizer. In rare cases, a mild encephalitis or peripheral neuritis may follow rubella.

**Rubeola (Red Measles)**
**Rubeola** is a highly contagious, acute viral disease of childhood. Transmitted by direct contact with droplets from infected persons, rubeola is caused by an RNA-containing paramyxovirus with an incubation period of 7 to 12 days, during which there are no symptoms. The virus enters the respiratory tract and attaches to dendritic cells and alveolar macrophages, amplifies in local lymphatic tissue, and progresses to systemic disease. Prodromal symptoms include high fever (up to 40.5°C [104.9°F]), malaise, enlarged lymph nodes, rhinorrhea, conjunctivitis, and barking cough. Within 3 to 4 days, an erythematous maculopapular rash develops over the head and spreads distally over the trunk, extremities, hands, and feet. Early lesions blanch with pressure, followed by a brownish hue that does not blanch as the rash fades. Characteristic pinpoint white spots surrounded by an erythematous ring develop over the buccal mucosa and are known as *Koplik spots*. These spots precede the rash by 1 to 2 days. The rash then subsides within 3 to 5 days.

Complications associated with measles may be caused by the primary infection or by a secondary bacterial infection. Measles encephalitis occurs in about 1 of 800 cases, and most children recover completely. Only a small minority of children develop permanent brain damage or die. Bacterial complications include otitis media and pneumonia, usually caused by group A hemolytic streptococcus, *Haemophilus influenzae*, or *S. aureus* infection.

Measles is prevented by vaccination. As discussed in the Rubella section (p. 1088), immunization is key to prevention. There is no specific treatment for measles, and supportive therapy is the same as that recommended for rubella. Antibiotic therapy is initiated if secondary bacterial infections develop.

**Roseola (Exanthema Subitum)**

**Roseola** is a presumed viral infection of children between 6 months and 2 years of age and can be seen in children up to 4 years of age. The incubation period is 5 to 15 days, followed by the sudden onset of fever (38.9°C to 40.5°C [102°F to 104.9°F]) that lasts 3 to 5 days. Following the fever, an erythematous macular rash that lasts about 24 hours develops primarily over the trunk and neck. Children usually feel well, eat normally, and have few other symptoms. There is usually no treatment.

**Small Pox**

**Smallpox (variolae)** was a highly contagious and deadly, but also preventable, disease caused by poxvirus variolae. Smallpox was eradicated worldwide in 1977. Routine vaccination in the United States was discontinued in 1972, and a new vaccine, ACAM2000, has been produced for the U.S. Strategic National Stockpile. Information is available from the Food and Drug Administration at
Chickenpox and Herpes Zoster

Chickenpox (varicella) and herpes zoster (shingles) are both produced by the varicella-zoster virus (VZV). VZV is a complex deoxyribonucleic acid (DNA) virus of the herpes group. The incubation period is 10 to 27 days, averaging 14 days. Vesicular lesions occur in the epidermis as infection occurs within keratinocytes. An inflammatory infiltrate is often present. Vesicles eventually rupture, followed by crust formation or the development of transient ulcers on mucous membranes. Varicella occurs in people not previously exposed to VZV, whereas herpes zoster (shingles) occurs in individuals who had varicella in the past. The virus enters the dorsal root ganglia and remains latent. Since the introduction of live attenuated varicella-zoster virus (VZV) vaccine in 1995, there has been a significant reduction in varicella incidence and its associated complications.  

Chickenpox.

**Chickenpox (varicella)** is a disease of early childhood, with 90% of children contracting the disease during the first decade of life. Being a highly contagious virus, chickenpox is spread by close person-to-person contact and by airborne droplets. Introduction of an infected person into a household results in a 90% possibility of susceptible persons developing the disease within the incubation period, usually 14 days. Children are contagious for at least 1 day before development of the rash. Transmission of the virus may occur until approximately 5 to 6 days after the onset of the first skin lesions in healthy children. In immunocompromised children, the virus is recoverable for a longer period, but infected children must be considered contagious for at least 7 to 10 days. Transmission occurs more readily in temperate climates than in tropical climates.

Normally, children who develop chickenpox have no prodromal symptoms. The first sign of illness may be pruritus or the appearance of vesicles, usually on the trunk, scalp, or face. The rash later spreads to the extremities. Characteristically, lesions can be seen in various stages of maturation with macules, papules, and vesicles present in a particular area at the same time (Figure 42-9). The vesicular lesions are superficial and rupture easily. New lesions will erupt for 4 to 5 days, until there are approximately 100 to 300 in different stages of development. The vesicles become crusted, and over time only the crust remains, although there may be an occasional vesicle on the palm later in the disease. Although uncommon, ulcerative lesions are sometimes seen in the mouth and, less commonly, on the conjunctiva and pharynx. Fever usually lasts 2 to 3 days, with body temperature
ranging from 38.5° to 40° C (101.3° to 104° F).

Complications are rare in children but more common in adults. They can include transient hematuria (from rupture of vesicles in the bladder), epistaxis, laryngeal edema, and varicella pneumonia. One case of chickenpox produces almost complete immunity against a second attack. Rarely, the fetus may be malformed (congenital varicella syndrome) if chickenpox develops in the first half of pregnancy. Infants whose mothers have chickenpox at any stage of pregnancy have a higher risk of developing herpes zoster during the first few years of life. Varicella-zoster immunoglobulin should be administered to neonates whenever the onset of maternal disease is between 5 days before and 2 days after delivery.
Uncomplicated chickenpox requires no specific therapy. Baths, wet dressings, and oral antihistamines occasionally help to relieve pruritus and to prevent secondary infection from developing as a result of scratching. Oral antistaphylococcal drugs should be given if secondary bacterial infection is present. Zoster immune globulin may be administered to immunodeficient individuals if given within 72 hours after exposure to chickenpox. Oral acyclovir may be valuable in immunosuppressed or other select groups of children. The varicella vaccine protects against both varicella and herpes zoster. However, wild-type (vaccine-resistant) viruses are a continuing threat.  

**Herpes zoster.**

Although **herpes zoster (shingles)** occurs mainly in adults, approximately 5% of cases are in children younger than 15 years. The pathophysiology and treatment are reviewed in [Chapter 41](#).

---

**Quick Check 42-2**

1. Compare the cause and presentation of impetigo and staphylococcal scalded-skin syndrome.

2. Describe rubella and rubeola.

3. How are chickenpox and herpes zoster related?
Insect Bites and Parasites

Insect bites and infestations are common causes of skin disorders in children and adults. Skin damage occurs by various mechanisms, including trauma of bites and stings, allergic reactions, transmission of disease, injection of substances that cause local or systemic reactions, and inflammatory reactions resulting from embedded and retained insect mouth parts and scratching of the skin.

Scabies

Scabies is a contagious disease caused by the itch mite *Sarcoptes scabiei* (Figure 42-10, A), which can colonize the human epidermis. Scabies is a common skin infection in tropical settings, affecting large numbers of people, particularly children. It is transmitted by close personal contact and by infected clothing and bedding. Scabies is often epidemic in areas of overcrowded housing and poor sanitation. Immunocompromised individuals are at greater risk. Scabies can facilitate *Streptococcus pyogenes* and *Staphylococcus aureus* skin coinfections with systemic complications. The scabies mite has adapted mechanisms to overcome host defenses including complement inhibitors. Infestation is initiated by a female mite that tunnels into the stratum corneum, depositing eggs and creating a burrow several millimeters to 1 cm long. Over a 3-week period, the eggs mature into adult mites, which sometimes are recognized as tiny dots at the ends of intact burrows.
Symptoms appear 3 to 5 weeks after infestation. The primary lesions are burrows, papules, and vesicular lesions, with severe pruritus that worsens at night. Pruritus is thought to be related to sensitization to the larval stages of the parasite. In older children and adults, the lesions occur in the webs of fingers; in the axillae; in the creases of the arms and wrists; along the belt line; and around the nipples, genitalia, and lower buttocks. Infants and young children have a different pattern of distribution, with involvement of the palms, soles, head, neck, and face (Figure 42-10, B). Secondary infections and crusting develop as a result of scratching and eczematous changes.

Diagnosis of scabies is made by observation of the tunnels and burrows and by microscopic examination of scrapings of the skin to identify the mite or its eggs or feces. Treatment involves the application of a scabicide, which is curative. All clothing and linens should be washed and dried in hot cycles or dry-cleaned.
Pediculosis (Lice Infestation)

The three known types of human lice are (1) the head louse (*Pediculus capitis*), (2) the body louse (*Pediculus corporis*), and (3) the crab or pubic louse (*Phthirus pubis*). They are parasites and survive by sucking blood. The female louse reproduces every 2 weeks, producing hundreds of nits as newly hatched lice mate with older lice. The mouthparts are shaped for piercing and sucking and are attached to the skin of the host while the louse is feeding. When piercing the skin, the louse secretes toxic saliva, and the mechanical trauma and toxin produce a pruritic dermatitis. Head and body lice are acquired directly by personal contact or indirectly by sharing of combs, brushes, or towels or contact with infested clothes, toys, furniture, carpets, or bedding. Crab lice are spread by close body contact, usually with an infected adult. Other common sources of transmission include sharing clothing or headsets.

Pruritus is the major symptom of lice infestation. With head lice, the ova attach to hairs above the ears and in the occipital region. The primary lesion caused by the body louse is a pinpoint red macule, papule, or wheal with a hemorrhagic puncture site. The primary lesion often is not seen, because it is masked by excoriations, wheals, and crusts. The crab louse is found on pubic hairs but also may be found in other body hair, such as eyelashes, mustache, beard, and underarm hair. Young children in particular may become infected with crab lice on their eyebrows or eyelashes.

The live louse, 2 to 3 mm long, is rarely observed. The ova, or nits, can be observed as oval, yellowish, pinpoint specks fastened to a hair shaft. The ova fluoresce under an ultraviolet light (Wood's lamp) and are observed best with a microscope. Nits are removed with a nit comb, and pediculicides, such as lindane shampoo or lotion, are the most effective treatment. Success or failure of therapy for ectoparasitic infestation depends much more on proper use of the topical preparation than on the type of scabicide or pediculicide used. All clothes, towels, bedding, combs, and brushes should be washed and dried in hot air or instead washed in boiling water, or clothes can be ironed to rid them of lice. Individuals who have close personal contact with the infected person also should be treated.

Fleas

Young children are very susceptible to fleabites. Bites occur in clusters along the arms and legs or where clothing is tight fitting, such as near elastic bands that circle the thigh or waist. The bite produces a urticarial wheal with a central hemorrhagic
puncture (Figure 42-11). Itching can be controlled with antihistamines. Treatment includes spraying carpets, crevices, and furniture with malathion or lindane powder. Infected animals should be treated, and clothes and bedding should be washed in hot water.

Bedbugs

Bedbugs (*Cimex lectularius*) are blood-sucking parasites that live in the crevices and cracks of floors, walls, and furniture and in bedding or furniture stuffing. They
are 3 to 5 mm long and reddish brown. Bedbugs are nocturnal, emerging to feed in darkness by attaching to the skin to suck blood, and are attracted by warmth and carbon dioxide. Feeding occurs for 5 to 15 minutes, and the bedbug then leaves. It will move long distances to search for food and can travel from house to house.

Immunologic reactions to bedbug saliva vary, but bites typically yield erythematous and pruritic papules. The face and distal extremities, areas uncovered by sleeping clothes or blankets, are preferentially involved. If the host has not been previously sensitized, the only symptom is a red macule that develops into a nodule, lasting up to 14 days. In sensitized children and adults, pruritic wheals, papules, and vesicles may form. Most lesions respond to oral antihistamines or topical corticosteroids, or both. Secondary infections require antibiotic treatment. Bedbugs are eliminated by inspecting and cleaning or disposing of bedding, mattresses, furniture, and other contaminated items and by using applications of approved insecticides, usually by a professional.49
Cutaneous Hemangiomas and Vascular Malformations

Cutaneous vascular anomalies are frequent tumors of early infancy and are categorized as either hemangiomas or vascular malformations.

**Cutaneous Hemangiomas**

*Cutaneous hemangiomas* are benign tumors that form from the rapid growth of vascular endothelial cells, which results in formation of extra blood vessels. Hemangiomas can be superficial or deep. \(^{50}\) *Superficial hemangiomas* are known as infantile (capillary) or *strawberry hemangiomas*. Deep lesions are known as cavernous or congenital hemangiomas. The etiology may be related to embolization of fetal placental endothelial cells with placental trauma or loss of placental angiogenic inhibitor of placental and maternal origin. Superficial hemangiomas are associated with endothelial glucose transporter 1 (GLUT1). There is proliferation of mast cells, which are thought to promote the angiogenesis. Infiltration of fat cells, fibrosis, and the rich vascular network give the lesions a firm, rubbery feel. Females are affected more often than males.

About 30% of infantile hemangiomas are apparent at birth, but usually emerge 3 to 5 weeks after birth. They grow rapidly during the first few years of life and become bright red and elevated with minute capillary projections that give them a strawberry appearance. Only one lesion is usually present and is located on the head and neck area or trunk (Figure 42-12). After the initial growth, the lesion grows at the same rate as the child and then starts to involute at 12 to 16 months of age. Approximately 90% of strawberry hemangiomas involute by 5 to 9 years of age, usually without scarring. Most superficial hemangiomas require no treatment. Hemangiomas located over the eye, ear, nose, mouth, urethra, or anus may require treatment because they interfere with function and have a higher risk for infection or injury.
Cavernous hemangiomas are a rare variant of superficial hemangiomas and are GLUT1-negative (Figure 42-13). They are present and fully grown at birth and are usually solitary lesions on the head or limbs that appear as a spongy purplish mass of tissue. They have larger and more mature vessels within the lesion. There are two groups of cavernous hemangiomas: rapidly involuting and noninvoluting. Rapidly involuting cavernous hemangiomas disappear by 12 months to 14 months of age, leaving an area of thin skin. Noninvoluting cavernous hemangiomas do not undergo involution.
Rapidly progressing hemangiomas are treated with a beta-blocker (e.g., propranolol) with regression occurring within 2 weeks and should be considered a first-line agent. Other therapies include systemic or intralesional steroids. Cryosurgery, laser surgery, sclerotherapy, and embolization are alternative treatment options. Interferons, vincristine, cyclophosphamide, and radiotherapy can suppress angiogenesis.

**Cutaneous Vascular Malformations**

**Cutaneous vascular malformations** are rare congenital anomalies of blood vessels present at birth but may not be apparent for several years. They grow proportionately with the child and never regress. The malformations occur equally among males and females. Occasionally they expand rapidly, particularly during the hormonal changes of puberty or pregnancy and in association with trauma. Vascular malformations are classified as low flow or high flow. **Low-flow malformations** involve capillaries, veins, and lymphatics. **High-flow malformations** involve arteries. In addition to locations within the skin, they may involve the gastrointestinal tract, bone (Maffucci syndrome or Sturge-Weber syndrome), facial capillary malformation, skin, eye, or brain (leptomeningeal hemangioma). **Overgrowth**
syndromes can occur with either high-flow or low-flow malformations, with overgrowth of the underlying structures (i.e., legs, arms, facial bones). The most common vascular malformations are nevus flammeus (port-wine stains) and salmon patches (stork bite, angel kiss).

Port-wine (nevus flammæus) stains are congenital malformations of the dermal capillaries. The lesions are flat, and their color ranges from pink to dark reddish purple. They are present at birth or within a few days after birth and do not fade with age. Involvement of the face and other body surfaces is common, and the lesions may be large (Figure 42-14). Treatments using cryosurgery or tattooing are not satisfactory. The pulsed dye laser is the treatment of choice to successfully lighten the color and flatten the more nodular and cavernous lesions. Waterproof cosmetics may be used to cover the lesions.

Salmon patches are macular pink lesions present at birth and located on the nape of the neck, forehead, upper eyelids, or nasolabial fold region. They are a variant of nevus flammæus, more superficial, and one of the most common congenital malformations in the skin. The pink color results from distended dermal capillaries, and 95% of patches fade by 1 year of age. Those located at the nape of the neck may persist for a lifetime. They generally do not present a cosmetic problem.
Other Skin Disorders

Miliaria

**Miliaria** is a dermatosis commonly seen in infants that is characterized by a vesicular eruption after prolonged exposure to perspiration with subsequent obstruction of the eccrine ducts. There are two forms of miliaria: miliaria crystallina and miliaria rubra. In **miliaria crystallina**, ductal rupture occurs within the stratum corneum and appears as 1- to 2-mm clear vesicles without erythema. They rupture within 24 to 48 hours and leave a white scale. In miliaria rubra, the ductal rupture occurs in the lower epidermis with inflammatory cells attracted to the site of the rupture. **Miliaria rubra** (prickly heat) is characterized by 2- to 4-mm discrete erythematous papules or papulovesicles (Figure 42-15). Both forms may become secondarily infected, requiring systemic antibiotics. The key to management is avoidance of excessive heat and humidity, which cause sweating. Light clothing, cool baths, and air conditioning assist in keeping the skin surface dry and cool.

![Figure 42-15](image-url) Miliaria Rubra. Note discrete erythematous papules or papulovesicles. (Courtesy Department of Dermatology, School of Medicine, University of Utah, Salt Lake City Utah.)

Erythema Toxicum Neonatorum

**Erythema toxicum neonatorum** (toxic erythema of the newborn) is a benign, erythematous accumulation of macules, papules, or pustules that appears at birth or 3 to 4 days after birth. The lesions first appear as a blotchy, macular erythematous rash. The macules vary from 1 mm to 1 cm in diameter. When papules or pustules develop, they are light yellow or white and 1 to 3 mm in diameter. There may be a few or several hundred lesions, and any body surface can be affected, with the
exception of the palms and soles, where there are no pilosebaceous follicles. The cause of the lesion is unknown but may be related to an innate immune response to the first commensal microflora with release of mast cell mediators. It is self-limiting and resolves spontaneously within a few weeks after birth. No treatment is required.

Quick Check 42-3

1. Give two examples of insect bites or parasites that affect children. What features are observed in each?

2. Compare a strawberry hemangioma with a cavernous hemangioma.
Did You Understand?

Acne Vulgaris

1. Acne vulgaris is a common disorder related to obstruction of pilosebaceous follicles and proliferation of *Propionibacterium acnes*, primarily of the face, neck, and upper trunk. It is characterized by both noninflammatory and inflammatory lesions.

2. Hydradinitis suppurativa is a chronic, inflammatory disease with occlusion of the pilosebaceous follicles, primarily where there are folds of skin. The lesions include inflammatory nodules, sinus tracts, fistulae, and scarring.

Dermatitis

1. Atopic dermatitis is an alteration in the skin barrier; occurs as red, scaly lesions on the face, cheeks, and flexor surfaces of the extremities in infants and young children; and is associated with inflammatory cytokines, elevated IgE levels, and a family history of asthma and hay fever.

2. Diaper dermatitis is a type of irritant contact dermatitis that develops from prolonged exposure to urine and feces and often becomes secondarily infected with *Candida albicans*.

Infections of the Skin

1. Impetigo is a contagious bacterial disease occurring in two forms: bullous and vesicular. The toxins from the bacteria produce a weeping lesion with a honey-colored crust.

2. Staphylococcal scalded-skin syndrome (SSSS) is a staphylococcal skin infection that produces an exfoliative toxin with painful blisters and bullae formation over large areas of the skin, requiring systemic antibiotic treatment.

3. Tinea capitis and tinea corporis are fungal infections of the scalp and body caused by dermatophytes.

4. Thrush is a fungal infection of the mouth caused by *Candida albicans*. 
5. Molluscum contagiosum is a poxvirus of the skin that produces pale papular lesions filled with viral and cellular debris.

6. Rubella (German or 3-day measles) is a communicable viral disease characterized by fever, sore throat, enlarged cervical and postauricular lymph nodes, and a generalized maculopapular rash that lasts 1 to 4 days.

7. Rubeola is a viral contagious disease with symptoms of high fever, enlarged lymph nodes, conjunctivitis, and a red rash that begins on the head, spreads to the trunk and extremities, and lasts 3 to 5 days. Both bacterial and viral complications may accompany rubeola.

8. Roseola is a benign disease of infants with a sudden onset of fever that lasts 3 to 5 days, followed by a rash that lasts 24 hours.

9. Smallpox (variola) was a highly contagious, deadly viral disease that has been eradicated worldwide by vaccination but may be a bioterrorist threat.

10. Chickenpox (varicella) is a highly contagious disease caused by the varicella-zoster virus. Vesicular lesions occur on the skin and mucous membranes. Individuals are contagious from 1 day before the development of the rash until about 5 to 6 days after the rash develops.

11. Herpes zoster (shingles) is a viral eruption of vesicles on the skin along the distribution of a sensory nerve caused by chickenpox virus that persists in sensory nerve ganglia.

**Insect Bites and Parasites**

1. Scabies is a pruritic lesion caused by the itch mite, which burrows into the skin and forms papules and vesicles. The mite is very contagious and is transmitted by direct contact.

2. Pediculosis (lice infestation) is caused by blood-sucking parasites that secrete toxic saliva and damage the skin to produce pruritic dermatitis. Lice are spread by direct contact and are recognized by the ova or nits that attach to the shafts of body hairs.

3. Fleabites produce a pruritic wheal with a central puncture site and occur as clusters in areas of tight-fitting clothing.
4. Bedbugs are blood-sucking parasites that live in cracks of floors, furniture, or bedding and feed at night. They produce pruritic wheals and nodules.

**Cutaneous Hemangiomas and Vascular Malformations**

1. Cutaneous hemangiomas are benign tumors that form from the rapid growth of vascular endothelial cells and result in formation of extra blood vessels.

2. Cutaneous vascular malformations are rare congenital anomalies of blood vessels present at birth.

3. A strawberry hemangioma is a vascular lesion present at birth that proliferates in size and then grows at the same rate as the child. Most lesions resolve spontaneously by 5 years of age.

4. A cavernous hemangioma is present at birth, with larger vessels than a strawberry hemangioma, and is bluish red. Cavernous hemangiomas usually involute by 9 years of age and may require surgical removal if located near the eyes, nares, or genitalia.

5. Salmon patches are macular pink lesions with dilated capillaries that usually resolve by 1 year of age.

6. Port-wine stains are congenital malformations of dermal capillaries that do not fade with age.

**Other Skin Disorders**

1. Miliaria are small pruritic papules or vesicles that result from obstruction of the sweat duct opening in infants.

2. Erythema toxicum neonatorum is a benign accumulation of macules, papules, and pustules that spontaneously resolves within a few weeks after birth.

52. Greene AK. Management of hemangiomas and other vascular tumors. *Clin

Absolute polycythemia Excessive red blood cell production; a physiologic response resulting from increased erythropoietin secretion in response to chronic hypoxia or as a symptom of polycythemia vera.

Absorption atelectasis See Atelectasis.

Acid maltase deficiency (glycogen storage disease type II or Pompe disease) An autosomal recessive metabolic disorder that damages muscle and nerve cells throughout the body by an accumulation of glycogen in the lysosome attributable to deficiency of the lysosomal acid α-glucosidase enzyme. The buildup of glycogen causes progressive muscle weakness (myopathy) throughout the body and affects various body tissues, particularly in the heart, skeletal muscles, liver, and nervous system.

Acne A common skin disease characterized by pimples on the face, chest, and back. It occurs when the pores of the skin become clogged with oil, dead skin cells, and bacteria.

Acne conglobata Severe cystic acne characterized by cystic lesions, abscesses, communicating sinuses, and thickened, nodular scars; usually does not affect the face.

Acne rosacea A chronic form of dermatitis of the face in which the middle portion of the face appears red with small red lines caused by dilation of capillaries.

Acne vulgaris An inflammatory eruption of the sebaceous follicles usually occurring on the face, upper back, and chest that consists of blackheads, cysts, papules, and pustules.

Noninflammatory acne Open comedones caused by the enlargement and dilation of a plug resulting from the accumulation of oil and dead skin cells inside the hair follicle and by closed comedones that form if the hair follicle pore remains closed; they appear as a tiny, sometimes pink bump in the skin.

Acquired immunodeficiency syndrome (AIDS) See Immune deficiency.
Acquired sideroblastic anemia See *Anemia*.

**ACTH deficiency** A condition characterized by decreased or absent production of adrenocorticotropic hormone (ACTH) by the pituitary gland, resulting in a reduction in the secretion of adrenal hormones and subsequent weight loss, lack of appetite, weakness, nausea, vomiting, and low blood pressure.

**Actinic keratoses** A condition in which a premalignant small, reddish, rough spot appears on skin chronically exposed to the sun.

**Acute colonic pseudo-obstruction (Ogilvie syndrome)** A massive dilation of the large bowel that occurs in critically ill patients and immobilized older adults. It is characterized by significant dilation of the cecum and absence of mechanical obstruction, and is related to excessive sympathetic motor input or decreased parasympathetic motor input.

**Acute confusional state (ACS)** A form of delirium caused by interference with the metabolic or other biochemical processes essential for normal brain functioning. Symptoms may include disturbances in cognition and levels of awareness, short-term memory deficit, retrograde and anterograde amnesia, and disturbances in orientation, accompanied by restlessness, apprehension, irritability, and apathy. The condition may be associated with an acute physiologic state, delirium, toxic psychosis, or acute brain syndrome.

**Acute coronary syndrome** A classification encompassing clinical presentations ranging from unstable angina through infarction.

**Acute cystitis** An inflammation of the bladder, which is the most common site of urinary tract infection.

**Acute epiglottitis** An infection that causes inflammation of the epiglottis and surrounding tissues and may lead to upper airway blockage.

**Acute gastritis** An inflammatory disorder of the gastric mucosa, usually caused by injury of the protective mucosal barrier by drugs, chemicals, or *Helicobacter pylori* infection.

**Acute glomerulonephritis** See *Glomerulonephritis*.

**Acute gouty arthritis** An abrupt pain in a joint, most often the great toe, which is swollen, hot, and shiny secondary to an attack of gout.
Acute idiopathic thrombotic thrombocytopenic purpura (TTP) See *Thrombocytopenia*.

Acute leukemia See *Leukemia*.

Acute liver failure (fulminant liver failure) A rare clinical syndrome resulting from severe impairment or necrosis of liver cells without pre-existing liver disease or cirrhosis. Acetaminophen overdose is the leading cause.

Acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) A spectrum of acute lung inflammations and diffuse alveolocapillary injury.

Acute lymphoblastic leukemia (ALL) See *Leukemia*.

Acute myelogenous leukemia (AML) See *Leukemia*.

Acute otitis media (AOM) An infection of the middle ear space, behind the eardrum (tympanic membrane); characterized by pain, dizziness, and partial loss of hearing.

Acute pancreatitis Inflammation of the pancreas resulting from obstruction to the outflow of pancreatic digestive enzymes caused by bile duct or pancreatic duct obstruction (e.g., gallstones). Usually a mild disease and resolves spontaneously.

Acute poststreptococcal glomerulonephritis (PSGN) See *Glomerulonephritis*.

Acute pyelonephritis Acute inflammation of the renal parenchyma and pelvis characterized by small cortical abscesses and yellowish streaks in the medulla resulting from the accumulation of pus in the collecting tubules and interstitial tissue.

Acute renal failure (acute renal injury, acute kidney injury) A sudden decline in kidney function with a decrease in glomerular filtration and accumulation of nitrogenous waste products in the blood as demonstrated by an elevation in plasma creatinine and blood urea nitrogen levels.

Acute respiratory distress syndrome (ARDS) Capillaries or alveoli of the lungs are damaged as a result of infection, injury, blood loss, or inhalation injury causing fluid to leak from the capillaries into the alveoli, resulting in pulmonary edema and collapse of some alveoli.

Acute tubular necrosis (ATN) The kidney undergoes ischemic or nephrotoxic
injury because of severe hypotension, aminoglycosides, or radiocontrast agents and produces granular and epithelial cell casts in urine.

**Addison disease (primary adrenal insufficiency)** Adrenal hypofunction resulting in bronzelike pigmentation of the skin, severe prostration, progressive anemia, low blood pressure, diarrhea, and digestive disturbance.

**Adenocarcinoma** Tumor arising from epithelial cells with a glandular or glandlike pattern.

**Adenomyosis** The presence of islands of endometrial glands surrounded by benign endometrial stroma within the uterine myometrium.

**Adenosine deaminase (ADA) deficiency** See *Immune deficiency*.

**Adrenarche** Growth of axillary and pubic hair and other physiologic changes induced by hyperactivity of the suprarenal cortex and adrenocortical secretion of androgenic hormones in early puberty.

**Agammaglobulinemia** See *Immune deficiency*.

**Ageusia** Loss of the sense of taste.

**Agranulocytosis** See *Immune deficiency*.

**Akinesia** Slowness or loss of normal motor function resulting in impaired muscle movement.

**Alcoholic cirrhosis** See *Cirrhosis*.

**Alcoholic fatty liver (steatosis)** The mildest form of alcoholic liver disease; can be caused by chronic ingestion of relatively small amounts of alcohol, may be asymptomatic, and is reversible with cessation of drinking.

**Alcoholic hepatitis (steatohepatitis)** A precursor of cirrhosis characterized by inflammation; degeneration and necrosis of hepatocytes; infiltration of neutrophils, macrophages, and lymphocytes; immunologic alterations; and lipid peroxidation.

**Algor mortis** Postmortem reduction of body temperature.

**Alkaline reflux gastritis** Inflammation of the stomach caused by reflux of bile and alkaline pancreatic secretions that contain proteolytic enzymes and disrupt the
mucosal barrier in the remnant stomach.

**Allergic contact dermatitis** Contact dermatitis attributable to allergic sensitization.

**Allostasis** Long-term or chronic exaggerated responses to stress.

**Alopecia** Loss of hair.

**Alopecia areata** An autoimmune T-cell–mediated chronic inflammatory disease directed at hair follicles that results in baldness, usually in round patches.

**Alpha-thalassemia major** See *Anemia*.

**Alpha-thalassemia minor** See *Anemia*.

**Alzheimer disease (dementia of Alzheimer type [DAT], senile disease complex)** A degenerative disease characterized by the presence of amyloid plaques and fibrillary tangles in the cortex and by atrophy and widened sulci in the frontal and temporal lobes.

**Amblyopia** Poor vision caused by abnormal development of visual areas of the brain in response to abnormal visual stimulation during early development.

**Amyotrophic lateral sclerosis (ALS) (sporadic motor system disease, sporadic motor neuron disease, motor neuron disease, Lou Gehrig disease)** A disease that breaks down tissues in the nervous system (a neurodegenerative disease); it is of unknown cause and affects the nerves responsible for movement.

**Anaphylactic shock** A state of shock caused by a severe allergic reaction that lowers blood pressure and results in urticaria, breathing difficulties, and possibly death.

**Anemia** Hemoglobin concentration is less than normal because of a deficiency in red blood cells, a low level of hemoglobin in cells, or both; it manifests as pallor of the skin and mucous membranes, weakness, dizziness, easy fatigability, and drowsiness caused by oxygen deficiency.

**Alpha-thalassemia major** Thalassemia in which all four α-chains of hemoglobin are defective, resulting in a fatal condition because oxygen cannot be released to the tissues.

**Alpha-thalassemia minor** Thalassemia in which two α-chains of hemoglobin are defective.
**Aplastic crisis** Temporary loss of bone marrow causes erythropoiesis, resulting in an acute fall in hemoglobin levels and subsequent anemia.

**Beta-thalassemia major (Cooley anemia)** Thalassemia in which α-chain synthesis and β-chain synthesis are uncoupled; β-chain production is depressed moderately in the heterozygous form, beta-thalassemia minor, and severely in the homozygous form, beta-thalassemia major, resulting in erythrocytes that have a reduced amount of hemoglobin and accumulations of free α-chains.

**Beta-thalassemia minor** See previous glossary term.

**Glucose-6-phosphate dehydrogenase (G6PD) deficiency** An inherited condition that is asymptomatic in the absence of exposure to particular substances such as certain medicines, mothballs, or severe infections; with exposure the red blood cells undergo destruction, producing excessive bilirubin that overloads the liver and causes jaundice.

**Hemoglobin H disease** A form of alpha-thalassemia in which a hemoglobin H gene is expressed but cannot bind oxygen.

**Hemolytic anemia** A condition in which red blood cells are destroyed in response to certain toxic or infectious agents or in certain inherited blood disorders and the rate of breakdown exceeds the body's ability to compensate.

**Hemolytic disease of the newborn (HDN) (erythroblastosis fetalis)** A condition that affects a fetus or newborn in which red blood cells break down because of antibodies made by the mother that are directed against the infant's red cells, potentially resulting in anemia, heart failure, jaundice, and brain damage.

**Hereditary sideroblastic anemia** Heterogeneous group of rare disorders characterized by anemia of varying severity caused by a defect in mitochondrial heme synthesis; occurs almost exclusively in males, suggesting a predominant recessive X-linked transmission.

**Hypoplastic anemia** A condition in which anemia results from greatly depressed, inadequately functioning bone marrow and smaller-than-normal erythrocytes.

**Iron deficiency anemia (IDA)** An insufficient dietary intake or absorption of iron, resulting in decreased incorporation of hemoglobin into red blood cells and subsequent feelings of fatigue, weakness, and shortness of breath as well as pale earlobes, palms, and conjunctivae.
**Macrocytic anemia (megaloblastic anemia)** A condition characterized by erythrocytes that are larger than normal; associated with deficiency of vitamin B\textsubscript{12} or folic acid caused by inadequate intake or insufficient absorption secondary to alcoholism or drugs that inhibit DNA replication.

**Microcytic-hypochromic anemia** A condition in which red blood cells are smaller than normal as a result of iron deficiency.

**Normocytic-normochromic anemia (NNA)** Erythrocytes are of normal size and hemoglobin content but of insufficient number; usually caused by hereditary spherocytosis, drug-induced anemia, and anemia secondary to malignancies.

**Pernicious anemia** An autoimmune disorder that causes a deficiency in intrinsic factor, resulting in the inability to absorb vitamin B\textsubscript{12} and a subsequent increase in the production of abnormal erythrocytes.

**Reversible sideroblastic anemia** Associated with alcoholism; results from nutritional deficiencies of folate.

**Sickle cell anemia (sickle cell disease [SCD])** An inherited autosomal recessive disorder of the blood caused by abnormal hemoglobin that distorts red blood cells and makes them fragile and prone to rupture and can cause anemia, joint pain, fever, leg ulcers, and jaundice.

**Sickle cell–Hb C disease** A heterozygous form of SCD in which the child simultaneously inherits a hemoglobin C gene from another parent.

**Sickle cell–thalassemia disease** A heterozygous form of SCD in which the child simultaneously inherits a thalassemia gene from another parent.

**Sickle cell trait** An inherited condition in which an individual carries only one gene for sickle cell disease and is without symptoms.

**Sideroblastic anemia (SA)** Refractory anemia of varying severity that is caused by altered mitochondrial metabolism and is marked by sideroblasts in the bone marrow.

**Thalassemia** A potentially fatal genetic disorder in which hemoglobin molecules are abnormal, resulting in severe anemia; enlarged heart, liver, and spleen; and skeletal deformation.

**Anencephaly** Anomaly in which the soft, bony component of the skull and much of
the brain are missing.

**Angelman syndrome (happy puppet syndrome)** An inherited syndrome of jerky puppetlike movements, frequent laughter, intellectual and motor disabilities, peculiar open-mouthed facies, and seizures.

**Angina pectoris** Chest pain caused by reduced cardiac blood flow and myocardial ischemia.

**Ankylosing spondylitis (AS, spondyloarthritis)** Chronic inflammation of the spine and sacroiliac joints with gradual fusion of the vertebrae that immobilizes the spine.

**Anorexia nervosa (AN)** A disorder with both psychologic and physiologic components that begins with dieting to lose weight and manifests into an inappropriate self-control behavior; continued restrictive eating may lead to starvation and eventually death.

**Anuria** Urine output less than 50 ml/day.

**Aplastic crisis** See *Anemia*.

**Appendicitis** Inflammation of the appendix as a result of blockage of the opening from the appendix into the cecum; the appendix wall becomes infected and ruptures, allowing the infection to spread throughout the abdomen and cause pain, anorexia, fever, nausea, vomiting, and diarrhea.

**Apraxia** A disorder of voluntary movement consisting of impairment of the performance of skilled or purposeful movements; results from acquired cerebral disease.

**Areflexia** Absence of reflexes.

**Arteriosclerosis** A condition in which the blood vessel walls thicken, harden, lose elasticity, and typically accumulate lipids, resulting in elevated blood pressure and a decrease in the diameter of the coronary arteries as well as pain when walking from decreased perfusion to leg vessels.

**Aseptic meningitis** A form of inflammation of the meninges and subarachnoid space surrounding the brain and spinal cord without evidence of bacterial infection; may be associated with viral infection, systemic disease, or drugs.

**Aspiration pneumonitis** A condition caused by the abnormal entry of fluids,
particulate matter, or secretions into the lower airways that can lead to chemical pneumonitis from entry of toxic material such as gastric acid, from bacterial infection, or by mechanical obstruction of the lower airways.

**Asthma** A chronic inflammatory disorder of the airways involving bronchial hyperresponsiveness and airway obstruction marked by periodic attacks of wheezing, shortness of breath, a tight feeling in the chest, and a cough that produces mucus because of an allergic reaction triggered by certain drugs, irritants, viral infection, exercise, or emotional stress.

**Ataxic cerebral palsy** A form of cerebral palsy associated with damage to the cerebellum and resulting in gait disturbances and instability; at birth the infant may have hypotonia, but develops stiffness of the trunk muscles later in infancy.

**Atelectasis** A part of or an entire lung collapses and the alveoli deflate as a result of surgery, smoking, or blockage of a bronchiole.

**Compression atelectasis** Air pressure in the pleural space pushes against the already recoiled lung, causing compression atelectasis, and against the mediastinum, compressing and displacing the heart and great vessels.

**Surfactant impairment** Decreased production or inactivation of surfactant, which is necessary to reduce surface tension in the alveoli and causes lung collapse during expiration; can occur because of premature birth, acute respiratory distress syndrome, anesthesia, or mechanical ventilation.

**Atopic dermatitis (AD) (allergic dermatitis)** A chronic hereditary skin disease characterized by intense itching and inflamed skin that causes redness, swelling, cracking, crusting, and scaling.

**Atrial septal defect (ASD)** A congenital heart disease involving the interatrial septum of the heart that separates the right and left atria, which results in misdirected blood flow between the two sides of the heart.

**Atrioventricular canal (AVC) defect (atrioventricular septal defect [AVSD], endocardial cushion defect [ECD])** A large hole is present in the center of the heart where the wall between the atria joins the wall between the ventricles, and the tricuspid and mitral valves are formed into a single large valve that crosses the defect.

**Atypical ductal hyperplasia (ADH)** Abnormal proliferating cells in breast ducts.
Atypical hyperplasia (dysplasia) Increased number of cells with some variation in cellular structure but without sufficient qualitative or quantitative features of carcinoma.

Atypical lobular hyperplasia (ALH) Abnormal proliferating cells in breast lobules.

Autonomic hyperreflexia (dysreflexia) A syndrome resulting from afferent stimuli that cause intense sympathetic discharge originating with spinal cord injury above the major splanchnic outflow; characterized by hypertension, bradycardia, sweating of the forehead, severe headache, and piloerection on distention of the bladder and rectum.

Azotemia Kidney dysfunction characterized by increased serum urea levels and frequently associated with increased creatinine levels.

B

Bacterial pneumonia An acute or chronic disease marked by inflammation of the lungs caused by bacterial infection.

Balanitis Inflammation of the glans penis caused by irritation by environmental substances, physical trauma, or infection.

Bare lymphocyte syndrome See Immune deficiency.

Barrett esophagus Chronic peptic ulceration of the esophagus; formation of precancerous lesions with possible progression to adenocarcinoma.

Bartholinitis (Bartholin cyst) Inflammation of one or both of the ducts that lead from the introitus (vaginal opening) to the Bartholin/greater vestibular glands.

Basal cell carcinoma A surface epithelial tumor of the skin originating from undifferentiated basal or germinative cells.

B-cell neoplasm See Lymphoma.

Becker muscular dystrophy A general term for a number of late-onset X-linked recessive hereditary, progressive degenerative disorders affecting skeletal muscles, and often other organ systems.
**Beckwith-Wiedemann syndrome** An inherited disorder characterized by exomphalos, macroglossia, and gigantism; often associated with visceromegaly, adrenocortical cytomegaly, and dysplasia of the renal medulla.

**Benign breast disease (BBD)** A spectrum of noncancerous changes in ducts and lobules of the breast, including irregular lumps, cysts, sensitive nipples, and itching.

**Benign prostatic hyperplasia (BPH, benign prostatic hypertrophy)** Enlargement of the prostate gland, which may press against the urethra and bladder, interfering with urine flow.

**Beta-thalassemia major (Cooley anemia)** See *Anemia*.

**Beta-thalassemia minor** See *Anemia*.

**Biliary atresia** A condition in newborn children in which the biliary tract is blocked or absent, causing bile accumulation and progressive liver failure.

**Biliary cirrhosis** See *Cirrhosis*.

**Blepharitis** Inflammation of the eyelids.

**B-lymphocyte deficiency** See *Immune deficiency*.

**Bradykinesia** Decreased spontaneity and movement; a feature of extrapyramidal disorders, such as Parkinson disease.

**Brainstem gliomas** A group of tumors located in the brainstem that are usually classified as high grade and result in the sudden onset of symptoms including headaches, vomiting, and visual disturbances.

**Bronchiectasis** Dilation of the bronchi in response to obstruction, necrotizing pneumonias, cystic fibrosis, or Kartagener syndrome (a hereditary syndrome consisting of dextrocardia, bronchiectasis, and sinusitis).

**Bronchiolitis** Inflammation of the bronchioles usually caused by viral infection.

**Bronchiolitis obliterans** Partial or complete obliteration of bronchioles and some bronchi by granulation and fibrotic tissue masses.

**Bronchiolitis obliterans with organizing pneumonia (BOOP)** Obstruction of the bronchioles and alveolar ducts by fibrous granulation tissue that is further
complicated by the development of pneumonia.

**Bronchopulmonary dysplasia (BPD)** A condition most often found in premature infants in which chronic pulmonary insufficiency occurs because of long-term artificial pulmonary ventilation.

**Bruton agammaglobulinemia** See *Immune deficiency*.

**Bulbar palsy** A form of palsy resulting from impaired function of the cranial nerves from degeneration of the motor neurons of primarily the brainstem; manifested as weakness and wasting of the various bulbar muscles, resulting in difficulty articulating words (dysarthria) and difficulty swallowing (dysphagia); fluid regurgitation is a major symptom and can cause aspiration.

**Burkitt lymphoma** See *Lymphoma*.

**C**

**C3 deficiency** See *Immune deficiency*.

**Cachexia** Illness and malnutrition seen in individuals with cancer that results in wasting and eventual death.

**Calculus or urinary stone (urolithiasis)** Masses of crystals, protein, or other substances that are a common cause of urinary tract obstruction in adults.

**Candidiasis** A fungal infection caused by an overgrowth of normal *Candida albicans* found in the skin and mucous membranes of the mouth, respiratory tract, or vagina.

**Caplan syndrome** Formation in coal workers of intrapulmonary nodules in pneumoconiosis that are histologically similar to subcutaneous rheumatoid nodules associated with rheumatoid arthritis.

**Carbuncles** A condition in which a bacterial infection of the hair follicle or sebaceous gland ducts becomes painful and discharges pus through various openings.

**Carcinoma** Epithelial cell tumor.

**Carcinoma in situ (CIS)** Preinvasive epithelial malignant tumors of glandular or squamous cell origin.
Cardiogenic shock A condition resulting from decreased cardiac output caused by heart disease in which the heart is unable to pump blood through the body, usually because of myocardial infarction.

Cardiomyopathy(ies) A diverse group of diseases primarily affecting the myocardium and resulting from tissue remodeling caused by myocardial and neurohumoral responses to ischemic and hypertensive alterations.

Cavernous (congenital) hemangioma A birthmark that is similar to the strawberry hemangioma but is more deeply rooted and may appear as a red-blue spongy mass of tissue filled with blood.

Cerebellar astrocytoma Brain tumor of the right or left cerebellar hemisphere that causes motor symptoms on the same side as the tumor.

Cerebral palsy (CP) A developmental brain injury that occurs before or shortly after birth and causes muscular impairment affecting motor function and also may alter speech and learning abilities.

Cervicitis Inflammation of the mucous membrane of the uterine cervix caused by infection, typically by chlamydia, genital herpes, or gonorrhea.

Cheyne-Stokes respiration An abnormal pattern of breathing in which tidal volume gradually increases followed by a gradual decrease and a period of apnea before returning to a normal respiratory pattern.

Chickenpox An infectious viral disease that is spread by direct contact or through the air by coughing or sneezing; it causes a blister-like rash that first affects the face and trunk and then can spread over the rest of the body; symptoms include severe itching, fatigue, and fever.

Choking asphyxiation Obstruction of the internal airways.

Cholangiocellular carcinoma (cholangiocarcinoma) Primary carcinoma of the liver that develops in the bile ducts.

Cholecystitis Inflammation of the gallbladder commonly caused by impaction of a gallstone that results in right upper quadrant pain and possibly rupture and abscess in the gallbladder.

Cholelithiasis The presence or formation of gallstones in the gallbladder or bile ducts.
Chondrosarcoma  A cancer of the cartilage that usually occurs in the pelvic bones, shoulder bones, and the upper part of the arms and legs.

Chronic active hepatitis  The persistence of clinical manifestations and liver inflammation after the acute stages with consistently abnormal liver function tests and persistent HBsAg creating a predisposition to cirrhosis and primary hepatocellular carcinoma.

Chronic bronchitis  Chronic bronchitis, particularly as a cause of chronic cough in smokers.

Chronic gastritis  Tends to occur in older adults with chronic inflammation, mucosal atrophy, and epithelial metaplasia; may be immune (fundal) or nonimmune (antral), depending on the pathogenesis and location of the lesions.

Chronic glomerulonephritis  See Glomerulonephritis.

Chronic granulomatous disease (CGD)  See Immune deficiency.

Chronic kidney disease (CKD)  Progressive loss of renal function associated with systemic diseases such as hypertension, diabetes mellitus, systemic lupus erythematosus, or intrinsic kidney disease, including kidney stones, acute kidney injury, chronic glomerulonephritis, chronic pyelonephritis, obstructive uropathies, or vascular disorders.

Chronic leukemia  See Leukemia.

Chronic lymphocytic leukemia (CLL)  See Leukemia.

Chronic mucocutaneous candidiasis  See Immune deficiency.

Chronic myelogenous leukemia (CML)  See Leukemia.

Chronic obstructive pulmonary disease (COPD)  Any of a group of irreversible respiratory diseases (chronic bronchitis, emphysema, α₁-antitrypsin deficiency) that are characterized by airflow obstruction or limitation.

Chronic pancreatitis  Inflammation of the pancreas resulting from repeated exacerbations of acute pancreatitis that lead to chronic changes; associated with obstruction from gallstones, autoimmune disease, gene mutations, smoking, occupational chemical exposure, and obesity.

Chronic pyelonephritis  Persistent or recurrent infection of the kidney leading to
Chronic relapsing thrombotic thrombocytopenic purpura (TTP) See *Thrombocytopenia*.

**Cirrhosis** Degeneration of liver tissue resulting in fibrosis with nodule and scar formation that compromises liver function.

**Alcoholic cirrhosis** Destructive inflammation of the liver caused by the toxic effects of alcohol metabolism, immunologic processes, oxidative stress from lipid peroxidation, and malnutrition.

**Biliary cirrhosis** A form of alcoholic cirrhosis in which damage and inflammation leading to cirrhosis begin in bile canaliculi and bile ducts, rather than in the hepatocytes.

**Coarctation of the aorta (COA)** A condition in which the aorta narrows in the area where the ductus arteriosus inserts; narrowing usually occurs preductal in children and postductal in adults.

**Common variable immune deficiency** See *Immune deficiency*.

**Communicating (extraventricular) hydrocephalus** A disorder in which the cerebrospinal fluid pathways are intact but cerebrospinal fluid absorption is impaired.

**Complete precocious puberty** Condition in which puberty begins prematurely with normal changes in the hypothalamic-pituitary-gonadal (HPG) axis with premature development of secondary sexual characteristics and premature closure of the epiphysis of long bones, resulting in lifelong short stature.

**Compressive syndrome (sensorimotor syndrome; crush syndrome)** A shocklike state that follows release of a limb or limbs or the trunk and pelvis after a prolonged period of compression, such as by a heavy weight; characterized by suppression of renal function, probably the result of damage to the renal tubules by myoglobin from the damaged muscles.

**Congenital adrenal hyperplasia** A group of autosomal recessively inherited disorders associated with a deficiency of one of the enzymes involved in cortisol biosynthesis, resulting in elevation of ACTH levels and overproduction and accumulation of cortisol precursors proximal to the block; androgens are produced in excess, causing virilization. The most common disorder is the 21-

scarring.
hydroxylase deficiency, caused by mutation in the cytochrome P450 21-hydroxylase gene (CYP21) on chromosome 6p.

**Congenital aganglionic megacolon (Hirschsprung disease)** A congenital defect in which the nerves that innervate the anus through the wall of the bowel are absent, resulting in enlargement of the bowel superior to the point where the nerves are missing and a subsequent decrease in peristalsis that results in chronic constipation.

**Congenital hydrocephalus** Excessive accumulation of cerebrospinal fluid present at birth and characterized by increased intracranial pressure (ICP). This increase may be caused by a blockage within the ventricular system in which the CSF flows, an imbalance in the production of CSF, or a reduced reabsorption of CSF that results in ventricular enlargement and increased ICP.

**Congenital (infantile) nephrotic syndrome (Finnish type)** A very rare form of nephrotic syndrome caused by a defect in a kidney protein resulting in excessive amounts of protein excreted in the urine.

**Congestive splenomegaly** Enlargement of the spleen accompanied by ascites, portal hypertension, and esophageal varices; most commonly seen in those with hepatic cirrhosis.

**Consumptive thrombohemorrhagic disorders** Heterogeneous group of conditions that demonstrate the entire range of hemorrhagic and thrombotic pathologic conditions.

**Contact dermatitis** An allergic response to an environmental antigen binding to specific carrier proteins contained in an individual's skin.

**Contrecoup injury** Brain injury resulting from the brain hitting the inside of the skull on the side opposite the site of blunt-force trauma.

**Cor pulmonale** Right-sided heart failure caused by prolonged pulmonary hypertension.

**Coronary artery disease (CAD)** Narrowing of the lumen of one or more of the coronary arteries, usually attributable to atherosclerosis, leading to myocardial ischemia; can cause congestive heart failure, angina pectoris, or myocardial infarction.

**Craniopharyngioma** A brain tumor that develops in the pituitary gland and most
often affects children, causing headache, seizure, diabetes insipidus, early onset of puberty, and delayed growth.

**Craniosynostosis (craniostenosis)** Premature ossification of the skull and closure of the sutures, resulting in abnormal skull expansion and asymmetric skull growth.

**Cri du chat syndrome** A hereditary congenital syndrome characterized by hypertelorism, microcephaly, severe mental deficiency, and a plaintive catlike cry; caused by deletion of the short arm of chromosome 5.

**Crohn disease (CD)** An autoimmune condition in which the intestines and possibly other regions of the digestive system are chronically inflamed and ulcerated, causing chronic diarrhea, disrupted digestion, and subsequent difficulty eating and digesting food.

**Croup** A viral infection that involves the larynx, trachea, and the airways leading to the lungs and that can result in serious breathing difficulties, hoarseness, sore throat, and a hacking cough.

**Cryptorchidism** The scrotum of one or both testes is absent because of failure of the testis to descend from the abdominal position during fetal development.

**Curling ulcer** Ischemic ulcers of the stomach and duodenal mucosa that develop within hours after an event, such as hemorrhage, multisystem trauma, severe burns, heart failure, or sepsis.

**Cushing disease** Adrenal hyperplasia caused by an ACTH-secreting basophil adenoma of the pituitary.

**Cushing syndrome** Increased synthesis and secretion of cortisol from a tumor of the adrenal cortex; caused by administration of glucocorticoid drugs or by the presence of an ACTH-secreting tumor of the anterior lobe of the pituitary gland (Cushing disease), resulting in weight gain, glucose intolerance, and muscle wasting.

**Cushing ulcer** A stress ulcer associated with severe head trauma or brain surgery.

**Cystic fibrosis (CF)** A genetic disorder of the exocrine glands caused by a mutation in the CF transmembrane regulator gene, resulting in impairment in chloride transfer across cell membranes and subsequent chloride and water accumulation in organs and in thickened secretions that block ducts and form cysts.
**Cystitis** A condition characterized by acute or chronic inflammation of the urinary bladder, usually caused by bacterial infection of the urethra; symptoms include frequent burning urination, blood in the urine, pain in the pubic area, chills and fever, back pain, and nausea. See *Painful bladder syndrome/interstitial cystitis (PBS/IC)* for further information.

**D**

**Dandy-Walker malformation** Congenital defect of midline cerebellar structures and the fourth ventricle in which hydrocephalus is caused by atresia of the foramina of Luschka or Magendie, which normally allow the fourth ventricle to empty into the areas surrounding the brain, leading the ventricular flow of CSF into a “blind pouch.”

**Dawn phenomenon** Abrupt increases in fasting levels of plasma glucose between 5 and 9 AM, in the absence of antecedent hypoglycemia; occurs in diabetic patients receiving insulin therapy.

**Deep venous thrombosis (DVT)** A blood clot or thrombus in a deep vein, usually of the leg.

**Degenerative disk disease (DDD)** Intervertebral disk tissue is replaced by fibrocartilage during aging; functional capacity is rarely altered.

**Detrusor areflexia** A lower motor neuron disorder that results in an underactive, hypotonic, or atonic bladder function with retention of urine and distention.

**Detrusor hyperreflexia (uninhibited or reflex bladder)** Upper motor neuron disorders in which the bladder empties automatically when it becomes full and the external sphincter functions normally.

**Developmental dysplasia of the hip (DDH)** A condition in which the hip joint of babies or young children is malformed, with the ball being completely out of the socket or the socket being too shallow to support the ball.

**Diabetes** Diseases having in common the triad of symptoms of polyuria, weight loss, and significant glucosuria.

**Diabetes insipidus** A disease caused by a deficiency in or resistance to antidiuretic hormone that is characterized by excretion of large amounts of dilute urine.
because of a decrease in water reabsorption in the kidney.

**Gestational diabetes mellitus (GDM)** Carbohydrate intolerance of variable severity with onset during pregnancy.

**Maturity-onset diabetes of the young (MODY)** A rare form of diabetes that appears during adolescence or early adulthood and results from a variety of single mutations in genes that reduce pancreatic production of insulin.

**Type 1 diabetes mellitus** A disorder of carbohydrate metabolism characterized by a decrease in insulin production, resulting in hyperglycemia, ketoacidosis, and eventually renal failure and coronary artery disease.

**Type 2 diabetes mellitus** A condition of glucose intolerance that normally appears first in adulthood and is exacerbated by obesity and an inactive lifestyle.

**Diabetic nephropathy** A progressive kidney disease caused by diabetes-induced angiopathy of capillaries in the glomeruli that causes nodular glomerulosclerosis.

**Diabetic neuropathy** Combined sensory and motor disorder often seen in older diabetic patients as a result of microvascular injury involving small blood vessels that supply nerves.

**Diabetic retinopathy** Damage to the retina caused by an overaccumulation of glucose or fructose that damages the blood vessels in the retina; in advanced stages, lack of oxygen in the retina causes fragile blood vessels to grow along the retina and in the vitreous fluid of the eye that may bleed and cause blurred vision.

**Diaper dermatitis** A type of dermatitis characterized by inflammation of the skin in the diaper area in infants caused by exposure of the skin to feces and urine.

**Diastolic heart failure** A condition in which heart contractions are normal but the ventricle does not relax completely; therefore, less blood enters the heart.

**Diffuse brain injury (diffuse axonal injury)** Injury to neuronal axons in many areas of the brain caused by stretching and shearing forces received during brain injury.

**DiGeorge syndrome** See *Immune deficiency*.

**Dilated cardiomyopathy (congestive cardiomyopathy)** A condition in which all
four chambers of the heart are enlarged and weakened, resulting in progressive congestive heart failure and the need for heart transplantation.

**Discoid (cutaneous) lupus erythematosus (DLE)** See [Lupus erythematosus](#).

**Disorders of desire (hypoactive sexual desire, decreased libido)** The most common sexual dysfunction in women; prevalence increases with age and may be a biologic manifestation of depression, alcohol or other substance abuse, prolactin-secreting pituitary tumors, or testosterone deficiency.

**Distal intestinal obstruction syndrome (DIOS)** A syndrome seen in cystic fibrosis secondary to impaction with feces and inspissated mucus.

**Diverticulitis** Inflammation of the herniations or saclike outpouchings of mucosa through the muscle layers of the colon wall.

**Diverticulosis** Presence of multiple bulging sacs pushing outward from the wall of the large intestine that may become infected and rupture, causing abdominal pain, tenderness, and fever.

**Down syndrome** Trisomy or translocation of chromosome 21, resulting in intellectual disability; distinctive facial appearance with a low nasal bridge, epicanthal folds, protruding tongue, and flat, low-set ears; poor muscle tone (hypotonia); and short stature. Congenital heart defects, reduced ability to resist respiratory tract infections, and increased risk for leukemia are common.

**Duchenne muscular dystrophy** An X-linked genetic disorder in which fat and fibrous tissue infiltrate and weaken muscle tissues such as in the legs and pelvis, lungs, and heart; usually results in death before adulthood.

**Dumping syndrome** Rapid emptying of hypertonic chyme from a surgically created residual stomach causing nausea, vomiting, bleeding, and diarrhea about 20 minutes after a meal.

**Duodenal ulcer** Most common type of peptic ulcer; usually associated with altered mucosal defenses, rapid gastric emptying, elevated serum gastrin levels, or acid production stimulated by smoking.

**Dysfunctional uterine bleeding (DUB)** Heavy or irregular bleeding in the absence of organic disease, such as submucous fibroids, endometrial polyps, blood dyscrasias, pregnancy, infection, or systemic disease.
**Dyssynergia** Development of lesions in the upper motor neurons of the brain and spinal cord; results in loss of coordinated neuromuscular contraction and overactive or hyperreflexive bladder function.

**E**

**Eczema** Most common inflammatory disorder of the skin; generally characterized by pruritus, lesions with indistinct borders, and epidermal changes.

**Eisenmenger syndrome** A progressively developing condition in which a congenital heart defect such as ventricular septal defect is left untreated and causes a reversed right-to-left shunt secondary to increased pressures on the right side of the heart because of pulmonary hypertension.

**Emphysema** Pulmonary inflammation resulting in increased work of breathing or physiologic dead space and abnormal permanent enlargement of gas-exchange airways (acini) accompanied by destruction of alveolar walls without obvious fibrosis.

**Empyema (infected pleural effusion)** A condition in which purulent fluid is persistently discharged into the pleural space as a result of complications of bacterial infections.

**Encephalitis** Inflammation of the brain usually caused by a virus.

**Endometriosis** A condition that is common in women of reproductive age in which the tissue lining the uterus is found outside of the uterus, resulting in pain and infertility.

**End-stage kidney disease (ESKD)** Significant loss of renal function; usually less than 10% of renal function remains.

**Eosinophilic esophagitis** Rare, idiopathic inflammatory disease of the esophagus characterized by infiltration of eosinophils associated with atopic disease, including asthma and food allergies.

**Ependymoma** Intracranial tumor that is most commonly found in children and typically arises from the inner lining of the fourth ventricle and the spinal canal.

**Epididymitis** A painful condition in which the epididymis becomes inflamed, usually as a result of a secondary bacterial infection that is triggered by a variety
of underlying conditions such as urinary tract or sexually transmitted infections.

**Epilepsy** A group of chronic neurologic disorders with paroxysmal brain
dysfunction from excessive neuronal discharge; symptoms vary widely from
complex behavioral abnormalities to focal convulsions, to momentary spells of
impaired consciousness.

**Epispadias** A birth defect in which the urethra opens on the upper penile surface.

**Erysipelas** A highly contagious bacterial infection that produces shiny, red swollen
areas and fever and can lead to blood poisoning and pneumonia.

**Erythema multiforme** A skin disease that is caused by allergies, seasonal changes,
or drug sensitivities, resulting in the formation of red macules, papules, or
subdermal vesicles on the skin and mucous membranes.

**Erythema toxicum neonatorum** A temporary eruption of redness of the skin, small
papules, and occasionally pustules in newborns that is associated with contact
dermatitis or hypersensitivity to milk or other allergens.

**Erythrodermic (exfoliative) psoriasis** See *Psoriasis*.

**Erythromyalgia** Chronic disorder characterized by warmth, pain, and redness,
occuring primarily in the feet and lower legs.

**Essential (primary) thrombocythemia (ET)** Excessive production of platelets
(platelet count greater than 400,000/mm³ of blood); may be primary or
secondary (reactive) and is usually asymptomatic until the count exceeds 1
million/mm³ of blood when intravascular clot formation (thrombosis),
hemorrhage, or other abnormalities can occur.

**Ewing sarcoma** A malignant neoplasm of bone, primarily those of the extremities,
including the shoulder girdle, with a predilection for the metaphysis;
histologically presents as conspicuous foci of necrosis in association with
irregular masses of small, regular, rounded, or ovoid cells.

**Exstrophy of the bladder** A congenital defect in which the lower abdominal wall is
malformed and ruptures.

**Extrapyramidal/nonspecific cerebral palsy** Any of a group of clinical disorders
considered to result from malfunction in the extrapyramidal system and marked
by abnormal involuntary movements; included are parkinsonism, athetosis, and
chorea.

**F**

**Fascioscapulohumeral muscular dystrophy (FSHD)** An autosomal dominant genetic disorder that begins in childhood and causes muscle wasting and weakness, primarily in the face, shoulder, and arms.

**Fetal alcohol syndrome (FAS)** A syndrome of altered prenatal growth and morphogenesis that occurs in infants born to women who were chronically alcoholic during pregnancy; it includes maxillary hypoplasia, prominence of the forehead and mandible, short palpebral fissures, microphthalmia, epicanthal folds, severe growth retardation, intellectual disability, and microcephaly.

**Fibromyalgia** Muscles, tendons, and joints are painful, stiff, and tender; often accompanied by restless sleep, fatigue, anxiety, depression, and disturbances in bowel function.

**Fibrosarcoma** A malignant tumor of fibrous connective tissue that usually is derived from immature proliferating fibroblasts.

**Focal segmental glomerulosclerosis (FSGS)** A condition in which glomerular capillaries with thickened basement membranes and increased mesangial matrix collapse in segments. Usually presents as nephrotic syndrome.

**Furuncle** Staphylococcal infection produces painful pus-filled inflamed hair follicles and involves surrounding skin and subcutaneous tissue.

**Fusiform aneurysm (giant aneurysm)** Large aneurysm that stretches to affect the entire circumference of the arterial wall.

**G**

**Galactorrhea (inappropriate lactation)** A condition in which milk-like fluid is secreted from the breast because of hormonal alterations that are not associated with childbirth or nursing.

**Gangliosidosis** Any disease characterized by abnormal accumulation of specific gangliosides within the nervous system (e.g., Tay-Sachs disease).
**Gastroesophageal reflux disease (GERD)** The reflux of acid and pepsin from the stomach to the esophagus that causes esophagitis.

**General adaptation syndrome (GAS)** The sum of all nonspecific reactions of the body to prolonged systemic stress, comprising alarm, resistance, and exhaustion.

**Gestational diabetes mellitus (GDM)** See *Diabetes*.

**Glaucoma** A disease of the eye characterized by increased intraocular pressure, excavation, and atrophy of the optic nerve; produces defects in the field of vision and eventual blindness.

**Glomerulonephritis** Inflammation of the renal glomeruli that may not produce symptoms or may present with hematuria and proteinuria.

**Acute poststreptococcal glomerulonephritis (PSGN)** Kidney disease secondary to infection with *Streptococci* in which bacterial antigens complex with antibodies in the blood, deposit in the kidneys, and initiate an immune complex-mediated hypersensitivity reaction.

**Chronic glomerulonephritis** A slowly progressive glomerulonephritis most often associated with other systemic disease, including diabetes, malaria, hepatitis, or systemic lupus erythematosus, that generally leads to irreversible renal failure.

**Gout** A disorder of uric acid metabolism that causes painful inflammation of the joints, commonly the big toe, and arthritic attacks resulting from elevated levels of uric acid in the blood and the deposition of negatively birefringent urate crystals around the joints.

**Gouty arthritis** Inflammation of the joints in gout.

**Graft rejection** Immunologic rejection of transplanted tissue or organs based on antigen differences between the donor and recipient.

**Acute graft rejection** Cell-mediated immune rejection that occurs within days to months after transplantation; immune response is usually against unmatched HLA antigens and develops after transplantation.

**Chronic graft rejection** Slow, progressive organ failure after a period of months or years of normal function by a developing weak cell-mediated immune response against minor histocompatibility antigens on the endothelial cells.
lining the blood vessels of the grafted tissue.

**Hyperacute graft rejection** Immediate rejection of a graft because of pre-existing antibodies against antigens expressed on the grafted tissue or organ.

**Graft-versus-host disease (GVHD)** Condition in which mature T cells in a transplanted graft (e.g., transfused blood) are capable of a destructive cell-mediated reaction against unmatched histocompatibility antigens on the tissues in the graft recipient.

**Graves disease** Autoimmune hyperthyroidism caused by antibodies that continuously activate TSH receptors, resulting in uncontrolled production of thyroxine and characterized by an enlarged thyroid gland, protrusion of eyeballs, a rapid heartbeat, and nervous excitability.

**Guillain-Barré syndrome (GBS) (Landry-Guillain-Barré syndrome, idiopathic polyneuritis, acute inflammatory polyradiculopathy, acute autoimmune neuropathy)** An acute, immune-mediated disorder of peripheral nerves, spinal roots, and cranial nerves that commonly presents as a rapidly progressive, areflexive, relatively symmetric ascending weakness of the limb, truncal, respiratory, pharyngeal, and facial musculature, with variable sensory and autonomic dysfunction; typically reaches its peak activity within 2 to 3 weeks, followed by a plateau period of similar duration, and gradual but complete recovery in most cases; often preceded by a respiratory tract or gastrointestinal tract infection and is associated with albuminocytologic dissociation of the cerebrospinal fluid.

**Guttate psoriasis** See *Psoriasis*.

**Gynecomastia** Abnormal breast tissue development on adolescent boys or men as a result of an imbalance in hormones.

**H**

**Heat exhaustion** Occurs when sufficient salt and water loss results in hemoconcentration with hypotension occurring secondary to fluid loss (hypovolemia), and the individual feels weak, is nauseated, and can suddenly collapse.

**Heat stroke** A life-threatening condition associated with high environmental temperatures and humidity causing core body temperature to rise as a result of
thermoregulatory failure.

**Hemochromatosis** Disorder of iron metabolism characterized by excessive absorption of ingested iron, saturation of iron-binding protein, and deposition of hemosiderin in tissue, particularly in the liver, pancreas, and skin; cirrhosis of the liver, diabetes (bronze diabetes), bronze pigmentation of the skin, and eventually heart failure may occur; also can result from administration of large amounts of iron orally, by injection, or in forms of blood transfusion therapy.

**Hemolytic anemia** See *Anemia*.

**Hemolytic disease of the newborn (HDN) (erythroblastsosis fetalis)** See *Anemia*.

**Hemolytic jaundice (prehepatic jaundice, nonobstructive jaundice)** Jaundice resulting from excessive hemolysis of red blood cells.

**Hemolytic-uremic syndrome (HUS)** A condition in which platelets aggregate within the kidney's small blood vessels, resulting in reduced blood flow to the kidney and subsequent kidney failure and destruction of the red blood cells; occurs usually after exposure to Shiga-like toxin from a strain of *E. coli*.

**Hemophilia A (classic hemophilia)** A genetic disorder in which a mutation in factor VIII causes prolonged clotting time, decreased formation of thromboplastin, and diminished conversion of prothrombin.

**Hemophilia B (Christmas disease)** A genetic disorder similar to hemophilia A in terms of symptoms but with a mutation in the factor IX gene.

**Hemophilia C (factor XI deficiency)** A genetic disorder characterized by a deficiency in factor XI, resulting in a mild form of hemophilia.

**Hemorrhagic stroke (spontaneous intracranial hemorrhage)** Stroke usually caused by hypertension that results in bleeding in the brain and typically increases intracranial pressure and may lead to death.

**Henoch-Schönlein purpura nephritis** Inflammation of the blood vessels causing bleeding into the skin, mucous membranes, internal organs, and other tissues; pain and inflammation in the joints; abdominal pain; gastrointestinal bleeding; inflammation of the kidneys; subcutaneous edema; encephalopathy; and inflammation of the testis.

**Heparin-induced thrombocytopenia (HIT)** See *Thrombocytopenia*. 
Hepatic encephalopathy A condition that is usually caused by liver cirrhosis and portal hypertension in which toxins produced by the gut pass into the systemic circulation and damage brain cells, resulting in impaired cognition, tremor, and a decreased level of consciousness.

Hepatocellular carcinoma (hepatocarcinoma; HCC) Primary carcinoma of the liver developing in hepatocytes.

Hepatopulmonary syndrome Intrapulmonary vasodilation, intrapulmonary shunting, and hypoxia and portopulmonary hypertension (pulmonary vasoconstriction and vascular remodeling) are common respiratory complications of advanced liver disease and portal hypertension.

Hepatorenal syndrome (HRS) Acute renal failure occurs because of a decrease in renal blood flow secondary to liver disease.

Hereditary hemochromatosis (HH) Autosomal recessive chronic liver disease caused by excessive intestinal absorption of elemental iron; characterized by elevated serum iron saturation, transferrin, and ferritin levels; improves with phlebotomy; increased risk of developing cirrhosis, liver cancer, and liver failure.

Hiatal hernia An anatomic abnormality in which the esophageal hiatus is larger than normal, causing part of the stomach to protrude through the diaphragm and up into the esophagus or chest.

Hirsutism Abnormal growth and distribution of androgen-sensitive hair growth on the face, body, and pubic area in a male pattern that occurs in women.

Hodgkin lymphoma (HL) See Lymphoma.

Hormonal hyperplasia Growth of cellular layers chiefly in estrogen-dependent organs, such as the uterus and breast. After ovulation, for example, estrogen stimulates the endometrium to grow and thicken for reception of the fertilized ovum.

Huntington disease (HD) An autosomal dominant disease causing a progressive increase in involuntary, jerky, dyskinetic movements; mental deterioration; and premature death.

Hydrops fetalis Edema formation in the fetal subcutaneous tissue because of an enzyme deficiency or any one of several other disorders.
Hypercoagulability (thrombophilia) Genetic or acquired abnormality of the coagulation system with an increased risk for thrombosis.

Hyperosmolar hyperglycemic nonketotic syndrome (HHNKS) A complication seen in diabetes mellitus in which very marked hyperglycemia occurs, causing osmotic shifts in water in brain cells, and resulting in coma. It can be fatal or lead to permanent neurologic damage.

Hypersensitive pneumonitis (extrinsic allergic alveolitis) An allergic, inflammatory disease of the lungs caused by inhalation of organic particles or fumes.

Hypertrophic cardiomyopathy A genetic disorder caused by various mutations that thicken the heart muscle, possibly leading to obstruction of blood flow and heart dysfunction; this is a common cause of sudden death in young athletes.

Hypogammaglobulinemia See Immune deficiency.

Hypoplastic left heart syndrome (HLHS) A condition in which the left side of the heart, including the aorta, aortic valve, left ventricle, and mitral valve, is underdeveloped and blood returning from the lungs flows through an opening in the atrial septum and the right ventricle pumps the blood into the pulmonary artery and then into the aorta.

Hypospadias A birth defect in which the urethral opening is abnormally placed, opening anywhere from the tip of the glans penis, to the shaft, or to the junction of the penis and scrotum or perineum in males; usually opens in the vagina in females.

Icterus neonatorum (neonatal jaundice) Jaundice in newborn infants caused by functional immaturity of the liver; usually subsides within the first few days of life.

Idiopathic pulmonary fibrosis (IPF) An excessive amount of fibrous or connective tissue in the lung.

Idiopathic thrombocytopenic purpura (ITP) (autoimmune or primary thrombocytopenic purpura) See Thrombocytopenia.
IgA nephropathy (Berger disease) The most common form of idiopathic acute glomerulonephritis in developed countries, especially Asia; cause is unknown.

IgA pemphigus The most benign form of pemphigus characterized by tissue-bound and circulating IgA antibodies targeting desmosomal or nondesmosomal cell surface components in the basement membrane of the epidermis.

Immune deficiency A group of disorders in which one or more components of the immune or inflammatory response is impaired, resulting in increased susceptibility to infections. Deficiencies may be either primary (caused by genetic defects) or secondary (caused by nongenetic factors, such as infections and other physiologic or pathophysiologic conditions.

Primary combined T- and B-lymphocyte deficiency A group of immune deficiencies in which both T and B lymphocytes are defective. The most severe of these deficiencies is called severe combined immune deficiency (SCID).• Adenosine deaminase (ADA) deficiency A form of SCID caused by an autosomal recessive mutation in the enzyme ADA, leading to death of rapidly dividing cells, particularly lymphocytes. •Bare lymphocyte syndrome Forms of SCID characterized by an inability of lymphocytes and macrophages to present antigen because of defects in class I (MHC class I deficiency) or class II (MHC class II deficiency) MHC antigen expression. •Wiskott-Aldrich syndrome (WAS) An X-linked recessive trait resulting in chronic eczema with chronic suppurative otitis media, anemia, thrombocytopenic purpura, poor antibody response to polysaccharide antigens, and dysfunctions of cell-mediated immunity. •X-linked SCID A form of SCID with arrested maturation of T and NK cells and the production of immature B cells as a result of a defect in the IL-2 receptor gamma (γ)-chain (IL-2Rγ), which is shared with many other cytokine receptors.

Primary complement deficiency A group of conditions in which specific proteins of the complement system are absent or suboptimal, resulting in diminished complement activity. •C3 deficiency The most severe complement defect; an associated deficit of C3b, which is a major opsonin, results in a risk for recurrent life-threatening infections with encapsulated bacteria. •Mannose-binding lectin (MBL) deficiency A defect of the lectin pathway of complement activation resulting in an increased risk of infection with microorganisms that have polysaccharide capsules rich in mannose.

Primary immune deficiencies of b-cell function •Agammaglobulinemia A
condition in which no antibodies are produced. • B-lymphocyte deficiency A group of disorders in which B-cell development is defective, resulting in lower levels of circulating immunoglobulins and increased susceptibility to infections in which antibodies are the primary protective mechanism. • Bruton's agammaglobulinemia A defect in B-cell development results in lower levels of circulating immunoglobulins and increased susceptibility to infections in which antibodies are the primary protective mechanism. • Common variable immune deficiency The most commonly diagnosed immune deficiency; hypogammaglobulinemia of IgG and other antibody classes; normal numbers of B cells, with or without associated T-cell defects. • Hypogammaglobulinemia A condition in which immunoglobulin levels are much lower than normal. • Selective IgA deficiency Failure to produce IgA, with or without diminished production of other classes of antibody.

Primary phagocytic deficiency A group of conditions in which phagocytosis is diminished, resulting in increased bacterial infections. • Chronic granulomatous disease (CGD) Both X-linked and autosomal forms of mutations of the NADPH oxidase complex, resulting in diminished production of hydrogen peroxide and other oxygen products necessary for the bactericidal activity of myeloperoxidase. • Severe congenital neutropenia Inadequate numbers of neutrophils resulting in a variety of recurrent and severe bacterial infections beginning early in life.

Secondary immune deficiencies • Acquired immunodeficiency syndrome (AIDS) An epidemic, transmissible retroviral disease caused by infection with the human immunodeficiency virus (HIV), resulting in destruction of T-helper cells, suppression of both antibody and cellular immune responses, and development of life-threatening infections with opportunistic organisms. • Agranulocytosis Complete absence of granulocytes in the blood is usually secondary to arrested hematopoiesis in the bone marrow or massive cell destruction in the circulation. • T-lymphocyte deficiency A group of disorders in which T-cell development is defective, resulting in lower levels of cellular immunity. Diminished T helper cell function may also decrease the production of antibody. These include: • Chronic mucocutaneous candidiasis A primary defect of T-lymphocyte response to a specific infectious agent, the yeast *C. albicans*. • DiGeorge syndrome A genetic disorder caused by deletion of a piece of chromosome 22 that results in cardiac defects, abnormal facies, thymic aplasia, cleft palate, and hypocalcemia.

Immune thrombocytopenic purpura (ITP) See *Thrombocytopenia*. 
**Imperforate anus** A congenital defect in which the anal opening is absent because of the presence of a membranous septum or complete absence of the anal canal.

**Impetigo** A contagious bacterial infection that produces superficial red blisters that rupture and produce thick yellow crusts that commonly occur on the face but can spread to other regions of the body easily.

**Infectious mononucleosis (IM)** A disease caused by the Epstein-Barr virus or the cytomegalovirus that is transmitted by exchanging saliva or blood or by coughing and sneezing and acts by infecting the B cells and atypical T cells, resulting in fever, sore throat, and fatigue.

**Infertility** The inability to conceive after 1 year of unprotected intercourse with the same, opposite-sex partner.

**Intracerebral hematoma (intraparenchymal hemorrhage)** Blood accumulation that partially clots inside the brain, usually in the frontal and temporal lobes.

**Intraductal papilloma** Array of papillary cells that grow from the wall of a cyst into the lumen of the duct; growth occurs within a dilated duct often near or beside the nipple, causing benign nipple discharge.

**Intrarenal (intrinsic) acute kidney injury (AKI)** A sudden decline in kidney function with a decrease in glomerular filtration and an accumulation of nitrogenous waste products in the blood (elevation in plasma creatinine and blood urea nitrogen levels); may result from ischemic acute tubular necrosis (ATN), nephrotoxic ATN (i.e., exposure to radiocontrast media or antibiotics), acute glomerulonephritis, vascular disease (malignant hypertension, disseminated intravascular coagulation, and renal vasculitis), allograft rejection, or interstitial disease (drug allergy, infection, tumor growth).

**Inverse psoriasis** See *Psoriasis*.

**Iron deficiency anemia (IDA)** See *Anemia*.

**Irritable bowel syndrome (IBS)** A chronic noninflammatory disease with a psychophysiologic basis; characterized by abdominal pain, diarrhea or constipation, or both; no detectable pathologic change.

**Irritative syndrome (radicular syndrome)** A combination of changes usually seen with compromise of a spinal root within the intraspinal canal; these include neck or back pain and, in the affected root distribution, dermatomal pain,
paresthesias, or both; decreased deep tendon reflexes; and occasionally myotominal weakness.

J

Jaundice (icterus) Yellowish brown staining of the skin and the conjunctivae caused by high bilirubin levels in blood secondary to excessive erythrocyte breakdown, obstruction in or around the liver, or liver disease.

Juvenile idiopathic arthritis (JIA) Chronic pauciarticular arthritis and destruction of joints beginning in childhood and often going into remission at puberty.

K

Kaposi sarcoma (KS) A rare cancer of connective tissue caused by herpesvirus 8 (HHV8) in which many bluish red nodules appear on the skin, especially skin of the lower extremities; occurs in a particularly virulent form in individuals with AIDS.

Kawasaki disease A vascular disease characterized by an inflamed heart and vessels; a coronary artery aneurysm, thickening, and stenosis; a fever that lasts at least 5 days; and at least four of the following: inflammation with reddening of the whites of the eyes; red, swollen hands or feet or peeling skin; rash; swollen lymph glands in the neck; inflamed lips or throat; or red “strawberry” tongue.

Klinefelter syndrome Smallness of testes with fibrosis and hyalinization of seminiferous tubules, variable degrees of masculinization, azoospermia, infertility, and increased levels of urinary gonadotropins; associated typically with an XXY chromosome complement although variants include XXYY, XXXY, and XXXXY.

Kwashiorkor A condition in which children do not receive enough protein in their diet, resulting in a swollen and severely bloated abdomen secondary to decreased albumin levels in the blood, skin changes resulting in a reddish discoloration of the hair and skin in dark-skinned children, severe diarrhea, fatty liver, muscle atrophy, and restricted development.
**Lactase deficiency** A condition in which insufficient lactase is present in the small intestine to digest lactose, resulting in lactose intolerance characterized by diarrhea, bloating, and gas in response to exposure to lactose.

**Lactose intolerance** A condition caused by lactase deficiency in which lactose is not metabolized, making it impossible for the small intestine to absorb it and causing excessive gas production and diarrhea when exposed to lactose-containing foods.

**Left heart failure (congestive heart failure)** Inability of the left ventricle to maintain its circulatory load, with a corresponding rise in pressure in the pulmonary circulation usually with pulmonary congestion and ultimately pulmonary edema.

**Legg-Calvé-Perthes disease** Blood supply to the head of the femur near the hip joint is interrupted, resulting in osteonecrosis of the corresponding epiphysis.

**Leukemia** An acute or chronic malignant disease of the bone marrow and blood-forming organs; excessive proliferation of white blood cells occurs and is usually accompanied by dysfunctional blood cells, anemia, impaired blood clotting, and enlargement of the lymph nodes, liver, and spleen.

**Acute leukemia** Characterized by undifferentiated or immature cells, usually a blast cell, and the onset of disease is abrupt and rapid with a short survival time.

**Acute lymphoblastic/lymphocytic leukemia (ALL)** Excessive production and continuous multiplication of malignant and immature white blood cells (lymphoblasts) in the bone marrow that progresses rapidly if left untreated.

**Acute myelogenous leukemia (AML)** Excessive number of immature myeloid cells (myeloblasts) in the blood and bone marrow crowding out the marrow and decreasing the function of other cells.

**Chronic leukemia** The predominant cell is more differentiated but does not function normally, with a relatively slow progression of the malignancy.

**Chronic lymphocytic leukemia (CLL)** Malignant transformation and progressive accumulation in the marrow of monoclonal B lymphocytes; rarely are CLL malignancies of T-cell origin.
**Chronic myelogenous leukemia (CML)** Production of heterogeneous myeloid cells in the bone marrow, the majority of which express the Philadelphia chromosome; CML is considered a myeloproliferative disorder.

**Lichen planus** A recurrent rash of small, flat-topped bumps and rough scaly patches appearing on the skin, in the lining of the mouth, and in the vagina in response to inflammation or an allergy to a specific medication.

**Localized scleroderma (morphea)** Rare and idiopathic sclerosis of the skin, usually with childhood onset.

**Locked-in syndrome** Quadriplegia and mutism with intact consciousness and preservation of some eye movements; usually results from a vascular lesion of the anterior pons.

**Lupus erythematosus** Any of a group of autoimmune connective tissue disorders that commonly produce red scaly lesions and are accompanied by fever, malaise, myalgias, fatigue, and weight loss.

**Discoid (cutaneous) lupus erythematosus (DLE)** Lupus erythematosus limited to the skin; can progress to systemic lupus erythematosus (SLE).

**Systematic lupus erythematosus (SLE)** A chronic, multisystem, inflammatory disease; is one of the most common, complex, and serious of the autoimmune disorders.

**Lyme disease (borreliosis)** Tick-borne spirochete bacterial infection that is characterized by a rash in the area of the bite, headache, neck stiffness, chills, fever, myalgia, arthralgia, malaise, fatigue, and possible development of arthritis in large joints.

**Lymphoblastic lymphoma (LL)** See *Lymphoma*.

**Lymphoma** Cancer arising from cell proliferation in lymphoid tissue.

**B-cell neoplasm** A group of lymphomas including myelomas that originate from B cells at various stages of differentiation; previously part of non-Hodgkin lymphoma.

**Burkitt lymphoma** An aggressive malignancy of the B lymphocytes characterized by a large osteolytic lesion in the facial bones and associated with Epstein-Barr virus infection.
**Hodgkin lymphoma (HL)** A cancer of lymphoid tissue in which the lymph nodes, spleen, and liver become enlarged with the presence of Reed-Sternberg cells and is often accompanied by anemia, fever, and eventually death if not treated at an early stage; also referred to as Hodgkin disease.

**Lymphoblastic lymphoma (LL)** A progressive neoplasm arising in the thymus; most are of T-cell origin; a variant of acute lymphoblastic leukemia; common cause of NHL in children.

**Mycosis fungoides** Most common cutaneous T-cell lymphoma; present as focal or widespread erythematous patches or plaques, follicular papules, comedone-like lesions, and tumors.

**NK-cell neoplasm** A group of lymphomas that originate from NK cells at various stages of differentiation; previously part of non-Hodgkin lymphoma.

**Non-Hodgkin lymphoma (NHL)** A group of malignancies of lymphoid tissue classified as B-cell, T-cell, and NK-cell lymphomas that mimic Hodgkin lymphoma but do not produce the cells characteristic of Hodgkin lymphoma; have been reclassified as B-cell, T-cell, or NK-cell neoplasms.

**T-cell neoplasm** A variety of lymphomas that originate from T cells at various stages of differentiation; previously part of non-Hodgkin lymphoma.

**Lysosomal storage diseases** A group of more than 30 disorders that result from impaired lysosomal function, leading to mucopolysaccharidoses, lipid storage disorders, mucolipidoses, leukodystrophies, and glycoprotein storage disorders.

**M**

**Macrocytic anemia (megaloblastic anemia)** See *Anemia*.

**Malignant hyperthermia** An inherited life-threatening disorder that causes muscle rigidity, a hypermetabolic state, tachycardia, and increased body temperature in response to administration of general anesthetics.

**Malnutrition** Lack of nourishment from inadequate amounts of calories, protein, vitamins, or minerals; caused by improper diet, alterations in digestion or absorption, chronic disease, or a combination of these factors.

**Marasmus** A childhood disorder characterized by protein and energy malnutrition,
resulting in dry skin, loss of adipose tissue from normal areas of fat deposits such as buttocks and thighs, and behavior that is fretful and irritable.

**Maturity-onset diabetes of the young (MODY)** See *Diabetes*.

**McArdle disease** A metabolic disorder involving an enzyme defect that causes deficiency of muscle phosphorylase, which helps break down glycogen, and consequently this disorder causes an energy deficit in the muscles, resulting in muscle pain and cramping.

**Meconium ileus** Obstruction with thickened meconium in the intestine of a newborn child as a result of a lack of trypsin and associated with cystic fibrosis of the pancreas.

**Medulloblastoma** A malignant cerebellar tumor near the fourth ventricle that is most often found in children and consists of neoplastic cells that resemble the undifferentiated cells of the neural tube.

**Ménière disease (endolymphatic hydrops)** Dilation of the membranous labyrinth of the inner ear that is thought to be due to impaired absorption of endolymph in the endolymphatic sac; the pathologic finding in Ménière disease.

**Meningioma** A slow-growing mass of the meninges that is usually benign but increases intracranial pressure.

**Meningocele** Neural tube defect in the skull or spinal column that forms a cyst filled with cerebrospinal fluid through which the meninges of the brain protrude.

**Metabolic syndrome** A condition of unknown cause that presents with symptoms of insulin resistance, obesity, hypertension, dyslipidemia, and systemic inflammation.

**Microcephaly** Defect in which failure of normal brain growth causes delayed skull growth and production of a small head.

**Microcytic-hypochromic anemia** See *Anemia*.

**Microscopic colitis** A relatively common cause of diarrhea; occurs primarily in females and older adults.

**Migraine headache** Headache that usually begins in the temporal region unilaterally after vascular changes of cranial arteries and may cause irritability, nausea, vomiting, constipation or diarrhea, and photophobia.
**Mild concussion (mild traumatic brain injury)** Temporary axonal disturbances without the loss of consciousness in response to a violent blow, jarring, shaking, or other closed-head injury.

**Miliaria** A skin disease caused by partially obstructed sweat glands that results in small and itchy rashes usually located in skinfolds and on areas of the body that may rub against clothing, such as the back, chest, and stomach.

**Minimal change nephropathy (MCN)** The foot processes of the renal capillary basement membrane are fused and deformed because of a T-cell disorder that reduces the anion component of the basement membrane and allows proteins to leak into the renal tubule.

**Minimally conscious state (MCS)** A condition in which a severely brain-damaged patient is capable of deliberate behavior distinguishable from unconscious reflexive actions.

**Mitral valve prolapse syndrome** The mitral valve cannot close properly because of one or both flaps being too large, possibly resulting in mitral valve regurgitation.

**Molluscum contagiosum** A viral infection of the skin occurring in young children that affects the body, arms, and legs; it is spread through direct contact, saliva, or shared articles of clothing and is considered a sexually transmitted disease in adults, affecting the genitals, lower abdomen, buttocks, and inner thighs.

**Monoclonal gammopathy of undetermined significance (MGUS)** Production of monoclonal antibodies by noncancerous plasma cells that accumulate in the blood.

**Motility diarrhea** Diarrhea caused by excessive motility decreases transit time, mucosal surface contact, and fluid absorption secondary to resection of the small intestine (short bowel syndrome), surgical bypass of an area of the intestine, fistula formation between loops of intestine, irritable bowel syndrome–diarrhea predominant, diabetic neuropathy, hyperthyroidism, and laxative abuse.

**Moyamoya disease** An abnormality of the blood vessels that supply the frontal region of the brain in which vessels constrict or become completely occluded, resulting in diminished blood flow. The body attempts to compensate by growing new vessels at the base of the brain, which appear as a puff of smoke on
angiography.

**Mucopurulent cervicitis (MPC)** Inflammation of the cervix with purulent endocervical exudate that may be asymptomatic or cause abnormal vaginal discharge and vaginal bleeding.

**Multiple myeloma (MM)** Most common and most aggressive plasma cell tumor; a clonal plasma cell cancer characterized by the slow proliferation of malignant cells as tumor cell masses in the bone marrow that usually results in destruction of the bone; most secrete large amounts of monoclonal proteins that resemble intact immunoglobulins.

**Multiple organ dysfunction syndrome (MODS)** Progressive disease often involving the ultimate failure of two or more organ systems after a severe illness or injury; disease process is initiated and perpetuated by uncontrolled systemic inflammatory and stress responses and is characterized by a hypermetabolic and hyperdynamic state that persists as organ dysfunction develops.

**Multiple sclerosis (MS)** Chronic demyelinating disease of the central nervous system that causes inflammation and scarring of myelin sheaths.

**Muscular dystrophy** A general term for a number of hereditary, progressive degenerative disorders affecting skeletal muscles, and often other organ systems.

**Myasthenia gravis** Neuromuscular disorder caused by an autoimmune response in which antibodies to acetylcholine receptors impair neuromuscular transmission.

**Mycosis fungoides** See *Lymphoma*.

**Myelodysplastic syndrome (MDS)** A group of hematologic conditions characterized by ineffective production of blood cells, resulting in anemia that requires chronic blood transfusion.

**Myoadenylate deaminase deficiency (MDD)** A genetic disorder in which an enzyme deficiency prevents the conversion of adenosine monophosphate (AMP) to inosine monophosphate, resulting in increased AMP loss and the inability to synthesize adenosine triphosphate for energy.

**Myocardial infarction** A heart condition of sudden onset in which muscle tissue dies because of a lack of blood flow, resulting in varying degrees of chest pain
or discomfort, weakness, sweating, nausea and vomiting, and possibly loss of consciousness.

**Myositis** Inflammation of a muscle, usually a voluntary muscle, resulting in pain, tenderness, and sometimes spasm in the affected area.

**Myositis ossificans** A condition in which bone is deposited in muscle tissue, causing pain and swelling.

**Myxedema** Cutaneous edema caused by deposition of connective tissue (e.g., glycosaminoglycans and hyaluronic acid) and associated with hypothyroidism and Graves disease; characterized by dry skin, pretibial myxedema, swelling around the lips and nose, mental deterioration, and a decrease in basal metabolic rate.

N

**Necrotizing enterocolitis (NEC)** A condition of extensive ulceration and necrosis of the ileum and colon in premature infants during the neonatal period.

**Necrotizing fasciitis** A rare, rapidly spreading inflammation starting in the fascia, muscles, and subcutaneous fat with subsequent necrosis of the overlying skin; it is initiated by bacterial infection and treated with antibiotics; often requires surgical débridement.

**Nephritic syndrome** A disorder of the glomerular filtration membrane in which plasma proteins and red blood cells pass into the urine, resulting in mild proteinuria, hematuria, and mild hypertension.

**Nephroblastoma (Wilms tumor)** A malignant renal tumor of young children that compresses the normal kidney parenchyma, causing an abdominal mass, blood in the urine, and fever and may be associated with anorexia, vomiting, and malaise; often inherited as an autosomal dominant trait.

**Nephrotic syndrome** A disorder of the glomerular filtration membrane that permits proteins to pass into the urine, resulting in proteinuria, hypoalbuminemia, hyperlipidemia, and systemic edema.

**Neural tube defect (NTD)** Lack of closure of the neural groove caused by an arrest of the normal development of the brain and spinal cord during the first month of embryonic development.
**Neuroblastoma** A malignant tumor containing neuroblast cells that originate in the autonomic nervous system or the adrenal medulla; is most common in infants and young children.

**Neurogenic shock (vasogenic shock)** A type of shock caused by the sudden loss of sympathetic nervous system signals to the smooth muscle in vessel walls, causing the vessels to relax and a decrease in peripheral vascular resistance and blood pressure.

**NK-cell neoplasm** See *Lymphoma*.

**Nonalcoholic fatty liver disease (NAFLD)** Accumulation of fat in hepatocytes, primarily in the form of triglycerides, occurring in the absence of or with little alcohol intake; causes progressive inflammation and scarring that is usually asymptomatic for years.

**Nonalcoholic steatohepatitis (NASH)** A more serious form of nonalcoholic fatty liver disease resulting from hepatocellular injury, inflammation, and fibrosis; this condition is difficult to distinguish from alcohol-induced liver fibrosis; may progress to cirrhosis, end-stage liver disease, and an increased risk for hepatocellular carcinoma.

**Nonbacterial infectious cystitis** See *Painful bladder syndrome/interstitial cystitis (PBS/IC)*.

**Nonbacterial prostatitis** Prostatitis causes chronic pain that disappears and returns without warning but shows no signs of bacterial infection in the prostatic fluid even though the semen and other fluids from the prostate contain immune cells that the body produces in response to infection.

**Non-Hodgkin lymphoma (NHL)** See *Lymphoma*.

**Noninfectious cystitis** See *Painful bladder syndrome/interstitial cystitis (PBS/IC)*.

**Noninflammatory acne** See *Acne*.

**Noninflammatory joint disease** A disease in which alterations in the structure or mechanics of the joint result in pain during motion.

**Nonoliguric renal failure** Excretion of more than 500 ml/day of urine concurrent with renal failure; although adequate volume of urine is excreted, renal tubules have impaired reabsorption and concentration and dilution function so that
filtration is defective, resulting in accumulation of uremic toxins in the blood.

**Nonossifying fibroma (fibrous cortical deficit)** A benign fibrous tissue tumor forms in the metaphysis of any of the long bones but usually occurs in the thigh and shin bones in children and adolescents.

**Nonpuerperal hyperprolactinemia** The presence of excessive amounts of prolactin (the pituitary hormone that stimulates milk production) in the blood not related to pregnancy or childbirth; most common cause of galactorrhea.

**Normocytic-normochromic anemia (NNA)** See *Anemia*.

O

**Obstructive jaundice** Jaundice related to extrahepatic or intrahepatic obstruction.

**Obstructive sleep apnea syndrome (OSAS)** A disorder of sleep characterized by airway obstruction and episodes of apnea accompanied by snoring.

**Obstructive uropathy** The blockage of urine flow, often by ureteral or kidney stones, resulting in the reflux of urine and subsequent injury to kidneys.

**Onychomycosis (tinea unguium)** A fungal infection of the fingernails or toenails that causes thickening, roughness, and splitting of the nails.

**Open pneumothorax (communicating pneumothorax)** See *Pneumothorax*.

**Optic glioma** Tumor originating from glial cells in the brain that affects the optic nerve; commonly seen in children with neurofibromatosis.

**Orthopnea** Shortness of breath (dyspnea) that occurs when an individual lies flat and is common in individuals with heart failure.

**Orthostatic (postural) hypotension** A sudden drop in blood pressure when a person assumes a standing position, resulting in dizziness, lightheadedness, blurred vision, and temporary loss of consciousness.

**Osmotic diarrhea** Nonabsorbable substance in the intestine draws water into the lumen by osmosis, resulting in large-volume diarrhea; caused by drinking solutions with excessive sugars, salt, or vitamin C; maldigestion syndromes.

**Osteoarthritis (OA)** Inflammatory degenerative joint disease in which synthesis
and degradation of the articular cartilage in the movable joints are altered, resulting in wearing and destruction of cartilage.

**Osteochondrosis (Osgood-Schlatter disease)** A condition in children that results from the tendons pulling on the epiphysis of long bones, causing pain just below the knee, irritation and swelling, and possibly abnormal bone growth.

**Osteogenesis imperfecta (brittle bone disease)** A genetic disease in which collagen production is deficient, making the bones abnormally fragile and causing recurring fractures with only minimal trauma, deformity of long bones, a bluish coloration of the sclerae, and often the development of otosclerosis.

**Osteomalacia** A disease in which vitamin D or calcium deficiency or excessive renal phosphate loss causes a softening of the bones with accompanying pain and weakness.

**Osteomyelitis** A bacterial infection of the bone and bone marrow that occurs through open fractures, penetrating wounds, surgical operations, or by infiltration of the bloodstream; causes pain, high fever, and formation of an abscess at the site of infection.

**Osteoporosis** A disease in which the bones become porous and weakened, making them easily fracture and slow to heal.

**Overactive bladder syndrome (OAB)** A chronic syndrome of overactivity of the detrusor muscle; characterized by urgency with involuntary detrusor contractions during the bladder filling phase.

**Oxygen toxicity** An iatrogenic inflammatory condition caused by prolonged exposure to high concentrations of supplemental oxygen resulting from damage to alveolocapillary membranes, disruption of surfactant production, and interstitial and alveolar edema; caused by oxygen-free radicals.

**P**

**Paget disease (osteitis deformans)** A bone disorder in which excessive bone remodeling causes enlarged, deformed bones that can weaken the bone integrity and result in bone pain, arthritis, deformities, or fractures.

**Painful bladder syndrome/interstitial cystitis (PBS/IC) (see Cystitis)** A condition occurring in women ages 20 to 40 years who have symptoms of cystitis, such as
frequency, urgency, dysuria, and nocturia, for more than 6 weeks' duration; usually related to bacterial infection.

**Nonbacterial infectious cystitis** Cystitis with negative urine cultures and no other known etiology; most common in immunocompromised individuals and related to viral, mycobacterial, chlamydial, or fungal infection.

**Noninfectious cystitis** Cystitis without evidence of infection; usually autoimmune or related to exposure to radiation or chemotherapy treatment for pelvic or urogenital cancers.

**Pancreatic insufficiency** A condition in which the pancreas does not secrete enough hormones and digestive enzymes for normal digestion to occur, resulting in malabsorption, malnutrition, vitamin deficiencies, and weight loss.

**Pancreatitis** Inflammation of the pancreas, usually resulting in abdominal pain.

**Panhypopituitarism** A condition in which the secretion of all anterior pituitary hormones is inadequate or absent; caused by a variety of disorders that result in destruction or loss of function of all or most of the anterior pituitary gland.

**Papulosquamous disorder** Collective reference to inflammatory disorders characterized by papules, scales, plaques, and erythema, including psoriasis, pityriasis rosea, and lichen planus.

**Paraneoplastic pemphigus** See *Pemphigus*.

**Paraphimosis** A condition in which the foreskin becomes trapped behind the glans penis and cannot return to its normal flaccid position covering the glans penis.

**Parkinson disease** Degeneration of the basal ganglia dopaminergic nigrostriatal pathway that causes hypokinesia, tremor, and muscular rigidity.

**Parkinsonism (Parkinson syndrome, parkinsonian syndrome)** A neurologic condition characterized by tremors, rigidity, hypokinesia, and postural instability as a result of degeneration of the corpus striatum or substantia nigra caused by Parkinson disease and other conditions related to toxins or metabolic conditions.

**Paroxysmal nocturnal dyspnea (PND)** Attacks of breathing discomfort, shortness of breath, and coughing that occur at night with varying intensity so that individuals must sit up or stand to relieve dyspnea; may occur in individuals
with heart failure or lung disease.

**Partial obstruction of the bladder outlet or urethra** Partial obstruction related to deposition of collagen within the smooth muscle bundles of the detrusor muscle; causes an increase in the force of detrusor contraction.

**Pelvic inflammatory disease (PID)** Inflammation of the female genital tract caused by microorganisms, typically those that are sexually transmitted such as chlamydia and gonococci; characterized by severe abdominal pain, high fever, vaginal discharge, and possibly infertility.

**Pelvic organ prolapse (POP)** Bladder outlet obstruction in women caused most commonly by a cystocele (the downward protrusion of the bladder into the vagina) that descends below the level of the urethral outlet.

**Pemphigus** A group of autoimmune skin diseases marked by groups of itching blisters and raw sores on the skin and mucous membranes.

**Paraneoplastic pemphigus** The most severe form of pemphigus; is associated with lymphoproliferative neoplasms and affects internal organs, including lungs, thyroid, kidney, smooth muscle, and gastrointestinal tract.

**Pemphigus foliaceus** A milder form of pemphigus involving loss of cell-to-cell adhesion (acantholysis) at the subcorneal level with blistering, erosions, scaling, crusting, and erythema usually of the face and chest.

**Pemphigus vulgaris** The most common form of pemphigus with acantholysis at the suprabasal level and initiated by IgG autoantibodies against the desmoglein adhesion molecules, resulting in acantholysis in the epidermis with fluid accumulation and blister formation; oral lesions precede the onset of skin blistering.

**Periodic paralysis** One of a group of diseases in which muscular weakness or flaccid paralysis occurs without loss of consciousness, speech, or sensation.

**Peripheral artery disease (PAD)** Any of a group of diseases caused by the obstruction of large peripheral arteries secondary to atherosclerosis, inflammatory processes, embolism, or thrombus formation that causes ischemia.

**Peyronie disease (bent nail syndrome)** A condition in which fibrous plaques grow in the soft tissue of the penis because of injury of the internal cavity of the penis
that is accompanied by bleeding and scar tissue formation at the tunica albuginea of the corpora cavernosa.

**Phagocytic deficiency** See *Immune deficiency*.

**Phenylketonuria (PKU)** A genetic disorder in which the body lacks the enzyme necessary to metabolize the amino acid phenylalanine to tyrosine, resulting in accumulation of phenylalanine and subsequent brain damage and progressive intellectual disability.

**Pheochromocytoma** A tumor of the adrenal medulla that causes the chromaffin cells to secrete increased amounts of epinephrine or norepinephrine.

**Phimosis** The foreskin of the penis of an uncircumcised male cannot be fully retracted.

**Pick disease (frontotemporal dementia [FTD])** Progressive circumscribed cerebral atrophy; a rare type of cerebrodegenerative disorder manifested primarily as dementia, in which there is striking atrophy of portions of the frontal and temporal lobes.

**Pityriasis rosea** A skin disorder, thought to be caused by a virus, in which patches of ovular pink rash appear primarily on the trunk and extremities.

**Plaque psoriasis** See *Psoriasis*.

**Pneumoconiosis** A chronic disease of the lungs typically seen in miners, sandblasters, and metal grinders that is caused by repeated inhalation of dust particles, including iron oxides, silicates, and carbonates, that collect in the lungs and become sites for the formation of fibrous nodules that eventually replace lung tissue.

**Pneumonia** An infection of one or both lungs caused by a bacterium, virus, fungus, or other organism that enters the body through respiratory passages and causes high fever, chills, chest pain, difficulty breathing, cough with sputum, and possibly bluish skin from insufficiently oxygenated blood.

**Pneumothorax** The collapse of a lung and subsequent escape of air into the pleural cavity between the lung and the chest wall that is caused by trauma, environmental factors, or spontaneous occurrence and results in a sudden pain in the chest.
Open pneumothorax (communicating pneumothorax) Spontaneous and traumatic pneumothorax in which air pressure in the pleural space equals barometric pressure because air that is drawn into the pleural space during inspiration (through the damaged chest wall and parietal pleura or through the lungs and damaged visceral pleura) is forced out during expiration.

Tension pneumothorax The site of pleural rupture acts as a one-way valve, permitting air to enter on inspiration, but preventing its escape by closing during expiration and leading to air pressure in the pneumothorax exceeding barometric pressure.

Polycystic kidney disease (PKD) A progressive disease characterized by formation of multiple cysts of varying size scattered diffusely throughout both kidneys, resulting in compression and destruction of renal parenchyma, usually with hypertension, gross hematuria, and uremia leading to progressive renal failure.

Polycystic ovary syndrome (PCOS) A hormonal condition in which multiple ovarian cysts form because of elevated levels of androgens, resulting in hirsutism, obesity, menstrual abnormalities, infertility, and enlarged ovaries.

Polycythemia vera (primary polycythemia) A chronic, progressive disease that is characterized by overgrowth of the bone marrow, excessive red blood cell production, and an enlarged spleen and causes headache, inability to concentrate, and pain in the fingers and toes.

Pompe disease See Acid maltase deficiency.

Port-wine (nevus flammeus) stain A birthmark caused by superficial and deep dilated capillaries in the skin that produce a reddish to purplish discoloration of the skin, usually on the face, but can occur anywhere on the body.

Postconcussive syndrome Physical and personality changes that may occur after concussion of the brain, including amnesia, headache, dizziness, tinnitus, irritability, fatigueability, sweating, heart palpitations, insomnia, and difficulty concentrating.

Postrenal acute kidney injury Rare complication of urinary tract obstruction that affects the kidneys bilaterally (e.g., bilateral ureteral obstruction, bladder outlet obstruction–prostatic hypertrophy, tumors or neurogenic bladder, and urethral obstruction); obstruction causes an increase in intraluminal pressure upstream from the site of obstruction.
**Potter syndrome** A syndrome of renal agenesis with hypoplastic lungs and associated neonatal respiratory distress, hemodynamic instability, acidosis, cyanosis, edema, and characteristic (Potter) facies; death usually occurs from respiratory insufficiency, which develops before uremia.

**Precocious puberty** A condition in which a boy or girl undergoes the changes associated with puberty at an unexpectedly early age; often caused by a pathologic process that increases the secretion of estrogens or androgens.

**Premenstrual dysphoric disorder (PMDD)** Recurrence in the luteal phase of the menstrual cycle of distressing physical, psychologic, or behavioral changes that impair interpersonal relationships or interfere with usual activities.

**Premenstrual syndrome (PMS)** A group of symptoms that occur in many women from 2 to 14 days before menstruation begins, including abdominal bloating, breast tenderness, headache, fatigue, irritability, depression, and emotional distress.

**Prerenal acute kidney injury** Rapid development of renal hypoperfusion with elevation of serum creatinine and urea levels.

**Presbyopia** A form of farsightedness usually accompanying advanced age in which the lens loses elasticity and becomes unable to accommodate and focus light for near vision.

**Priapism** A painful condition in which the erect penis maintains an erection in the absence of physical and psychologic stimulation.

**Primary amenorrhea** Continued absence of menarche and menstrual function by 14 years of age without the development of secondary sex characteristics or by age 16 years if these changes have occurred.

**Primary (congenital) immune deficiency** See Immune deficiency.

**Primary dysmenorrhea** Painful menstruation because of a functional disturbance rather than because of inflammation, growths, or anatomic factors.

**Primary hyperaldosteronism (Conn disease, primary aldosteronism)** An adrenocortical disorder caused by excessive secretion of aldosterone and characterized by headaches, nocturia, polyuria, fatigue, hypertension, potassium depletion, hypokalemic alkalosis, hypervolemia, and decreased plasma renin activity; may be associated with small benign adrenocortical adenomas.
Primary hyperparathyroidism Usually the result of a benign parathyroid tumor that secretes parathyroid hormone and increases circulating calcium levels; this condition is accompanied by hypercalcemia, nausea, vomiting, lethargy, depression, muscular weakness, and an altered mental state.

Primary hypertension (essential hypertension, idiopathic hypertension) Elevated blood pressure of unknown etiology accompanied by increased total peripheral vascular resistance by vasoconstriction, increased cardiac output, or both.

Prinzmetal angina A form of angina pectoris characterized by pain that is not precipitated by cardiac work; it is of longer duration and usually more severe, and is associated with unusual electrocardiographic results including elevated ST segments.

Progressive bulbar palsy (see Bulbar palsy) A slowly progressive neurodegenerative disorder of the motor neurons of the cerebral cortex, spinal cord, and brainstem, resulting in progressive symptoms of bulbar palsy that may advance to loss of ability to manipulate food in the mouth, inability to swallow, choking, and emotional changes; may lead to aspiration of food and fluid and death from pneumonia.

Progressive spinal muscular atrophy A progressive degenerative disorder of the motor neurons of the spinal cord causing muscular weakness and wasting, typically beginning in the distal portions of the limbs and spreading proximally.

Prolactinoma The most common type of anterior pituitary tumor; produces visual disturbances and prolactin excess that results in infertility and changes in menstruation in females and impotence, loss of libido, and infertility in males.

Prostatitis Inflammation of the prostate gland caused by urinary tract infection.

Psoriasis A noncontagious autoimmune skin disorder in which the skin becomes scaly and inflamed when cells in the outer layer of skin reproduce faster than normal and accumulate as plaques on the skin surface.

Erythrodermic (exfoliative) psoriasis Widespread red, scaling lesions that cover a large body surface area; often accompanied by itching or pain associated with constitutional symptoms (fever, chills, fatigue) and skin infections.

Guttate psoriasis Sudden appearance of small papules on the trunk and extremities, occasionally after a streptococcal respiratory tract infection in children.
Inverse psoriasis Rare development of large, smooth, dry, and deep red lesions in skinfolds (i.e., axilla or groin).

Plaque psoriasis Most common form of psoriasis; begins with well-demarcated, thick, silvery, scaly erythematous inflammatory lesions with epidermal hyperproliferation and the presence of activated T lymphocytes that may become mild, moderate, or severe, depending on the size, distribution, and inflammation of the lesions.

Pustular psoriasis Blisters of noninfectious pus that develop over areas of plaque psoriasis.

Pulmonary artery hypertension (PAH) Increased blood pressure in the pulmonary artery attributable to vasoconstriction that may eventually lead to fibrosis, increased workload, hypertrophy of the right ventricle, and right heart failure; etiology may be idiopathic, familial, or associated with other diseases.

Pulmonary embolism (PE) Dislodgement of a blood clot from its site of origin and embolization to the arterial blood supply of one of the lungs, resulting in shortness of breath and difficulty breathing, rapid breathing that is painful, cough, and (in severe cases) hypotension, shock, loss of consciousness, and death.

Pustular psoriasis See Psoriasis.

Pyramidal/spastic cerebral palsy Palsy resulting from damage or defects in the brain's corticospinal pathways (upper motor neuron) in either one or both hemispheres.

R

Raynaud phenomenon A condition in which the blood vessels spasm because of inadequate blood supply, resulting in discoloration of the fingers and/or toes after exposure to changes in temperature or emotional events.

Rectocele A condition caused by childbirth or hysterectomy in which the region between the rectum and vagina bulges toward the vagina, resulting in a sense of pressure or protrusion within the vagina, the feeling of incomplete emptying of the rectum, difficulty passing stool, discomfort or pain during evacuation or intercourse, constipation, vaginal bleeding, fecal incontinence, prolapse of the
bulge through the opening of the vagina, or rectal prolapse through the anus.

**Refeeding syndrome** Metabolic disturbances that occur upon initiating parenteral or enteral nutritional therapy to individuals who are severely malnourished; starvation results in movement of phosphate, magnesium, and potassium ions out of the cells and into the plasma and refeeding increases insulin levels and stimulates movement of glucose and these ions back into the cells, resulting in dangerously low levels in the plasma (hypophosphatemia, hypomagnesemia, hypokalemia, hyponatremia, hypocalcemia, and vitamin deficiency) and other potentially fatal metabolic complications.

**Relative polycythemia** A relative increase in the number of red blood cells caused by loss of the fluid portion of the blood.

**Renal agenesis** Only one functional kidney is present at birth.

**Renal dysplasia** Abnormal tissue development in one or both kidneys.

**Respiratory distress syndrome (RDS) of the newborn** A condition, also known as hyaline membrane disease (HMD), that is a type of respiratory distress in newborns, most often in prematurely born infants, those born by cesarean section, or those having a diabetic mother; the immature lungs do not produce enough surfactant to retain air so the air spaces empty completely and collapse after exhalation.

**Retinoblastoma** An autosomal dominant or sporadic disorder in which a malignant tumor forms in the retina of one or both eyes; typically found in infants.

**Rhabdomyolysis** A potentially fatal condition in which skeletal muscle breaks down as a result of injury such as physical damage to the muscle, high fever, metabolic disorders, excessive exertion, convulsions, or anoxia of the muscle for several hours; large amounts of myoglobin are usually excreted.

**Rheumatic fever** An inflammatory disease that is associated with recent streptococcal infection and causes inflammation of the joints, fever, jerky movements, nodules under the skin, and skin rash and often is followed by serious heart damage or disease secondary to antibodies that react both with streptococcal antigens and with those of the heart valve.

**Rheumatic heart disease (RHD)** Sequela to rheumatic fever in which heart valves are repeatedly inflamed, developing fibrosis and thickening that can result in valve deformities, stenosis, or regurgitation.
**Rheumatoid arthritis** An autoimmune disease that causes chronic inflammation of the joints and the tissue around the joints and other organs.

**Ringed sideroblast** An erythroblast in which one third or more of the nucleus is encircled by 10 or more siderotic granules that may be caused by antituberculous drugs and alcohol abuse.

**Roseola** A viral disease in infants and young children that causes fever and a spotty rash that appears shortly after the fever has subsided.

**Rotavirus** A viral infection seen in young children that causes diarrhea by attacking the lining of the small intestine, resulting in the inability to absorb fluid and electrolytes.

**Rubella** An infectious viral disease of children and young adults that is spread by a droplet spray from the respiratory tract of an infected individual; the disease causes a rash that lasts about 3 days with tender and swollen lymph nodes behind the ears.

**Rubeola** An infectious viral disease of young children, also known as measles, that is spread by a droplet spray from the nose, mouth, and throat of individuals in the infective stage and causes a rash, white spots in the mouth, a rash on the face that spreads to the rest of the body, and fever.

**Russell-Silver syndrome (Russell-Silver dwarfism)** A growth disorder manifesting as intellectual disability, proportionate short stature, leg length discrepancy, and a small, triangular-shaped face.

**S**

**Saccular aneurysm (berry aneurysm)** A localized, progressively growing sac that affects only a portion of the circumference of the arterial wall and may be the result of congenital anomalies or degeneration.

**Salmon patches (nevus simplex)** Patches, also known as stork bites, of small, pink, flat spots that are small dilated blood vessels visible through the skin and are usually found on the forehead, eyelids, and upper lip; between the eyebrows; and on the back of the neck.

**Sarcoma** Tumor of the connective tissue cells.
**Scabies** Skin infestation with the itch mite *Sarcoptes scabiei*; acquired through close contact with an infected person or contaminated clothing and produces intense itching.

**Sclerosing adenosis** A condition in which the number of acini per terminal duct is more than twice the number of normal terminal ducts and is associated with a significantly increased risk of subsequent breast carcinoma.

**Scoliosis** A condition in which the spine is curved sideways to varying degrees; occurs because of either physiologic curvature or functional curvature in which contraction of the paraspinal muscles of the back creates a vertebral curve.

**Seborrheic dermatitis** Scaly, flaky, itchy, and red skin on the scalp, face, and trunk because of a yeast infection.

**Seborrheic keratosis.** A benign proliferation of cutaneous basal cells that produces smooth or warty elevated lesions; seen primarily in older people and presents as multiple lesions on the chest, back, and face.

**Secondary (acquired) immune deficiency** See *Immune deficiency*.

**Secondary amenorrhea** Menstruation begins at puberty but then is subsequently suppressed for three or more cycles or for 6 months in women who previously menstruated.

**Secondary dysmenorrhea** Altered menstruation because of inflammation, infection, tumor, or anatomic factors.

**Secondary hyperparathyroidism** A condition of elevated levels of parathyroid hormone resulting from disease such as renal failure in which parathyroid hormone concentration is elevated in response to vitamin D deficiency.

**Secondary hypertension** A condition of elevated blood pressure that is associated with other conditions, primarily with renal disease by a renin-dependent mechanism or a fluid volume–dependent mechanism.

**Selective IgA deficiency** See *Immune deficiency*.

**Septic shock** A condition caused by systemic infection that results in decreased tissue perfusion and oxygenation and can lead to multiple organ dysfunction syndrome and death.
Serum sickness A form of hypersensitivity caused by injection of soluble antigen such as antiserum, which activates a type III hypersensitivity response (formation of soluble circulating antigen-antibody [IgG or IgM] complexes) that activates the complement system.

Severe combined immune deficiency (SCID) See Immune deficiency.

Severe congenital neutropenia See Immune deficiency.

Shock A condition in which the circulatory system is unable to provide adequate circulation to the body tissues because of inadequate pumping by the heart, a reduction in blood volume, or a reduction in blood pressure; it results in slowing of vital functions and possibly death.

Sickle cell anemia See Anemia.

Sickle cell disease (SCD) See Anemia.

Sickle cell–Hb C disease See Anemia.

Sickle cell–thalassemia disease See Anemia.

Sickle cell trait See Anemia.

Sideroblastic anemia (SA) See Anemia.

Simple fibroadenoma Benign solid tumors composed of both fibrous and glandular tissue.

Sliding hiatal hernia The most common type of hernia, occurring when the proximal portion of the stomach moves into the thoracic cavity through the esophageal hiatus, an opening in the diaphragm for the esophagus and vagus nerves.

Smallpox (variolae) An infectious viral disease that is caused by a poxvirus and result in high fever, aches, and widespread eruption of large sores that leave scars.

Smoldering myeloma A condition in which abnormal plasma cells produce a monoclonal protein, but no symptoms or complications of myeloma are present and may not be present for several years.

Spina bifida occulta The mildest form of congenital disorder of incomplete
closure of the embryonic neural tube; the outer part of some vertebrae may not be completely closed, but the defect is not apparent to the unaided eye and usually causes no serious neurologic dysfunctions.

**Spinal stenosis** Narrowing of the spinal canal as a result of congenital anomaly or spinal degeneration, resulting in pain, paresthesias, and neurogenic claudication.

**Spondylolisthesis** Forward displacement of one of the lower lumbar vertebrae over the vertebra below it or over the sacrum.

**Squamous cell carcinoma (SCC)** A tumor of the epidermis and the second most common human cancer.

**Stable angina pectoris** A condition in which ischemic attacks occur at predictable frequencies and duration after activities that increase myocardial oxygen demands, such as exercise and stress.

**Staphylococcal scalded-skin syndrome (SSSS)** A disease in infants that is caused by a staphylococcal infection with release of an exfoliative toxin that results in peeling of large areas of skin.

**Stevens-Johnson syndrome** An inflammatory eruption of circular lesions that can cover the majority of the skin and mucous membranes and usually occurs after a respiratory tract infection or as an allergic reaction to drugs or other substances.

**Strawberry (capillary) hemangioma** A red birthmark caused by densely packed blood vessels that usually appears on the face, scalp, back, and chest and disappears during childhood.

**Stress-related mucosal disease (stress ulcer)** Acute peptic ulcer that occurs in association with various other pathologic conditions, including burns, cor pulmonale, intracranial lesions, and surgical operations.

**Structural scoliosis** A side-to-side curvature of the spine.

**Subacute thyroiditis (subacute granulomatous thyroiditis, de Quervian thyroiditis)** A painful inflammation of the thyroid that develops suddenly in a patient who has had a viral infection, such as mumps or an upper respiratory tract illness. Pain radiates throughout the neck and patients feel ill and feverish.

**Sudden infant death syndrome (SIDS)** A syndrome, also known as crib death, that is characterized by the sudden, unexpected, and unexplained death of an
apparently healthy infant less than 1 year of age.

**Superior vena cava syndrome (SVCS)** Restriction of the blood flow through the superior vena cava secondary to compression by malignancies or lymphadenopathy.

**Synchondrosis** A cartilaginous joint creating a union between two immovable bones, such as the synchondroses of the cranium, the pubic symphysis, the sternum, and the manubrium.

**Syndesmosis** A fibrous union in which two bones are connected by interosseous ligaments, such as the anterior and the posterior ligaments in the radioulnar and tibiofibular articulations; is usually converted into bone before adult life.

**Syndrome of inappropriate antidiuretic hormone (ADH) secretion (SIADH)** A condition in which the release of ADH from the posterior pituitary is elevated relative to serum sodium levels, resulting in increased water reabsorption by the kidneys and fluid overload.

**Systemic inflammatory response syndrome (SIRS)** A generalized inflammatory response that may lead to depressed cardiac function and decreased organ perfusion.

**Systemic lupus erythematosus (SLE) (see Lupus erythematosus)** A chronic, multisystem, inflammatory disease and one of the most common, complex, and serious of the autoimmune disorders.

**Systolic heart failure** A condition in which the heart muscle contracts so weakly that insufficient oxygenated blood is pumped throughout the body.

**T**

**Tay-Sachs disease (GM2 gangliosidosis)** A fatal autosomal recessive lysosomal storage disorder in which the lysosomal enzyme hexosaminidase A (HexA) is deficient, leading to accumulation of gangliosides in the brain and nerve tissue, intellectual disability, convulsions, blindness, and premature death.

**T-cell neoplasm** See *Lymphoma*.

**Tension pneumothorax** See *Pneumothorax*.

**Tethered cord syndrome** A group of neurologic disorders related to malformation
of the spinal cord in which the cord becomes abnormally attached or tethered as a result of scar tissue that develops as the cord transcends the vertebral canal with growth; tethering may decrease blood flow.

**Tetralogy of Fallot** A congenital condition that is characterized by four malformations including ventricular septal defect, misplacement of the origin of the aorta, narrowing of the pulmonary artery, and enlargement of the right ventricle.

**Thalassemia** See *Anemia*.

**Thromboangiitis obliterans (Buerger disease)** Inflammation of the medium-sized arteries and veins because of thrombotic occlusion, resulting in ischemia and gangrene.

**Thrombocythemia (thrombocytosis)** A chronic disorder of sustained megakaryocyte proliferation that increases the number of circulating platelets and results in megakaryocytic hyperplasia, splenomegaly, and complications by hemorrhagic and thrombotic episodes.

**Thrombocytopenia** A reduced number of circulating platelets.

**Chronic relapsing thrombotic thrombocytopenic purpura** A rare familial form of TTP characterized by recurring episodes of thrombocytopenia; usually seen in children.

**Heparin-induced thrombocytopenia (HIT)** A form of drug-induced thrombocytopenia caused by IgG antibodies against the heparin–platelet factor 4 complex, leading to platelet activation and thrombocytopenia.

**Idiopathic thrombocytopenic purpura (ITP) (autoimmune or primary thrombocytopenic purpura)** The most common cause of thrombocytopenia, secondary to increased immune-mediated platelet destruction; can be acute or chronic.

**Immune thrombocytopenic purpura (ITP)** A condition in which the number of platelets in the blood is reduced by the production of antibodies against platelets, resulting in ecchymoses and hemorrhages from mucous membranes, anemia, and extreme weakness.

**Thrombotic thrombocytopenic purpura (TTP)** Altered blood coagulation caused by an enzymatic deficiency that is characterized by a reduced number of platelets
in the blood, the formation of blood clots in tissue arterioles and capillaries, and neurologic damage.

**Thrombotic thrombocytopenic purpura (TTP)** See *Thrombocytopenia*.

**Thrush** A yeast infection of the mouth and throat that presents as creamy white curdlike patches on the tongue, inside the mouth, and on the back of the throat and that is commonly associated with yeast infection of the esophagus.

**Thyrotoxicosis** Excessive concentrations of thyroid hormones in the body that are marked by increased metabolic rate, heat intolerance, goiter, reproductive disorders, excessive sweating, and other alterations in systemic function.

**Tinea capitis** Fungal infections of the skin classified according to their location on the body.

**Tinea corporis (ringworm)** A fungal infection of the scalp; much more common in children than adults.

**Tinea infection** One of a group of fungal skin infections that include athlete's foot, folliculitis, jock itch, ringworm, and pityriasis versicolor.

**Tinnitus** Hearing ringing, buzzing, or other sounds without an external cause.

**T-lymphocyte deficiency** See *Immune deficiency*.

**Tophaceous gout** A form of purine metabolism disorder characterized by formation of chalky deposits of sodium biurate under the skin and in the joints.

**Toxic epidermal necrolysis (TEN)** A rare adverse reaction to certain drugs in which a large portion of the skin becomes intensely red, may develop blisters, and peels off.

**Trachoma (granular conjunctivitis or Egyptian ophthalmia)** A contagious, chronic inflammation of the mucous membranes of the eyes; caused by *Chlamydia trachomatis*.

**Transcortical dysphasia (transcortical sensory dysphasia, mixed transcortical dysphasia, isolated speech center)** A type of aphasia with poor comprehension but fluent, grammatically correct speech. Patients can communicate well and are capable of good repetition.

**Transient ischemic attack (TIA)** Brief episode in which the brain receives
insufficient blood supply; symptoms depend on the site of the blockage.

**Transposition of the great arteries (TGAs)** The aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle.

**Tricuspid atresia** Congenital absence of the tricuspid orifice, circulation being made possible by the presence of an atrial septal defect.

**Truncus arteriosus** A congenital defect in which a large great vessel arises from a ventricular septal defect and does not divide into the aorta and pulmonary artery, resulting in one vessel carrying blood both to the body and to the lungs.

**Tuberculosis (TB)** An infectious disease of humans caused by *Mycobacterium tuberculosis* that results in the formation of tubercles on the lungs and other tissues of the body.

**Turner syndrome** Gonadal dysgenesis with short stature, undifferentiated (streak) gonads, and variable abnormalities such as webbing of the neck, low posterior hair line, increased carrying angle of elbow, cubitus valgus, and cardiac defects. The genotype is XO (45,X) or X/XX or X/XXX mosaic. The phenotype is female.

**Type 1 diabetes mellitus** See *Diabetes*.

**Type 2 diabetes mellitus** See *Diabetes*.

**U**

**Ulcerative colitis** Chronically inflamed and ulcerated mucosal and submucosal lining of the large intestine, resulting in abdominal pain, diarrhea, and rectal bleeding.

**Unstable angina** A condition in which unprovoked ischemic attacks occur at unpredictable frequencies and may increase in severity.

**Uremia** Syndrome of renal failure resulting in elevated blood urea nitrogen and creatinine levels.

**Uremic syndrome** A complex of symptoms resulting from the accumulation of urea and other nitrogenous compounds and toxins in the blood, leading to alterations in levels of fluid and electrolytes, metabolic acidosis, anemia, hyperphosphatemia, and hypocalcemia; symptoms include hypertension,
anorexia, nausea, vomiting, diarrhea or constipation, malnutrition and weight loss, pruritus, edema, anemia, and neurologic, cardiovascular disease, and skeletal changes.

**Ureterohydronephrosis** Dilation of both the ureter and the pelvicaliceal system.

**Ureteropelvic junction (UPJ) obstruction** An impediment to the drainage of urine from the kidney, usually attributable to partial or intermittent blockage of the renal collecting system at the junction of the renal pelvis and ureter.

**Uterine prolapse** Descent or herniation of the uterus into or beyond the vagina because of weakness of the pelvic musculature, ligaments, and fascia or obstetric trauma and lacerations sustained during labor and delivery.

**V**

**Vacuolar myelopathy** HIV-induced loss of myelin and spongy degeneration of the spinal cord that may cause spastic paraparesis, sensory ataxia in lower limbs, and unsteady gait.

**Vaginismus** A form of sexual dysfunction that is caused by a psychologic disorder or vaginal inflammation in which the muscles at the entrance to vagina contract and prevent sexual intercourse.

**Vaginitis** Infection of the vagina usually caused by a fungus that may cause itching or burning and a discharge.

**Vaginosis** Vaginal irritation without white blood cells or other indication of infection.

**Varicocele** A painful condition in which the veins in the scrotum that develop in the spermatic cord enlarge, and if the valves that regulate blood flow from these veins become dysfunctional, blood does not leave the testis, thereby causing swelling in the veins above and behind the testis.

**Venous stasis ulcer** A condition affecting the lower leg in which leaky valves, obstructions, or regurgitation in veins impairs blood flow back to the heart, resulting in pooling of blood in the lower leg and subsequent tissue damage.

**Ventricular septal defect (VSD)** A congenital malformation in which the wall between the left and right ventricles has a hole that allows blood to travel
between the left and right ventricles, potentially leading to congestive heart failure.

**Vesicoureteral reflux (VUR)** Reflux of urine from the bladder into the ureter.

**Vestibular nystagmus** Involuntary rapid movement of the eyeball that is due to disturbance of the vestibular system; eye movements are rhythmic, with slow and fast components.

**von Willebrand disease** An inherited disease in which the von Willebrand factor proteins that are made in the blood vessel walls and function to control platelet activity are abnormal or absent, resulting in a tendency to hemorrhage.

**W**

**Wallerian degeneration** The degeneration of a nerve fiber that has been separated from its nutritive center by injury or disease; characterized by segmentation of the myelin and resulting in atrophy and destruction of the axon.

**Wilms tumor** See *Nephroblastoma*.

**Wilson disease** A genetic disease in which the ability to metabolize copper is impaired, resulting in an accumulation of copper deposits in organs such as the brain, liver, and kidneys and subsequent organ dysfunction and failure.

**Wiskott-Aldrich syndrome (WAS)** See *Immune deficiency*.

**X**

**X-linked SCID** See *Immune deficiency*.

**Z**

**Zollinger-Ellison syndrome** The association of atypical, intractable, sometimes fulminating peptic ulcers with extreme gastric hyperacidity and benign or malignant gastrinomas in the pancreas.

Acute bronchitis, 703
Acute colonic pseudo-obstruction, 913-914
Acute confusional states, 367-370, 367b
Acute coronary syndromes
  description of, 610
  myocardial infarction. See Myocardial infarction
  pathophysiology of, 616, 616f
  unstable angina, 616-617, 617b, 618f
  unstable atherosclerotic plaque, 616-617, 617f
Acute cough, 688
Acute cystitis, 753-754
Acute epiglottitis, 716t, 717
Acute gastritis, 914
Acute gouty arthritis, 1019, 1020f
Acute hematogenous osteomyelitis, 1041-1042
Acute infectious diarrhea, 961
Acute inflammation, 149-150
Acute inflammatory response, 147-148, 249

**Acute kidney injury**
- classification of, 761t
- clinical manifestations of, 762
- definition of, 760
- evaluation of, 762-763
- intrarenal, 761-762, 761t-762t
- mechanisms of, 761f
- oliguria, 124, 761f, 762
- pathophysiology of, 760-762
- postrenal, 762
- prerenal, 760, 761t-762t
- progression of, to chronic kidney disease, 763
- RIFLE criteria for, 760, 761t
- treatment of, 762-763

**Acute liver failure**, 931

**Acute lung injury**, 695-697

**Acute lymphocytic leukemia**
- in children, 564
  - description of, 303, 526-530, 527f, 527t

**Acute mesenteric arterial insufficiency**, 923-924
Acute monoblastic leukemia, 565f

Acute myelogenous leukemia
  in children, 564
  description of, 526-530, 527f, 527t

Acute myeloid leukemia, 564

Acute nonlymphocytic leukemia, 527-528

Acute otitis media, 352

Acute pain, 339-340

Acute pancreatitis, 936-937, 936f

Acute poststreptococcal glomerulonephritis, 772-773

Acute pyelonephritis, 754-755, 775

Acute rejection, 210

Acute respiratory distress syndrome, 695-697, 697f
  multiple organ dysfunction syndrome as cause of, 646

Acute rheumatic fever, 628-629, 629f

Acute tubular necrosis, 761-762

Acute-phase reactants, 149, 150t

Acyanotic heart defects, 655

Acyclovir, 1090

ADAMTS13, 542, 544

Adaptation
  cellular. See Cellular adaptation
  definition of, 73
  diseases of, 214-215
  potassium, 122

Adaptation stage, of general adaptation syndrome, 214-215

Adaptive immunity
  cells of, 142
description of, 134, 135
inflammation versus, 158
innate immunity and, 158
Adaptive resizing, 278-279
ADCC. See Antibody-dependent cellular cytotoxicity
Addison disease, 124, 482f, 484-485
A-delta fibers, 337, 342
Adenine, 38
Adenocarcinomas. See also Cancer; Carcinoma
colorectal, 939-940
definition of, 234
ductal, 942
gastric, 939
lung, 710, 710t, 711f
mammary, 234
prostate, 868
Adenohypophysis. See Anterior pituitary
Adenomas
growth hormone-secreting, 465
pituitary, 464, 466
Adenomyosis, 818
Adenosarcoma, 816
Adenosine deaminase deficiency, 191, 194
Adenosine diphosphate, 505
Adenosine monophosphate deaminase deficiency, 1024
Adenosine triphosphate
cardiac requirements for, 579, 634b
cardiomyocyte use of, 580
in cellular metabolism, 16, 637
description of, 501-502
skeletal muscle use of, 985
sodium-potassium pump affected by, 80-81
ADH. See Antidiuretic hormone

Adipocytes
  cancer-associated, 281
description of, 3
interlobular, 104f
in obesity, 924

Adipocytokines, 924b

Adipokines
  coronary artery disease risks, 613
description of, 475, 590
obesity effects on, 602
Adiponectin, 475, 841, 924b, 925

Adipose tissue, 31t-33t, 925b

Adjuvant chemotherapy, 260-261

Adolescence, 780-781

Adolescents, 131. See also Childhood cancers

Adoptive cell therapy, 261

Adrenal cortex
  disorders of
    Addison disease, 484-485
    congenital adrenal hyperplasia, 483
    Cushing syndrome, 481f-482f, 482-483
description of, 482
hyperaldosteronism, 483-484
hormones produced by, 453-456, 453f
hyperfunction of, 482
hypofunction of, 482, 484-485

Adrenal glands
adrenal cortex. See Adrenal cortex
adrenal medulla. See Adrenal medulla
aging effects on, 457b
aldosterone secretion by, 455-456, 455f
anatomy of, 453, 453f
androgens secreted by, 456, 484
estrogens secreted by, 456, 484
glucocorticoids produced by, 453-455, 454f
mineralocorticoids produced by, 455-456, 455f

Adrenal medulla
hormones produced by, 456
tumors of, 485

Adrenarche, 781

Adrenergic receptors
α-, 221, 329, 331t-332t
β-, 221, 329

Adrenergic transmission, 329

Adrenocorticotropic hormone
Cushing syndrome caused by excessive secretion of, 482-483, 482f-483f
deficiency of, 463
description of, 218, 225
functions of, 445-447, 447t
secretion of, 455
synthesis of, 455
Adrenomedullin, 590-591
Aerobic glycolysis, 247
Affective-motivational system, 338

**Afferent loop obstruction**, 918
Afferent lymphatic vessels, 594
Afferent neuron, 319-320
Afferent pathways, 307, 336
Aflatoxins, 941
Afterload, 582, 632, 634f

Age
   innate immunity affected by, 154b
   total body water changes based on, 114-115
Age-related macular degeneration, 349
Agglutination, 162-163

Aging. See also Elderly
   aortic valve degeneration caused by, 626
   benign prostatic hyperplasia caused by, 863-864
   biologic changes associated with, 108f
   of bones, 986-987
   breast changes secondary to, 836-837
   cellular, 107-109
   chest wall affected by, 684b
   chronologic, 107
   definition of, 107

   endocrine glands affected by, 457b
   extracellular matrix affected by, 108
   eye changes secondary to, 348t
female reproductive system changes secondary to, 797-798
frailty secondary to, 109
gas exchange affected by, 684b
gastrointestinal system affected by, 903b
growth hormone affected by, 447b, 457b
hearing changes secondary to, 354b
hematologic values affected by, 511
heteroplasmy levels affected by, 109
insulin-like growth factor in, 447b
of joints, 987
life span versus, 107
male reproductive system changes secondary to, 798
of muscles, 987-988
nervous system changes secondary to, 332b
olfaction changes secondary to, 354b
pituitary gland changes, 457b
pulmonary system affected by, 684b
renal function affected by, 743b
replicative, 107
skin changes caused by, 1079b
stress-age syndrome and, 228b
systemic, 109
taste changes secondary to, 354b
thyroid gland changes, 457b
tissue changes associated with, 109
Agitated delirium, 367-369

**Agnosia**, 367

Agonal gasps, 362t
Agonal rhythm, 638t-639t
Agonist, 986
Agranulocytes, 492-494, 493t
**Agranulocytosis, 523**
AIDS. See *Acquired immunodeficiency syndrome*
Air pollution
- cancer caused by, 292-293, 292f
- coronary artery disease risks, 613
description of, 87b
Air trapping, 701-702, 703f
Airway(s). See also *Pulmonary system*
- conducting, 671-672, 673f-674f
- gas-exchange, 672-673, 672f, 674f
Airway obstruction
- in children, 715, 716f
description of, 699
Airway remodeling, 698-699
Airway resistance, 680
**Akathisia, 379t**
**Akinesia, 380**
Alarm reaction, 215f
Alarm stage, of general adaptation syndrome, 214-215, 215f
**Albinism, 100**
Albumin
description of, 100, 490
plasma, 116
Alcohol
- breast cancer risks and, 841
cancer and, 281, 281t, 283f
cellular injury caused by, 90-93
deaths caused by, 90
immune defects caused by, 92
metabolism of, 90-91, 91f, 283f
nutritional status affected by, 90
prenatal exposure to, 92-93
recommended daily intake of, 91
Alcohol dehydrogenase, 90-93
Alcoholic cirrhosis, 932
Alcoholic fatty liver, 98, 99f, 932
Alcoholic hepatitis, 92f
Alcoholic liver disease, 91-92, 932
Alcoholic steatohepatitis, 932
Alcoholism, 91-92
Alcohol-related neurodevelopmental disorder, 423b
Aldosterone
  blood pressure affected by, 590
  nephron function affected by, 741
  potassium regulation by, 122
  secretion of, 455-456, 455f
  sodium balance affected by, 116-117, 455, 600-601
Alkaline phosphatase, 969t
Alkaline reflux gastritis, 918
Alkalosis
  contraction, 128
  metabolic, 127-128
    hypochloremic, 127
signs and symptoms of, 128
respiratory, 130
Alleles
autosomal dominant, 50
description of, 49
Allergens, 206-211
**Allergic alveolitis**, 205-206, 695
**Allergic conjunctivitis**, 350
**Allergic contact dermatitis**, 207f, 1060-1061, 1061f
**Allergy**
bee sting, 206-207
causes of, 203t
definition of, 199
food, 922
gastrointestinal, 202
Alloantigens, 208
**Alloimmune diseases**
description of, 199

Working memory, 366t

Wound
  contraction of, 153-154
  dehiscence of, 154
  disruption of, 154
  infection of, 178t-179t

Wound healing
  by primary intention, 151f, 152
  by secondary intention, 151f, 152
  cancer and, 237-238
  diabetes mellitus effects on, 153
  drug effects on, 153
  dysfunctional, 153-154
  epithelialization during, 153
  fibrin deposition in, 153
  fibroblasts in, 153
  granulation tissue in, 153
  inflammation phase of, 152, 152f
  macrophages in, 152-153
  maturation phase of, 153
  new tissue formation phase of, 152-153
  nutrition during, 153
  obesity effects on, 153
  open wound, 152
  processes involved in, 152
  proliferative phase of, 152-153
  prolongation of, 153
  remodeling phase of, 153
Wound infection, 153-154
Wound repair, macrophages in, 146

X
X chromosomes, 62-63
X inactivation, 54
Xanthinuria, 749
Xenobiotics, 84-85, 86f, 279
Xenoestrogens, 841-842
Xeroderma pigmentosum, 242-244
X-linked recessive traits, 55, 56f

Y
Yellow marrow, 974

Z
Z bands, 982, 984f
Z line, 579-580
Zeaxanthin, 349
Zollinger-Ellison syndrome, 916
Zona fasciculata, 453
Zona glomerulosa, 453
Zona reticularis, 453
Zonula adherens, 13f
Zoonotic infections, 178t-179t, 182-184
Prefixes and Suffixes Used in Medical Terminology

<tr>
<td>-algia</td>
<td>Pain</td>
</tr>
<tr>
<td>-aps, -apt</td>
<td>Fit; fasten</td>
</tr>
<tr>
<td>-arche</td>
<td>Beginning; origin</td>
</tr>
<tr>
<td>-ase</td>
<td>Signifies an enzyme</td>
</tr>
<tr>
<td>-blast</td>
<td>Sprout; make</td>
</tr>
<tr>
<td>-censis</td>
<td>A piercing</td>
</tr>
<tr>
<td>-cide</td>
<td>To kill</td>
</tr>
<tr>
<td>-clast</td>
<td>Break; destroy</td>
</tr>
<tr>
<td>-crine</td>
<td>Release; secrete</td>
</tr>
<tr>
<td>-cytosis</td>
<td>Increase in number</td>
</tr>
<tr>
<td>-ctomy</td>
<td>A cutting out</td>
</tr>
<tr>
<td>-drenis</td>
<td>Vomiting</td>
</tr>
<tr>
<td>-emia</td>
<td>Refers to blood condition</td>
</tr>
<tr>
<td>-flux</td>
<td>Flow</td>
</tr>
<tr>
<td>-gen</td>
<td>Creates; forms</td>
</tr>
<tr>
<td>-genesis</td>
<td>Creation, production</td>
</tr>
<tr>
<td>-gram</td>
<td>Something written</td>
</tr>
<tr>
<td>-graph(ly)</td>
<td>To write, draw</td>
</tr>
<tr>
<td>-hydrate</td>
<td>Containing H₂O (water)</td>
</tr>
<tr>
<td>-ia, -sia</td>
<td>Condition; process</td>
</tr>
<tr>
<td>-iatis</td>
<td>Abnormal condition</td>
</tr>
<tr>
<td>-ic, -ac</td>
<td>Pertaining to</td>
</tr>
<tr>
<td>-in</td>
<td>Signifies a protein</td>
</tr>
<tr>
<td>-ism</td>
<td>Signifies “condition of”</td>
</tr>
<tr>
<td>-itis</td>
<td>Signifies “inflammation of”</td>
</tr>
<tr>
<td>-lemma</td>
<td>Sheath, covering</td>
</tr>
<tr>
<td>-lepsy</td>
<td>Seizure</td>
</tr>
<tr>
<td>-lith</td>
<td>Stone; rock</td>
</tr>
<tr>
<td>-logy</td>
<td>Study of</td>
</tr>
<tr>
<td>-lunar</td>
<td>Moon; moonlike</td>
</tr>
<tr>
<td>-malacia</td>
<td>Softening</td>
</tr>
<tr>
<td>-megaly</td>
<td>Enlargement</td>
</tr>
<tr>
<td>-metric, -metry</td>
<td>Measurement, length</td>
</tr>
<tr>
<td>-oid</td>
<td>Like; in the shape of</td>
</tr>
<tr>
<td>-oma</td>
<td>Tumor</td>
</tr>
<tr>
<td>-opia</td>
<td>Vision, vision condition</td>
</tr>
<tr>
<td>-oscopy</td>
<td>Viewing</td>
</tr>
<tr>
<td>-ose</td>
<td>Pertaining to, sugar</td>
</tr>
<tr>
<td>-osis</td>
<td>Condition, process</td>
</tr>
<tr>
<td>-ostomy</td>
<td>Formation of an opening</td>
</tr>
<tr>
<td>-otomy</td>
<td>Cut</td>
</tr>
<tr>
<td>-opia</td>
<td>Lack</td>
</tr>
<tr>
<td>-philic</td>
<td>Loving</td>
</tr>
<tr>
<td>-phobic</td>
<td>Fearing</td>
</tr>
<tr>
<td>-phragm</td>
<td>Partition</td>
</tr>
<tr>
<td>-plasia</td>
<td>Growth, formation</td>
</tr>
<tr>
<td>-plasm</td>
<td>Substance, matter</td>
</tr>
<tr>
<td>-plasty</td>
<td>Shape; make</td>
</tr>
<tr>
<td>-plegia</td>
<td>Paralysis</td>
</tr>
<tr>
<td>-prax</td>
<td>Breath, breathing</td>
</tr>
<tr>
<td>-(r)rhage, -(r)rhagia</td>
<td>Breaking out, discharge</td>
</tr>
<tr>
<td>-(r)hraphy</td>
<td>Sew, suture</td>
</tr>
<tr>
<td>-(r)hrhea</td>
<td>Flow</td>
</tr>
<tr>
<td>-some</td>
<td>Body</td>
</tr>
<tr>
<td>-tensin, -tension</td>
<td>Pressure</td>
</tr>
<tr>
<td>-tonic</td>
<td>Pressure, tension</td>
</tr>
<tr>
<td>-tripsy</td>
<td>Crushing</td>
</tr>
<tr>
<td>-ule</td>
<td>Small, little</td>
</tr>
<tr>
<td>-uria</td>
<td>Refers to urine condition</td>
</tr>
